The next scheme is to deliver calcium carbide to houses, and let the consumers make their own acetylene. All that is needed is to add water. This sounds very simple. In the beginning of the century, gas was to be made on the spot in the same sort of way. All you did was to put coal in a retort and heat it, and off came the gas. Yet this was never practised, except in special cases, and gas never came into use generally until it was distributed by pipes ready for use. There are, of course, a few country houses and isolated establishments where they make a fluid they call illuminating gas. Exactly the same thing happened with the electric light. Each house was to have a gas engine and a dynamo, and generate its own power. Then the next idea was that the accumulators were to be left at the houses with the milk, and changed next day, or week, or month; but this never came into practice either. These two schemes correspond very fairly with those of distributing carbide for use in generators, and distributing liquid acetylene in bottles. The generators would always be troublesome in an ordinary house. No doubt the light would be much cheaper and better than that of gas as commonly used, but that is by no means everything. People forget that the average households are controlled by women. Women may understand people, but they are completly wanting in the faculty of understanding things, and they have the unreasoning conservatism and conventionality belonging to the undeveloped mind as seen in boys and savages. A woman hates everything new, and would never understand how to work an acetylene generator until it had been in use for generations, and it was considered part of the duty of a good housekeeper to make good acetylene, as it used to be to make good beer. Of course, even then it would be done by rule of thumb. There is more than this. The first thing a woman asks when she sees anything new, be it a mousetrap or a telephone, is, "Will it explode?" Now, no one can say on his honour that an acetylene generator won't explode. He does not think it will, in fact he feels sure it won't, and he sincerely hopes it won't, but an explosion might possibly occur. This settles the matter. The only thing to be done would be to utilise a woman's instinctive hero worship and belief in authority, and to arrange that acetylene generators should be recommended by her clergyman or doctor. I say her doctor advisedly, as she does not believe in other women's doctors.

The plan of distributing liquid acetylene in iron bottles sounds more promising, as very little goes a long way, and the bottles could be connected to the house service by the acetylene company without the women of the house having anything to do with the matter. Acetylene is given off on the addition of water to the carbide, at enough pressure to liquefy in a cold bottle at once; and it might be purified at the same time. It must be remembered, however, that the comparison must be made as to cost, not with gas burned in the ordinary bat's-wing burner, which is generally not even good of its kind, but with the incandescent mantle. If any one is going to improve his lighting, he will not take up acetylene, as against the incandescent burner, unless it is better. Acetylene gives, for a cubic foot, about three times the light of the Auer burner; so that, at 20*s*. per 1000 cubic feet, it corresponds to gas at 6*s*. 9*d*. Gas seldom costs 6*s*. 9*d*. per 1000. Besides, it is easier to put in the Welsbach burners; but, if a considerable alteration is to be made, the electric light may be preferred.

All the same, there is a very large opening for acetylene, apart from competition with coal gas. For country houses, and in carriages, omnibuses, trains, and on board ship, it ought to have its own way. One of the chief things wanted is a good burner that will not give smuts under any conditions.

A good portable acetylene lamp is also much needed. If the lamp generates its own acetylene, there is the difficulty of having it attended to properly, at least by maid-servants. Even paraffin lamps are seldom in good order where there are no men servants, and the old colza-oil lamps never were. There are other difficulties, however. The action of the carbide on the water is so energetic that, each time they touch, too much acetylene is given off, and some sort of gas-holder is needed. I have tried mixing alcohol with the water to reduce the vigour of the action, and it works fairly well. I have lately found that this plan has been already fully worked out. Another difficulty is that the water gives off vapour which generates acetylene, so that, when the lamp is out of use, acetylene is being generated slowly. This means that the lamp will smell, and the smell of acetylene is not pleasant.

Small bottles of liquid acetylene for portable lamps should be no more difficult to deal with than mineral-water siphons; and a small steel-tube bottle would run a light and portable ten-candle-power lamp for a long time. The want of portability is the great drawback to gas. The electric light is a little better, but not much. The result is that candles are still used. Acetylene lamps would not ruin the carpets or cement the piano keys together.

Too much has been generally said about the poisonous nature of acetylene. Experiments show that it is not at all a serious poison, and its smell is a great safeguard. It uses so little air in burning that, on the whole, it would be a very much more healthy illuminant than gas, oil, or candles, especially if it contains no sulphur. Healthy breathing is not generally sufficiently appreciated yet. Many people still sit in close rooms and sleep with their windows shut, and the smaller air-consump-

tion of acetylene would not really appeal to them very much. Besides, according to experiments recently made on polluted air, the evils of vitiated atmosphere have been greatly exaggerated. Though acetylene, like carbon disulphide, is an endothermic compound, it is not easily exploded. Fulminate of silver only fires it locally. The explosion does not spread. Carbon disulphide explodes under curious conditions. If some is put in a bulb, and an air-pump connected and used, it will go off. I do not know if acetylene has any analogous properties.

Calcium carbide may come to be used in the manufacture of alcohol, benzine, and other organic products; but it is too soon to prophesy its future in these directions. A great deal must depend on its price, and one of the chief items is the cost of electrical power. It is to be hoped that it will soon be made by non-electrical methods, and its price may then be reduced considerably. JAMES SWINBURN.

THE ACETYLENE LIGHT FOR PORTRAITURE, &c.

THE illustration shows Messrs. Thorne & Hoddle's method of utilising generated acetylene for studio purposes, or for use in taking drawing-room or ball room portraits. Inside the reflector are twelve 60 candle-

power burners. The method of generating and using acetylene has lately been described several times in our pages. It is only necessary for us here to remark that the light is admirably suited for portraiture.

ONE WORD MORE ON PHOTOGRAPHY AND ART.

[Edinburgh Photographic Society.]

THERE was recently read before this Society an exceptionally interesting paper by the Professor of Fine Art on the question whether photography was capable of being made to produce artistic results. The view taken by the lecturer was not the one which commends itself to the vanity of photographers. We do not like to think that it is impossible, in the nature of the case, that our finest prints should have any artistic value. Most of us perhaps hope, every time we take off the cap, that this time we are for ever to disprove such contentions; and, if after development and printing we are willing to admit that the print does not altogether come up to our expectations—that we have missed the simplicity and richness of effect that we aimed at, and that the question about photography and art has not yet, therefore, been finally disposed of—let us hope that our opponents, instead of using this admission as a final argument against us, will acknowledge that our modesty deserves encouragement; for, indeed, photographers need all the encouragement they can get. Our opponents' view is not always expressed so courteously, or from so full a knowledge of the subjects involved, as in Professor Baldwin Brown's lecture. We are used to being dismissed in a much more summary manner. We mean no harm to anybody; we pretend no rivalry with painters, etchers, or draughtsmen; but the moment we are caught trying, in our own humble way, to make pictures, we are told to get out of this. We have been angling, it seems, in preserved waters, and the water bailiff counts it an aggravation, rather than an extenuation, of our offence that, as he would persuade us, there is no hook at the end of our line. Our business, we are told, is not with pictures at all; we are to confine ourselves to making strictly mechanical diagrams of things or of bits of things, to aid the painter in his picture-making. In other words, the painter is to have all the fishing to himself; but he agreeably suggests that there can be no objection to our digging for worms; and, that we may have an irresistible motive to this enticing pursuit, he adds that the worms, when found, will be "of interest and value" to him.

At present, however, we have to consider a statement of the view that photography cannot be a vehicle of artistic expression which is not a mere unconsidered prejudice thrown at our heads, but is the outcome of a very full examination of the whole question. Even if we feel that we need not commit ourselves to Professor Baldwin Brown's conclusion, we appreciate the compliment he has paid us in giving the claims of photography such careful consideration; and, as it is not every day that we get one who can so justly claim an expert's right to speak on artistic matters to climb our stairs and address us on such subjects as this, we must examine carefully the exact position taken up, and particularly the very careful distinction the lecturer made between the sense of the words "beautiful" and "artistic." "Artistic" was taken as implying something more than merely beautiful. And I think it may be admitted that, while the distinction is a sound and necessary one, it is one that the great majority of photographers practically overlook. Even of those who devote themselves to what we roughly call artistic photography, there are very few who even aim at more than what Professor Baldwin Brown would call beautiful rather than artistic results. In the following enumeration of the four special qualities that were put forward as necessary in a work of art, it may be noted that the first two are, almost beyond dispute, within the reach of photographers. It was in respect possibly of the third, and certainly of the fourth, that the lecturer held that the very conditions under which we as photographers work preclude us from gaining results that can be called, in the technical and restricted sense, artistic. The four qualities were:—

1. A harmonious general impression of colour and light, and shade, and form, gained by a careful subordination of details to general effect.

2. This general effect must be dominated by a single idea, to convey to our apprehensions some artistic statement, and in order that it may do so there will need to be emphasis and accent in the piece, as well as breadth and harmony.

3. This statement must be a personal one. We must feel the artistic individuality as the influence which binds together the elements of the scene and makes the whole intelligible to us as a unity. On this style depends.

4. This personality must be expressed in the whole outward execution of the piece. The work is the artist's composition; let it be also in his handwriting.

Let us assume it to be conceded that, within certain limits of which the photographer is fully conscious, he can secure, first, the harmonious general impression; and, second, what is perhaps implied in the first, the subordination of the whole to one dominating pictorial idea. This brings us to the third point—the personal element, the sense of an individuality behind the work, the feeling a good picture gives us that an artistically sensitive mind has looked on or imagined the scene before us, and, experiencing some thrill of beauty in it, has taken it up, purged it of all that was irrelevant to the particular aspect that charmed, and presented the remainder in such a pointed and telling way, with all necessary modifications and accentuations, as to express in the clearest and straightest terms just the aspect which awoke the original sentiment in the mind of the artist. Those of us who aim at pictorial photography will, I think, recognise in this process of remodelling, and eliminating, and emphasising, the work they find themselves engaged in when they are preparing their subject, and also at the later stages of developing and printing. We form in our minds some tolerably distinct idea of the effect we want to produce. Then, looking to what is before the camera, we find this, that, and the other object superfluous, and therefore a blemish. By the sweat of our brow, therefore, we remove them. This fabric is too obtrusive in pattern or texture; it must either be replaced or softened by adjustment of focus. This line is ugly or uninteresting; we must rearrange, or merge it, by a variation of light, into the background. All these operations, as well as such processes as local restraint or acceleration in development, screening during printing, and many other methods in daily use, are resorted to with the direct purpose of removing obstacles to a straightforward expression of a strictly personal idea. Even in landscape work, similar means are used to gain adequate self-expression. I am talking, of course, of genuine pictorial landscape, not of the topographical views in the stationers' windows. If we cannot move about the features of the face of nature at our will, we can do a good deal to control their relative value and position on the plate by carefully choosing the one out of an infinite number of possible points of view which seems best to express the sentiment we desire to convey. Then we have to consider the question of lighting; in what position must the sun be to illuminate the scene in just the way that suits our purpose? And in conjunction with lighting there is the condition of the atmosphere; to what extent will a slight haze or vapour help us, or, in some cases, interfere with us in getting the effect we want—in securing breadth by the loss of impertinent local detail, and gradation from the strongest touches in the foreground to the delicate gauzelike tones in the distance. Thus, by observing, planning, and waiting, we often get, if we as often fail to get, just that combination of conditions which enables us to secure the aspect we had conceived, and the resulting print is, in a real and not overstrained sense, a personal statement. The picture will be an individual one, showing what those qualities were which we desired to reproduce, and so revealing something of our personal bias and predilections. Another man would have aimed at a different effect, would have chosen a different point of view, a

different light, a different state of the atmosphere; would have included a larger or a less angle, have insisted on a sharper or a more diffused focus; and, in developing and printing, he would have shown that our impression of the scene was not his one, and that what to us were the essential and characteristic features of the piece were to him superfluous details to be modified or suppressed. While, therefore, we do not overlook the obvious limitations under which photographers work, as compared with painters, nor claim that a photograph can be an individual expression of feeling in the same degree that a painting can, I think we are fully entitled to claim, what is enough for our purpose, that it is capable of recording, and even that it does inevitably record, the feeling, or the absence of feeling, of the individual who produced it.

Before going on to consider what was given as the fourth essential quality in a work of art, it is worth while noticing that even the art of painting existed practically without it up till two or three hundred years ago. Before that time painters did not express their individuality in the *outward execution* of their work in the same full sense in which Rembrandt and Velazquez did, or in which Mr. Whistler, for instance, does in our own day. Following Professor Baldwin Brown's comparison of this expression of self in technique to handwriting, we might almost say that in the early history of painting the ideal was that of copperplate. Only comparatively recently has the value of characteristic personal handwriting been recognised. You do not find among the early painters that emotional variety of surface, that individually expressive touch, that suggestive brush work, which is so essential an element in the best modern art. If the surface is not actually uniform in texture, such variety as there was was due rather to the exigencies of following the various textures in the subject than to the differences of manner and degree in which the constituent parts of the subject found a response in the imagination of the painter, in their relation to the whole effect. In putting together these notes, I happened to have before me reproductions of two portraits which illustrate this difference of method. One was Holbein's portrait of the Duke of Norfolk (the original of which is, I think, in Hampton Court); the other was the noble *Philip IV.*, in the National Gallery, in London, by Velazquez. In the first, the satin sleeves, the velvet cloak, the ermine cape, are all faithfully elaborated, and there is not a touch of the brush that is not imitative and minutely descriptive of these various surfaces. In the other portrait there is no attempt to give information as to the materials in which Philip of Spain was dressed. All the beauty and dignity of rich, quiet costume is there, but not such an inventory of fabrics as would enable you to order a duplicate suit of your tailor. In each of the two portraits there is a chain round the neck of the subject. Holbein gives you every detail of the goldsmith's work. You can read the same motto printed on at least eight of the circular panels which form the alternate links. Velasquez, on the other hand, merely shows you the handsome effect of a chain, its value as decoration; and as a painter, concerned only with beauty, he had no further business with it. The artist has to show us, not indisputable facts as to the construction of things, but only a beautiful aspect of things. And yet it would be obviously absurd to say that, because painters before a certain period had not arrived at the expressive or interpretative, and not merely realistic or imitative, technique which Rembrandt and Velazquez introduced, therefore their work was interesting and even beautiful, but not artistic.

While, however, we feel that we must admit as works of art, because we have felt their charm, pictures which are not distinguished by any very individual character in the outward execution, it has to be admitted that this quality of expressiveness in the technique is nowadays an indispensable element in painting; and, though we need not admit that the absence of it in photography must necessarily disqualify photography as a possible means of getting artistic results, it is, nevertheless, an interesting question whether or not this quality is within the reach of photographers. We know what the painters' answer usually is; and we should certainly expect their judgment to be a correct one, unless we can show that there is any reason, in the nature of the case, why they should be apt to be misled into a mistaken opinion. But there is, I think, one circumstance which has almost inevitably the effect of making painters jump to a wrong conclusion. I mean the fact that painting is a very much more pliable medium for the expression of ideas than photography at present is, or probably ever can be. The painter cannot help being struck with the *comparative* inflexibility of photography, and slips too readily into the assumption that it is an *absolute* inflexibility. In looking at a photograph, even if it happens to be one of pictorial intention (and I do not think, by the bye, that painters are much in the way of seeing the best photographs), the painter probably notices lines he would have altered, values he would have readjusted, and so on. To his brush these would have been matters easily controlled up to the last moment; but, photography being, as he assumes, at best a mechanical rendering of a well-arranged subject, he goes off with the reflection that no such control is possible to the camera. This is just where he falls into the mistake. We have not, it is true, the absolute power of reconstruction, of suppression, of elaboration that the painter has. But to admit this is a vastly different thing from confessing that we have no means of showing how our subject appeals to us in the way in which we put it on the plate and on the print. It is as if a violinist were to finger a piano, and, finding that he could not, for instance, sustain a single tone with expressive variations of crescendo and diminuendo, as he can on the violin, thereby producing some of his most beautiful and artistic effects, were to conclude that the piano is a purely mechanical instrument, incapable of expressing any personal sentiment. But every instrument, and every art, has its own technique; and, to competently criticise an art, you must have learned something of its particular technique, which is, as it were, the language in which it speaks to you. No man can have any intimate appreciation of modern painting who has not at least some general idea of how the colour is laid on; and, to judge even our humbler art, some education is necessary in the methods by which effects are produced. The trained violinist may quite well be but an indifferent judge of piano playing. He may be listening for effects and qualities which are quite foreign to the genius of that instrument, and overlooking others that are characteristic and vital. Similarly, the painter errs in condemning photographs for not exhibiting the qualities that he is accustomed to look for in a painting, and his eye is not educated to recognise the special qualities by which individuality is expressed in a photograph.

It is, of course, unnecessary, in speaking to photographers, to go over the means at our disposal of expressing our personal apprehension of our subject—those methods and devices, I mean, often used as it were unconsciously, which convey to the sensitive critic not only what it was in nature that we felt, but also to some extent how we felt it. Nor do I think that artists, whether in painting or in photography, should be too conscious of their methods or too analytical of the means by which they have gained effects. I sometimes wonder whether Velazquez, for instance, was aware of the extent to which his splendid artistic vision overlooked what was superfluous and irrelevant. Did he not perhaps believe that he painted what was before him, and paint it in the best way he knew, without too deliberate a choice of methods, or consciousness of glazes, scumbles, and "underneaths?" So I think we shall be wise if, finding, every man for himself, old and new uses for the tools and materials with which we work, we do not talk about them too much, or crystallise them into conscious tricks and processes, but gain such a familiarity with them that in our practical work the best way of doing a thing comes ready to our hand. But that there is, within certain daily expanding limits, an amount of latitude that allows an artist to declare himself, should be obvious to any one who places the work of, say, Mr. Crooke or Mr. Craig Annan, alongside of that of the purely commercial photographer, who merely provides good likenesses and sometimes even has respect to the laws, if not to the spirit, of composition. Without, therefore, attempting to detail the various technical means employed to gain artistic, instead of purely realistic, results, without setting forth the ways in which development of the negative can be intelligently controlled and the print made to yield carefully considered effects, and without taking up the thorny questions of retouching and combination-printing, we may, I think, confidently press the question whether the fine work of men such as those I have named does not show an *artistic technique* which the other lacks, and whether, apart from the superiority in posing and lighting, there is not what may almost be called a difference in texture, a quality which even the eye that has not been trained to understand the methods of photography cannot but recognise as indicating the obedience of tools and materials to the thought of the artist. The fact that on the one side the work has charm and pictorial interest, and suggests inevitably an artistic mind behind it, and that on the other the work is bald and lifeless, implies a difference in degree of expressiveness; and, where there are degrees of expressiveness, there art finds, and must find, an opportunity. To state the argument by an extremely modest analogy, a man's handwriting expresses his individuality in a very high degree; every letter, every dot and stroke, every curtailment, and every flourish, reveal something of the character of the man who wrote them. In comparison with handwriting, printing may seem a mere mechanical process; and, in a sense, so it is. But has not printing its own expressiveness? Open any book, and the page will tell you whether the printer was an artist or not. And in the same way, though in a greater degree, photography, though it cannot pretend to the nicety and suppleness of painting as a medium of artistic feeling, is yet a combination of processes which may be used handsomely or meanly, and which may be made to give results as widely apart as a cheap advertisement is from a fine title-page.

I hope I may have said enough to achieve my object, that is, to start some discussion on the general question. At the same time, the best refutation of the view that art can have no place in photography must come from the studio and the dark room rather than from the lecture-hall; and I feel sure that no one will be more pleased if we should be stimulated to gain in our work something more of the flexibility, the simplicity, the emphasis, and the reticence of great art, than our late lecturer.

JOHN WARRACK, JUN.

THE CAPABILITIES OF THE THREE-COLOUR PROCESS FROM A COMMERCIAL POINT OF VIEW.

IT is only necessary to go back a few years, to the time when half-tone engraving first become general, says Mr. M. Wolfe in the *Practical*

Process Worker, to see the rapid strides that pictorial illustrations have taken, not only in the current literature of the day, but in everything of an advertising nature. Merchants and business people of every description recognise in good pictures of the articles they have for sale the best means for selling them. How quickly the old woodcut illustrations gave way to the true half-tone, until at the present time there is no magazine but what has its quota of fine half-tone illustrations; there is scarcely a catalogue but what has its principal wares pictured in half-tone.

As it was true of the advancement of half-tone illustrations, so it will be true of the new claimant to public favour, the new three-colour process. I have every reason to believe the three-colour process will have the same rapid advancement as the half-tone. What more natural to please the eye than an illustration in colour! If the half-tone as a true representative of the subject in black and white is so far ahead as to displace wood-engraving, what may be said of the same subject in its true colour? The three-colour process is yet in its infancy, but already it is making rapid advancement in public favour. In the reproduction of paintings, water-colour sketches, it has no equal in its fidelity to the originals, while its value as an illustrator of all articles in colour that are of a commercial value will soon be unquestioned, and will be as far ahead of the half-tone process as the half-tone was of the old methods.

The time is not far ahead when every photo-engraver of any standing will be compelled to adopt it. There is money to be made at it if rightly undertaken; the chief obstacle in the adoption of the process is the amount of work and care that is necessary to make a success, the adoption of dry plates and dry-plate methods to secure the first or orthochromatic effects; the preparing of the orthochromatic plates and the making of the colour filters. It is absolutely necessary that the engraver adopting the process understands the above thoroughly; *but it can be done*, it only wants *vim*. A word to the wise, etc.

As to the character of the work to be done, it is as varied as there are articles for sale. Take, for instance, fancy covers for catalogues, samples of rugs, silks, lamps, lamp shades, fancy upholstered furniture, fancy clocks, vases, carpets, oilcloths, and a great many things too numerous to mention. The manufacturer or dealer understands the value of good and attractive pictures of his wares, and to be rightly represented it must be in colours, and he is willing to pay a price accordingly, for the very good reason that it will well repay him for doing so.

The reproduction of paintings, water-colour sketches, and even photographs in colours for books and pamphlets, in addition to the above, should make a valuable source of revenue to the photo-engraver.

Sept. 22, 1896. R. P. DRAGE, *Hon. Sec.*

The above balance-sheet has been submitted to and passed by the Council of the Convention.

NATIONAL ASSOCIATION OF PROFESSIONAL PHOTOGRAPHERS.

ANNUAL MEETING.

THE Annual Meeting of the Association was held at Anderton's Hotel, Fleet-street, on Monday, September 28, Mr. W. Barry (Hull), the President, in the chair.

There were present, amongst others, Messrs. Adamson (London and Glasgow), Bromwich, Hon. Secretary (Kidderminster), Boak (Driffield), Eddison (Leeds), Fall (London), Freke (Cardiff), Illingworth (Halifax), Simpson (Grantham), Weston (London), Whaley (Doncaster), Whitlock (Birmingham), Whorwell (Dover), and D. J. O'Neill, Secretary.

The members and representatives of the photographic press dined together in the evening at Anderton's Hotel.

Apologies for non-attendance had been received from several members, and some resignations had been received since the last meeting at Leeds (Convention week), accompanying which were various letters expressing sympathy with the objects of the Association and regret that, by reason of the small support and scanty membership on the part of the profession, the Council had been unable to do as much for the general welfare as they had desired.

With reference to the suggestion on the agenda, as to the "Association being conducted on social lines," a full and lengthy discussion took place.

It was explained by the Chairman that a similar proposition had been made before, duly notified to the members, and fully discussed on Tuesday, July 14, 1896, at the meeting at Leeds. It was then resolved—"That this Association has done good service to the professional photographers, and it is now advised to continue it in the same purpose and use, with an increase of the social element."

It was now resolved that this Association be conducted on the same lines as hitherto, and that the next summer meeting be held at Worcester early in June, ladies being specially invited. The Secretary reported cash balance in hand, and submitted an analysis of the attendance at all meetings since the formation of the Association: London, November 9, giving an average of nineteen for the five meetings on that date, while the other nine meetings at other dates, held in Manchester, Leeds, Birmingham, Sheffield, and the Matlock Summer Excursion, showed an average of fourteen.

A statement having appeared in the *Photographic Review* that this Association had received its deathblow at Leeds (Convention week), the Secretary reported that he had refuted that statement in a letter to that magazine, which was duly inserted. Copies of same letter had been inserted in the leading photographic papers, and a copy sent to each member. The next annual meeting is to be held on opening day of the Royal Photographic Society's Exhibition, in London, September, 1897. Respecting the Photographic "Convention" Meeting, 1897, it was left to individual members to make their own arrangements, and not to issue any circular as from the N.A.P.P.

The Secretary was instructed to forward a vote of sympathy to Mr. C. E. Corke, of Sevenoaks, with reference to his recent treatment by the *Builder*, and to assure him that, if any further action be taken by him in this case, this Association will be pleased to further support him by resolution.

Our Editorial Table.

SPECIMENS OF PHOTO-MECHANICAL PRINTING.

London and Derby: Bemrose & Sons.

MESSRS. BEMROSE & SONS send us a book containing several specimens of photo-mechanical printing by a variety of processes. Photo-chromotypy, half-tone, photo-zincography, collotypes on art paper, enamel paper, cartridge and other surfaces, smooth and rough, are the processes selected for illustration, and the specimens throughout are extremely beautiful in execution. Even as specimens, we have seldom seen better examples of photo-mechanical printing.

CATALOGUES RECEIVED.

Thorn & Hoddle, 164 and 169, Camberwell New-road, S.E.

MESSRS. THORN & HODDLE'S little catalogue sets forth illustrated particulars of acetylene generators for enlarging, portrait, and domestic lighting purposes. The system employed for portraiture is shown by means of an illustration in another column. The catalogue should be found useful for reference by those adopting acetylene.

Newman & Guardia, 92, Shaftesbury-avenue.

A POCKET-BOOK of some thirty-two pages gives instructions for working the "N. & G." cameras and other photographic instruments. It is reprinted from the firm's complete catalogue.

News and Notes.

THE British Photo-print Company, of Montpelier-road, Twickenham, have purchased the business lately carried on by the Richmond College Company.

MESSRS. DAWBARN & WARD write: "It may interest your readers to know that Her Majesty the Queen has been pleased to accept a copy of *Shakespeare's Town and Times*, of which you kindly gave a review on August 7."

ROYAL PHOTOGRAPHIC SOCIETY.—Ordinary Meeting, Tuesday, October 13, at the Gallery, 5A, Pall Mall East, at 8 p.m. The President (Captain W. de W. Abney, C.B.) will deliver his annual address. Presentation of the medals.

THE Hackney Photographic Society's Annual Exhibition has been fixed for November 17, 18, 19, and 20 next, at the Morley Hall, Hackney. Judges to be Messrs. F. Hollyer, F. C. Lambert, and E. J. Wall; Hanging Judge, Mr. A. Mackie. Entry forms will be ready next week.

THE PHOTOGRAPHIC CLUB.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock on Wednesday evening, October 14. Mr. C. Hoddle will give a demonstration of *Acetylene Gas for Ordinary Use and Lantern Projection*. Members will have an opportunity of trying their new slides.

EDDISON, LIMITED.—This Company held its First General Annual Meeting at its registered office, 1, Commercial-street, Leeds, on Saturday, October 3, under the presidency of the Managing Director. The Auditor submitted his report, and the Chairman expressed his satisfaction at the results of their first year's trading (as shown in the accounts, which had been forwarded to each shareholder), and his confident hope of still better results in the future. A dividend of ten per cent. per annum was declared on all fully paid-up shares, and a substantial reserve fund established.

OXFORD CAMERA CLUB.—The first meeting of the winter session will be held on Monday, October 12, at 8 p.m., in the University Museum. The American set of lantern slides, from the Royal Photographic Society, will be exhibited. Members are reminded that this day, October 12, is the last day for sending in pictures for competition for the Exhibition. It is hoped that all members will do their best to make the Exhibition a success. As the programme for the winter is now under consideration, the Secretaries will be glad to receive from members, as soon as possible, offers of papers, demonstrations, or lantern exhibitions, with a note of the time most convenient to them.

MR. F. J. MOULT writes: "Owing to the great increase in my business during the last two years, and the necessity for assistance in the management, I have taken into partnership my brother, Mr. George E. Moult. The title of the new firm will be Moult Bros. We have taken on a lease the premises situated at No. 141, Oxford-street (lately occupied by Messrs. Perken, Son, & Rayment), which we have styled 'The West-end Photographic Stores.' A great variety of photographic apparatus, chemicals, materials, &c., will be kept in stock. Especial attention will be given to the department devoted to the developing, printing, and enlarging of amateurs' negatives. A dark room, absolutely free of charge, will be reserved for the use of amateurs wishing to change plates, films, &c., and all possible help and instruction in developing and printing will be given free to purchasers of apparatus."

PRINTING UNDER DEEP GREEN GLASS.—At a meeting of the Calcutta Microscopical Society lately, the Hon. Secretary (Mr. W. J. Simmons) showed some prints of photo-micrographs he had made on ordinary albumenised paper under a deep green glass shade. The prints were toned and fixed in the usual baths, and, as regards the paper and chemicals used, there was nothing out of the ordinary; but Mr. Simmons invited attention to the brilliant blackness of the tone of the prints. This he attributed to the green glass shade under which they were printed, whereas, under ordinary white glass, the tone, he said, would have been of the ordinary purple-brown character. His conclusion may be accepted if it is meant that the green light filter he used admitted of better gradations in the tone of the prints; indeed, without some such filter, a large proportion of the tones would probably have been lost; but the colour of the prints is most likely due to the amount of forcing they got in the toning bath. I would, however, recommend Mr. Simmons' plan to those who sigh for exquisitely graded prints full of delicate detail.—*Journal of the Photographic Society of India.*

THE AFFILIATION OF PHOTOGRAPHIC SOCIETIES.—The first of the series of six lectures on popular phases of photography, organized by the above, was delivered by Mr. John A. Hodges on Monday, October 5, on the subject of *Lantern-slide Making*, at 12, Hanover-square, Mr. W. Thomas (Chairman of the Affiliation) presiding. The audience, an appreciative, if not a very numerous, one, was kept fully interested during the delivery of the lecture by a number of slides carefully selected and prepared to demonstrate the different points treated of by Mr. Hodges, and comprised comparative specimens made by the collodion and gelatine processes, others showing the advantages in certain cases of printing-in clouds, the proper selection of colour, and the vital importance of shape of mask. The merits and demerits of contact printing and of reduction in the camera, according to circumstances, were fully gone into by the lecturer with the help of examples, and an exhaustive paper on the subject brought to a close with a criticism of a few slides on the screen, with the idea of showing what to leave out, and what to introduce, and generally where they were open to improvement.

LEWISHAM CAMERA CLUB AND EXHIBITION.—This Club, which numbers about seventy members, held an Exhibition of members' work last week, in which the pictures were supplemented by a very fine show of old apparatus and photographs, which included the original camera used by the late Walter B. Woodbury for balloon photography, an old camera for use with a non-achromatic lens, with a focussing scale on the top for the difference between the visual and chemical foci, and some paper negatives by the late J. G. Tunny, of Edinburgh, which showed that even in those days they knew not only how to make good negatives, but also artistic pictures. Here, too, were a turn-table for cameras made by George Jack in 1854, Johnson's pantoscopic camera, early Daguerreotypes, and pinhole negatives. All these things were lent by Mr. A. L. Henderson, who also showed models of his original plate-coating and emulsion-making things, and some fine enamels by his process. Amongst the pictures were some fine examples of commercial photography by Bedford Lemere, and amongst the members the most noticeable results were by Messrs. T. P. Rogers, H. M. C. Sprunt, Davidson, C. J. Lambert, Churchill, and Eastwood.

PHOTOGRAPHING THE CZAR AT BALMORAL. — A considerable portion of Tuesday, September 29, was taken up by photographing the Imperial and Royal company then at Balmoral Castle. This task was intrusted by the Queen to Mr. R. Milne, Ballater, and he succeeded in taking fourteen different pictures of the Royal personages at the memorable gathering. The Emperor was photographed first in his full-dress uniform as Colonel of the Scots Greys, wearing the ribbon and star of the Garter, next in the undress uniform of the regiment, and then in the uniform of a Russian regiment. The scene was the garden terrace, the background being the ivied wall of the balustrade. In the brilliant scarlet uniform of the Scots Greys, with the imposing bearskin, His Majesty presented a fine soldierly appearance. The Duke of Connaught, after having been photographed alone in undress uniform, was next taken as Colonel of the Scots Guards, and along with the Emperor. Perhaps the most interesting group of the day was that comprising four generations of the two Royal houses so closely related to each other. It consisted of the Queen, the Emperor and Empress, the Prince of Wales (in Highland costume), and the infant Grand Duchess Olga. A most effective picture was obtained in the corridor which leads from the main entrance to the ballroom. Another very fine group was composed of the Emperor and Empress, the Princess of Wales, Prince and Princess Charles of Denmark, Princess Victoria of Wales, Princess Victoria of Schleswig-Holstein, the Duke and Duchess of Connaught, and Princess Margaret and Princess Patricia of Connaught. Likenesses were also taken of the Empress's Cossack attendants in resplendent livery, and of the members of the Royal households. Possibly on no previous occasion has such a gathering of Royalty residing under the same roof been placed before the camera.

WEST SURREY PHOTOGRAPHIC SOCIETY.—Mr. C. E. White, the Hon. Secretary of the West Surrey Photographic Society, has a nice turn for alliteration. The Society's session opened at the Felix Institute, Lavender Hill, on Thursday evening, October 1, and the attractions, as set forth by Mr. White, consisted of cake, coffee, and conversation. These there were, and a great deal more that was equally enjoyable. The club-rooms were filled by members and their friends, including the President (Mr. George H. James), Mr. J. T. Price (Vice-President), Messrs. J. Agars, W. J. Channon, A. W. Curtiss, E. Pointon (members of the Committee), Mr. G. Bottle (Assistant Secretary), and the Hon. Secretary and Treasurer (Mr. C. E. White). The photographic work done by the Club is of a high order. One of the members, Mr. P. Martin, has just been awarded a medal by the Royal Photographic Society for a series of lantern slides, which depict night scenes in London. Other members are exhibitors at the chief galleries. A number of artistic pictures were on view last evening. A nice musical programme was carried out as follows:—Pianoforte solo, "Festival March," Mrs. Morgan; song, "Only once more," Mr. F. T. White; pianoforte solo, "Tambournon et Trompette," Mrs. Morgan; pianoforte duet, "Je suis pret," Miss and Mr. C. Halenan; song, "I'll sing thee songs of Araby," Mr. Smith; duet, "Reminiscences of Ireland," Messrs. Smith (brothers); song, "Come into the garden, Maud," Mr. T. White; pianoforte solo, "Marche des Troubadours," Mrs. Halenan; pianoforte duet, "La Reine," Mrs. and Miss Halenan; song, "Our Bazaar," Mr. E. J. Smith; pianoforte solo, "Grand Battle March," Miss Halenan; waltz, "Battle of Flowers," Mrs. Halenan. With a view to the encouragement of applied photography among its members, the Society is offering a prize of two guineas for a design with which to embellish the cover of its prospectus. An instructive programme has been arranged for the ensuing session. The social functions of the Society, however, have not been overlooked; one evening is to be devoted to "tea, talk, and tobacco."—*South Western Star.*

THE YERKES OBSERVATORY.—The great Lick Telescope is about to be superseded as the largest in the world, and will have to yield that pre-eminence to the Yerkes, says a contemporary, which will soon be ready for use in the building provided for its reception, at a spot about a mile from the town of William Bay, near Lake Geneva, in the State of Wisconsin, about seventy-five miles from Chicago, with the University of which the new establishment will be closely connected. The Yerkes Observatory was founded in 1892, through the munificence of Mr. Charles T. Yerkes, of Chicago. In that year Mr. Alvan G. Clark undertook the construction of an object-glass, 40 inches in diameter, for the principal telescope of this observatory. The instrument on which it was to be mounted was at once commenced, and completed in the following year, when it was exhibited at the Columbian Exposition of 1893. The object-glass has recently been tested by Professor Keeler, who considers that its definition is fully equal to that of the Lick, while its light-gathering power is considerably greater. The construction of the main building of the observatory was begun in April, 1895, and is now very nearly completed. Its form is that of a Roman cross, with three domes, and a meridian at the extremities. The principal dome (containing the great telescope, the tube of which, with its attachments, is about 75 feet long) is 90 feet in diameter and 110 feet high. On the ends of the arms of the cross are two smaller domes, to contain respectively a 12-inch refractor, transferred from the Kenwood Observatory, and a 24-inch reflector. Between them is the heliostat room, 100 feet long and 12 feet wide. The meridian room is at the end of the cross, farthest from the great dome, the latter being at the western end of the building, which lies east and west, and is about 330 feet long. Professor George E. Hale has been appointed Director of the Yerkes Observatory, and the well-known astronomers, Professors Burnham and Barnard (the latter of whom discovered the fifth satellite of Jupiter in 1892), will occupy positions there, while a separate department will be devoted to giving instruction in practical astronomy, to encourage astronomical study and research, at the University of Chicago, and train up a school of astronomers qualified in the future to further extend our knowledge of the most sublime and interesting of the sciences.

Patent News.

THE following applications for Patents were made between September 23 and September 30, 1896:—

DEVELOPING FILMS.—No. 20,831. "Improvements in Apparatus for Use in the Development and Treatment of Flexible Photographic Films or Tissue." A. P. OKELL.

ARTIFICIAL LIGHTING.—No. 20,877. "Improvements in and connected with Artificial Lighting Apparatus for Photographic and other Purposes." A. SALMON.

CHROMO-PHOTOGRAPHY.—No. 20,898. "Improvements in and relating to Chromo-photography." V. VAUCAMPS.

PORTABLE CAMERA.—No. 20,971. "Portable Photographic Camera." R. DAESCHNER.

SCREEN KINETOSCOPY.—No. 20,978. "Improvements in Apparatus for Obtaining, Exposing, and Projecting Pictures known as Animated Photographs." A. LOSCHER and R. KLEIN.

EXHIBITING PHOTOGRAPHS.—No. 21,015. "An Improved Method of Exhibiting Photographs." C. H. DANIELL.

CERAMIC PHOTOGRAPHY.—No. 21,081. "A New or Improved Method or Process of Producing Permanent Photographs on China and other Vitreous Surfaces." J. SLATER.

SURVEYING INSTRUMENTS.—No. 21,117. "Improvements in Instruments for Surveying with the Aid of Photography." J. B. LEE.

LANTERNS.—No. 21,203. "Improvements in Lanterns, Magic Lanterns, and the like." D. ALLAN.

SCREEN.—No. 21,269. "An Improved Screen for Optical Projection Purposes." Complete specification. L. WRIGHT and J. ANDERTON.

CHRONO-PHOTOGRAPHIC APPARATUS.—No. 21,381. "Improvements in Chronophotographic Apparatus." M. J. H. JOLY.

CHRONO-PHOTOGRAPHIC APPARATUS.—No. 21,382. "Improvements in Chronophotographic Apparatus Adapted for the Projection of Positives upon a Screen." M. J. H. JOLY.

CHRONO-PHOTOGRAPHIC APPARATUS.—No. 21,383. "An Apparatus for Use in Exposing the Positive Films used in Chrono-photographic Apparatus." M. J. H. JOLY.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK

October.	Name of Society.	Subject.
12	Bradford	*Bromide Printing.* Messrs. Nicholson and Newstead.
12	Camera Club	*Birds and Rocks.* Dr. Collins.
12	North Middlesex	*Venice and Lucerne.* W. F. Fenton-Jones.
12	Richmond	*Exhibitions and Hints to Exhibitors.* The President.
13	Ashton-under-Lyne	Lecture. W. Lamond Howie.
13	Birmingham Photo. Society	Demonstration on the Production of Carbon and Bromide Enlargements, Positives, and Negatives, by aid of the Society's Enlarging Lantern. W. Bateman and C. S. Bayuton.
13	Hackney	*The Treatment of Figures.* Rev. F. C. Lambert.
13	Lewisham	*At Home Subjects.* W. Thomas, F.R.P.S.
14	Camera Club	Testing Lantern Slides.
14	Leeds Camera Club	Beginners' Lecture.—II. *Exposure and Development.* A. Hombnrg.
14	Leytonstone	Special Meeting at New Headquarters.
14	Photographic Club	*Acetylene Gas for Ordinary Use and Lantern Projection.* C. Hoddle.
14	Southport	*The Practical Working of C.C. Paper.* George Cross.
15	London and Provincial	*Theory of Development.* E. Banks.
15	Camera Club	
15	Darwen	*Tour in Spain.* J. T. Leos.
15	Liverpool Amateur	Practical Demonstration. F. Anyon.
15	West Surrey	Lecture.
16	Croydon Microscopical	Conversational Meeting.
17	Leytonstone	Open Social Meeting.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

OCTOBER 1,—Mr. Bedding in the chair.

Mr. WALL announced that the room would in future be open to members at seven o'clock on Thursday evenings, when the journals would be available to readers, and he hoped, in this and other ways, to make things more lively.

So far as it was ready, the programme for the session was read, and the desirability of their co-operation to fill up vacant dates urged on the members.

Mr. WELFORD, in the course of some remarks, said it had been thought advisable that there should be a paid Recorder to take notes of the Association's proceedings, and he proposed that such should be done.

Mr. HENDERSON seconded the proposition, and it was carried unanimously.

It being announced as an Open Evening, when various objects of interest would be discussed, Mr. HENDERSON invited the members to give their opinions as to the lighting of a portrait negative, which he brought up, and which was taken in a studio with gas light, supplied from twenty incandescent burners, with an exposure of six seconds. It was, moreover, untouched. He also showed a dozen interesting examples of Talbotype negatives on waxed paper, which had been taken between the years 1840 and 1855. Gelatine prints of one or two were shown, and they exhibited very little trace of grain. The rapid with which they printed was surprising. In answer to a remark, he thought they would enlarge pretty well.

Mr. BECKETT said it would be impossible to avoid the presence of grain in enlarging such negatives.

Mr. J. E. HODD said, while on the subject of paper negatives, that Mr. Wellington discouraged waxing of his negative paper, as it was found to intensify the grain considerably.

Mr. HENDERSON remarked that the different qualities of paper had a lot to do with that. There was considerable difficulty with modern papers, and waxing was injurious unless the paper was absolutely permeated.

Mr. WALL suggested that the difficulty arose from the fact that English papers were sized with gelatine, while foreign papers were resin-sized.

Mr. A. HADDON, in commenting on the oft-repeated statement that gelatine is tanned by pyrogallol, said he had published, with another, a paper showing that pyro itself did not tan gelatine, and he had brought up the basis of their conclusions in the shape of two sealed tubes containing mixtures of dry pyro, gelatine, and water, which, from certain peculiarities, showed that pyro itself had no tanning action. When oxidised, however, pyro will tan.

The CHAIRMAN believed that, in all these statements to which Mr. Haddon took exception, it was meant that the tanning action of pyro was when it was used in combination with the other constituents of the developer. He could not recall a definite statement that pyro, *per se*, had any tanning action.

Mr. HODD said that, as photographers, we were only concerned with pyro in conjunction with the developer, and it was well known that, in such a form, it possessed a tanning influence over gelatine.

With regard to hyposulphite of soda being a powerful solvent of metallic silver, Mr. HADDON showed a piece of paper enclosed in a tube, which was sealed some twelve months ago, containing a ten per cent. solution of hypo, and it could be seen that the metallic silver was still in the paper. If the hypo were a solvent, it would all have gone. On the other hand, in the presence of oxygen, hypo has this power of dissolving metallic silver. Mr. Haddon also showed a portion of a plate in a tube containing hypo since November last, the gradations being preserved from end to end.

Mr. BECKETT, after a remark by Mr. Everitt, that a negative left in the fixing bath for some days experienced a reducing action, said that it was not always so. If the bath had been much used, it exercised an intensifying action, and this was very noticeable with some plates if left too long.

Mr. HODD had heard many complaints about the action of metabisulphite on pyro, so that in a short time its developing power was destroyed. The relative proportions, as recommended, were one ounce to one ounce, but he had satisfactorily used much less. In reply to an inquiry, he said the action would not be set up by the addition of alkali.

PHOTOGRAPHIC CLUB.

OCTOBER 1,—Mr. Frank Haes occupied the chair.

Mr. HORACE WILMER handed to the Chairman a very beautiful portrait of the late Mr. William Bedford, which, on behalf of Mrs. Bedford, he asked the Club to accept. In presenting the portrait, Mr. Wilmer said: "In presenting this portrait of her late husband, Mrs. Bedford hopes that it will help to keep his memory green in the hearts of those whose affection he valued."

Mr. FOXLEE expressed the thanks of the Club and his own pleasure at receiving so kindly a gift and reminder of their deceased friend.

Mr. BRIDGE added his expression of thanks and appreciation of the gift. He, with others, had valued the friendship of Mr. Bedford very highly, and the photograph would serve as a very pleasant reminder to them all of him.

Mr. HAES put the proposition formally to the members that the Hon. Secretary should write to the donor and express the Club's thanks for the gift.

The motion was carried unanimously.

The photograph, which appeared to be a carbon enlargement, about 18×12, framed in dark oak and gold, is an excellent and characteristic likeness.

Mr. FRY introduced Mr. George Peck, an amateur photographer from Amsterdam, and the CHAIRMAN, welcoming Mr. Peck, said he hoped he would spend a pleasant evening.

Mr. SNOWDEN WARD delivered his lecture upon

SHAKESPEARE AT HOME.

By means of an excellent set of lantern slides, many of which attained a high degree of pictorial merit, Mr. Ward interested a full attendance, in which were included many ladies, for upwards of an hour. Mr. Ward's lecture consisted of the relation of an interesting sequence of local traditions, upon which he had skilfully contrived to build up the poet's life as a child, a lad, and a man. He showed a set of photographs of the several records of the poet's features, and dealt with their probable verisimilitude, finally suggesting the Droeshout picture as probably possessing the highest claims to authenticity. Other interesting illustrations were: Copy of registration of birth; the font at which he was baptized; some curious frescoes upon which the lad probably gazed; the church in which he was buried, &c. Mr. Ward held his audience deeply interested.

The CHAIRMAN congratulated Mr. Ward upon his very excellent lecture, and the capital negatives and slides, which he understood were the work of Mrs. Ward, had proved deeply interesting. They had seen Shakespeare in his home life and surroundings more fully, and more intimately, and better than they could possibly have known him before.

Mr. O'NEILL, a visitor from Birmingham, asked to be allowed to support the Chairman's remarks. He knew the district well, and he thoroughly appreciated the value of the lecture, which he hoped to induce Mr. Ward to deliver in Birmingham at an early date.

The CHAIRMAN declared it unnecessary to pass a formal vote of thanks. The meeting had, by its spontaneous acclamation, signified its full appreciation of Mr. and Mrs. Ward's efforts.

Borough Polytechnic Photographic Society.—September 30, Annual General Meeting, Mr. A. Bedding in the chair.—The SECRETARY submitted a

report for the summer session, which showed that thirty excursions had been made during the season to various parts of Essex, Hertfordshire, Kent, Middlesex, and Surrey, special mention being directed to the first outing, which took place on Good Friday, to Kingston and the neighbourhood; also to the Whit Monday excursion to Windsor, and to the August Bank Holiday outing to St. Albans, which took the form of a picnic, and proved to be the "success of the season." The following officers were elected for the ensuing year:—*President:* Mr. Edric Bayley, L.C.C.—*Vice-Presidents:* Rev. A. W. Jephson, M.A., Messrs. C. J. Whittuck Rabbits, J.P., and Walter A. Wigram.—*Chairman:* Mr. Alfred Bedding.—*Librarian and Curator:* Mr. W. J. M. Nunn.—*Hon. Treasurer:* Mr. A. W. Lovell.—*Hon. Secretary:* Mr. P. C. Cornford.—*Assistant Hon. Secretary:* Mr. P. J. Brown. The Second Annual Exhibition of the Society will be held at the Institute, 103, Borough-road, S.E., on Monday, Tuesday, Wednesday, and Thursday, December 28, 29, 30, and 31. There will be open classes. Entries will close on December 12. Full particulars and entry forms can be obtained of the Hon. Secretary, Mr. P. C. Cornford, 103, Borough-road, S.E.

Hackney Photographic Society.—On the 29th ult., Mr. William Rawlings presiding, the feature of the evening was a very interesting lecture, illustrated by lantern slides, on the *Half-tone Process*, by Mr. W. Gamble.

FORTHCOMING EXHIBITIONS.

1896.	
Oct. 9–Nov. 7	Photographic Salon, Dudley Gallery, Piccadilly. Alfred Maskell, Dudley Gallery, Piccadilly.
,, 9–Nov. 12	Royal Photographic Society. R. Child Bayley, 12, Hanover-square.
,, 9, 10	Brixton and Clapham Camera Club. C. F. Archer, 1 Gauden-road, Clapham, S.W.
,, 26–31	Southport Social Photographic Club.
November 12	Dulwich Photographic Society.
,, 17–20.....	Hackney Photographic Society.
December 3, 4.....	Aintree Photographic Society. E. P. Heron, 2 Tilney-street, Orrell Park, Aintree, Liverpool.
Dec. 1896–Jan. 1897	Bristol International. Hon. Secretary, 20, Berkeley-square, Clifton, Bristol.

Correspondence.

☛ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

TONING DIFFICULTIES.

To the EDITORS.

GENTLEMEN,—"Perplexed Printer," in your issue of October 2, relates a similar experience to my own. I, at one time, had great difficulty in toning gelatino-chloride with the sulphocyanide bath. There was always a delightful uncertainty about the result, one never knowing whether a print which left the toning bath a good colour would come from the fixing bath blue, yellow, green, or some other undesirable shade. I followed the manufacturer's instructions in the letter, but to no purpose. At last I determined to throw over the instructions and work along my own lines. By a process of varying one factor and then another, I arrived at the following conclusions:—

1. That the sulphocyanide bath should *not* be used immediately after mixing.

2. That, when once mixed, it should be kept in complete darkness until wanted for use.

3. That the washing before toning should be both thorough and regular.

In agreement with these conditions, I adopted the two-stock system mixing my bath in the following proportions:—

Stock A.	
Gold chloride	60 grains.
Water	60 drachms.
Stock B.	
Ammonia sulphocyanide	4 ounces.
Water	16⅔ ,,
Stock C.	
Stock A.....	2 drachms.
Stock B	2 ,,
Water	5 ounces.

Stock C must be mixed at least twenty-four hours before using, and kept in total darkness. I generally mix it once a week, finding no difference in the toning at the end of the week from the beginning. To tone, take four ounces of stock C for each sheet of paper to be toned, which allows about two grains of gold chloride for the sheet, and add it to thirty ounces of water, or, what is better, the same amount of old toning bath. The four ounces should be added between the sheets, that is to say, if six sheets of paper are to be toned, it is better to add the stock in six portions, rather than put the whole quantity in the bath at the commencement.

By adopting this method, I believe "Perplexed Printer" would be able to tone his paper with regularity, and obtain any desired tone. It has worked the same with the several brands that I have tried.—I am, yours &c., JOHN A. RANDALL.

42, *Tonsley-hill, East-hill, Wandsworth. October* 3, 1896.

CONVENTION SLIDES AT PALL MALL.

To the EDITORS.

GENTLEMEN,—Referring to the views of scenes visited during the Leeds Convention which are to be shown on November 4 at the Exhibition of the Royal Photographic Society in Pall Mall, will you kindly allow me to inform all Convention members that the slides must reach my address before Wednesday, October 28?

To avoid duplicates, a Committee of Selection has been appointed by the Council to meet on the evening of October 28, at Anderton's Hotel, Fleet-street.

The slides, after exhibition at Pall Mall, will be retained by the Council for some little time, as many Convention members have expressed their desire to exhibit them in their different districts.—I am, yours, &c.,

R. P. DRAGE, *Hon. Secretary and Treasurer.*

95, *Blenheim-crescent, London, W.*

THE KINETOSCOPE.

To the EDITORS.

GENTLEMEN,—The question of the invention of the kinetoscope, which has recently been discussed in your columns, may possibly be to some extent cleared up by a reference to the specifications of patents for the year 1869. It appears that, as early as 1868, M. Roman Talbot brought into notice an optical toy containing photographs which were made to pass rapidly beneath a Stanhope lens, and which, by the persistence of vision, gave the effect of motion. This instrument he called the kinescope. The patent specification, published in the following year, relates to an instrument called the photoscope, by which microscopic photographs on strips of glass were made to move beneath a lens. The different pictures were so arranged as to give the effect of life or animation.

There is very little difference, except in perfection of detail, between these early instruments and the kinetoscope of to-day. The principle, at least, has been public property for nearly thirty years.—I am, yours, &c.,

J. VINCENT ELSDEN.

"ABOVE THE MORNING MISTS."

To the EDITORS.

GENTLEMEN,—In your criticism of my weak effort hung this year at the Salon, you pointedly asked for an explanation of the title *Above the Morning Mists.* Firstly, I must express my picture a failure, because it fails to fulfil its title, to the photographic critics, and they *should* know. The idea was a picture, viewed from the mountain, of a village in the valley below, and the mists of morn partially or nearly obscuring it (the village) from sight; whereas the standing or viewing point, and the cottages in the mid distance, are, to all intents and purposes, above the mist which lays lower in the valley.

I have no donbt the criticism is a thoroughly good one; but to me it is an enigma. I have looked at it and read it time after time, looking at it sideways—even going to the extent of standing on my head and viewing it with my feet, but have ignominiously failed to understand the —"If so, therefore, what," &c.

As I fear I am missing some information, which I should know, I shall be pleased to have the criticism made clearer. FRED COOP.

Grove Villa, College-road, Bromley.

[We have submitted the above letter to our Critic. "Therefore —what," he tells us, is an interrogative method of expressing surprise that Mr. Coop took the photograph, sent it to the Salon and got it hung. Mr. Coop's frank admission that the result is "weak," and a "failure," however, removes all cause for surprise on the second and third grounds. Our critic is not a gymnast, otherwise he would endeavour to take an inverted view of Mr. Coop's photograph as it hangs, in the hope that its admitted weakness would not be so conspicuous.—ED.]

THE PHOTOGRAPHIC SALON: A WARNING TO INTENDING EXHIBITORS.

To the EDITORS.

GENTLEMEN,—When an artist is invited to send pictures to an exhibition, it is understood that his work is of sufficient merit to be worthy of a place, and it would be an insult to reject it.

The Photographic Salon, being superior to all other art clubs (in its own estimation), thinks or acts differently.

You may be requested to submit photographs, and pay 10*s.* or 12*s.* for carriage, as the writer has done, not to speak of frames, and have all your pictures returned.

Of course, no photographer of repute will submit to be dodged a second time in the same manner, but there may be many others who may be allured in the same way, and "waste their sweetness on the desert air."
—I am, yours, &c., J. C. OLIVER.

2, *Royal-terrace, Glasgow, Oct.* 2, 1896.

THE LINKED RING.

To the EDITORS.

GENTLEMEN,—In an article on *Exhibitions and Judges* in your issue of the 25th ult. Mr. Child Bayley, referring to a previous communication from Mr. Maskell, supposes that the opinions therein expressed may be "regarded . . . . as the Linked Ring's aspect towards the question." Will you kindly allow me to use the publicity of your columns to disabuse Mr. Bayley of his belief, and to say that no single member of the Linked Ring is authorised to speak on behalf of it as a body. It exists on the basis of a friendly agreement to differ, and the opinions and liberty of its members are untrammelled by any necessity for accord on the subject in question or any other.—I am, yours, &c.,

HENRY E. DAVIS.

Camera Club, Charing Cross-road, W.C., October 3, 1896.

TAKING PHOTOGRAPHS FOR NOTHING.

To the EDITORS.

GENTLEMEN,—I have to-day received a circular from the firm of diarists already referred to in your pages and have answered it. I enclose you a copy of my reply which you are at liberty to publish.—I am, yours, &c., H. H. H. CAMERON.

70, *Mortimer-street, W., October* 1, 1896.

"70, *Mortimer-street, W., October* 1, 1896.

"SIR,—I am in receipt of your circular, but do not care to accept the terms of business therein proposed. As an alternative scheme, I myself am going to publish an Almanac, and with your permission shall attach a coupon which will entitle the bearer to call and demand one of your excellent diaries *free of charge;* this will, of course, cost you nothing, and must prove a splendid advertisement for you. I shall only appoint one diarist in your district.

"I may mention that all the other diarists in your district consider this proposal impertinent. "Yours, faithfully,

"H. H. H. CAMERON."

THE PHARMACY ACT.

To the EDITORS.

GENTLEMEN,—I observe that your readers are taking a lively interest in the discussion which is at present going on over the above Act. I, for one, would be very much disappointed if extensive ill feeling were to be developed between photographers and chemists. I do not, however, think that there is much danger of this. As a matter of fact, it is not photographers who are guilty of offences against the Pharmacy Act, but men who supply photographic goods and chemicals, partly, no doubt, to professional photographers, but mostly to amateurs.

These men assume various fanciful names, such as "Photographic Chemists," "Dealers in Photographic Chemicals," &c., under cover of which they make infringements of the Pharmacy Act.

About their guilt there can be no argument. The Pharmacy Act is perfectly plain. It draws up a schedule of poisons, which cannot be sold by any but those who have complied with the educational demands of the State. If these men have not complied with those demands, they must not sell scheduled poisons. This, I should think, ought to be about as plain as a hole in a ladder. If they wish to set the Act aside, the only honourable method they can adopt is to try and get it repealed. In order to this end, they will have to prove that it has been no safeguard to the public, that poisons are no safer in the hands of those who know about them than in the hands of those who don't; that, in short, science and skill are in no way superior to ignorance and lack of skill. To argue that the Act was never meant to interfere with this trader and the other outside the bounds of qualification is in my opinion unworthy of thoughtful men. The glory of British law is that it respects not persons. A man may have been selling poisons before the passing of the Act; but, if he is not registered, he must not sell them now. He may never have had an accident, and he may be as careful as the most careful chemist, but if he is not registered he must not sell poisons. The law may never have been brought to bear upon him until now, but he has been living in the shadow of it all these years, and, if it has at last fallen, he ought rather to be thankful that this catastrophe did not happen sooner than be angry because it has happened at all. After all, I cannot see why photographic dealers should make so bold a fight. The trade in scheduled poisons is not great. We all find it a labour at times to take signatures and make inquiries about a few pence worth of corrosive sublimate, for instance; and, as a matter of fact, unqualified dealers cannot legally keep a poison book, or take signatures at all. I cannot see that they would be much damaged by filling their orders and sending customers to chemists for things they may not supply. Customers would soon learn to know exactly what must be got from chemists, and unqualified dealers wouldn't be any the worse.

The Pharmacy Act has been in existence for a good many years now. It has not hitherto been very strictly applied. Similar Acts upon the Continent have made much more progress. It cannot be said that chemists have used it harshly against men who were old in business before it became law. The advance of science and national progress demand that this Act, and various other Acts of a similar type, be more stringently carried into effect. It is conclusively proved that the Pharmacy Act has been a great benefit to the nation; and, as a matter of fact, the nation soon abolishes laws which are found to be of no service. Most of the men who are offending against the Act have been acquainted with it all along, and must have known that they could not go on for ever breaking a law which is just as binding upon mankind as the law which forbids people to kill.—I am, yours, &c., JAMES REID.

Dumfries, October 1, 1896.

To the EDITORS.

GENTLEMEN,—Your correspondent, "Nemo," who, by the way, has chosen an exceedingly apt *nom-de-plume*, has a peculiar method of argument. His idea seems to be that of endeavouring to cover his opponents with every kind of malignant abuse and contempt.

I should like to know what title this photographic Shimei has to throw aspersions upon an honourable craft, the members of which probably have as much honesty, as the world goes, as the members of any other fraternity?

In a series of anecdotes, the falseness and absurdity of which would be patent to any reasonable person, he asks us to believe that chemists generally are charlatans, bumptuous, and, worst of all, dishonest. Now, there are bumptious as well as black sheep in every fold, and I doubt not that in every business as well as in this there are men who in this way deceive themselves, but not others; but, really, one is reminded of the old proverb, "Those who live in glass houses should not throw stones."

Who ever read a more bumptious letter than that of "Nemo?" Like most bumptious people, he gives himself away in every sentence. He lets us know that he is on speaking terms with an eminent London surgeon. It is a great pity that he doesn't improve these valuable conversations with his distinguished friend by asking him to set him right in his ideas of the Pharmacy Act relating to poisons. He would certainly inform him that the law does not require the signature in the poison-book with certain poisons, but it does with others, and for very good reasons. He would tell him that the Poisons Act was not framed by the Pharmaceutical Society, but by Parliament, and that the Society is intrusted by the Government with the duty of seeing it properly carried out. Oxalic acid and spirits of salts are dangerous chemicals, but they are things of daily necessity, and consequently are found in every household. They are not virulent poisons in the same sense as perchloride of mercury, two grains of which are sufficient to convert any person into a "Nemo." Common drugs, such as Epsom salts, or bicarbonate of soda, will produce death if they are only taken to the extent of a few ounces.

As a photographic chemist I should personally not have the smallest objection, from the pecuniary point of view, to any one selling corrosive sublimate. The law was framed, however, to protect the public, and, with poisonous substances, as with everything else, one has to draw the line somewhere. Your correspondent's remark about the ignorance of chemistry among chemists is distinctly untrue. In order to obtain the qualification of pharmaceutical chemist, the examination in organic and inorganic chemistry is of an equal stringency with the B.Sc. examination, and possibly "Nemo" will marvel to learn that a complete and an advanced knowledge of botany, and physics, and other subjects is essential to success in the examination. The fable about his having been charged eighteenpence for a gallon of distilled water I do not believe, nor, I am sure, will any one else; nor will any one, I am confident, support the principle that, because an individual has chanced to forget that supplying "Nemo" with goods previously cost this courteous customer eighteenpence only, instead of half-a-crown, he is necessarily dishonest. Dishonesty as often lies in making wrong interpretations of other people's actions as it does in taking advantage of their ignorance.—I am, yours, &c., A PHARMACEUTICAL CHEMIST.

October 3, 1896.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2, *York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

Debenham & Co., 5, Clifford-street, York.—*Photograph of Rev. Canon Temple.*

A. James Tyler, 8, Creek-road, March, Cambs.—*Photograph of railway collision at March Station on September* 23, 1896.

RECEIVED.—T. HAYWARD; F. WHALEY; A. EVANS. Thanks. Next week.

ACETYLENE FOR PORTRAITURE.—ACETYLENE LIGHT. See the present number of the JOURNAL; also write Messrs. Thorn & Hoddle, 169, Camberwell New-road.

LENSES FOR STEREO WORK.—PYRO. For such work as you describe, a pair of lenses of the rectilinear type, *not exceeding* four inches focus, would perhaps be best.

RETOUCHING MEDIUM.—PYRO says: "Would you kindly give me name of dealer in London supplying retouching medium mentioned in Harold Baker's letter in recent issue; also the name it is sold under?"—It is sold under the name of Harold Baker's retouching medium by Messrs. Houghton & Sons, 89, High Holborn, W.C.

PHOTO-LITHOGRAPHY.—R. SIMMONDS. As the transfer ink adheres all over the paper, it is pretty clear that the gelatine coating has become insoluble, *i.e.*, does not absorb water in the unacted portions (by light). Too long keeping after sensitising, exposure to light, &c., may be the cause. Dry quickly and use soon afterwards.

LENS APERTURE.—R. MATHER says: "I beg to draw your attention to Mr. Gruncell's interestiug letter on 'Flashlight Photography,' which appears in last week's issue of your valued JOURNAL. On p. 78, line 12, I read: 'My whole-plate flashlights are taken with one-sixteenth inch.' May I ask, Is this not a misprint for six inches?"—Probably a "six-inch lens" is meant.

A HISTORY OF PHOTOGRAPHY.—BOOKS says: "Will you kindly inform me whether there is such a book published that gives the full history of photography from the time it was first invented, and through what publisher can I obtain such a book?"—In reply: There is a very good *History of Photography* by Mr. W. Jerome Harrison. It is published, we think, by Messrs. Iliffe & Son, 3, St. Bride-street, E.C. We do not know the price.

ADDRESS WANTED.—W. G. STRETTON, of the Port Commissioners, Rangoon, says: "A few months ago I noticed an advertisement in your paper to this effect: 'To put clouds in bromide prints, 2*s.* 6*d.*.—Haig.' I forget the address. I remitted 2*s.* 6*d.* for the pamphlet by money order, but forgot to advise by letter. Will you kindly give the address through your columns?"—In reply: The address is, J. G. Haig, 14, Davisville-road, Shepherd's Bush, W.

HALF-TONE THREE-COLOUR NEGATIVES.—HELIOS says: "Would you please tell me if it is possible to take half-tone, three-colour negatives direct from original, using wet collodion? If so, what colour filters and sensitisers would you recommend for use with Fleming's heliochrome inks? If I procured a spectroscope and prism, would I experience much difficulty in making my own screens?"—In reply: See leading article in the present number of the JOURNAL.

PATENT SHUTTER.—DOUBTFUL asks: "Will you please tell me if the patent for shutter as advertised is a valid one, and if ——'s patent does not anticipate it, and which has already expired?"—We do not give advice on the subject of the validity or otherwise of photographic patents, and, if we did, we should hesitate to hazard an opinion with regard to shutters—their name is legion. If you are really interested in the matter, you had better consult an experienced patent agent.

COPYRIGHT.—T. BENCE. If the photograph was taken to your order, and the copyright in it duly assigned to you by the one who took it for a stipulated sum, the copyright is undoubtedly yours. Therefore you should lose no time in proceeding against the illustrated paper for its infringement. Considering the subject, and the fact that the photograph cannot be repeated, as well as its interest, we should advise you to assess the damages at a fairly substantial amount, particularly as the journal in question has a very large circulation.

CLASSES IN CONNEXION WITH THE SCIENCE AND ART DEPARTMENT.—SNARK says: "I shall be much obliged if you will inform me if there are any classes in photography held in connexion with the Science and Art Department at South Kensington, or anywhere else in or near London, otherwise than those at the Regent-street Polytechnic?"—In reply: We are not aware of such classes being held. Some reader may perhaps be able to say whether there are any; but the City and Guilds Technical Institute of London conduct examinations in connexion with the Polytechnic and similar classes.

LENS.—J. R. CROSSE. The lenses in question are in high repute. Your measurement of the focus, "about six or seven feet from a gas flame," is too indefinite to form any opinion on. We should say, from what we know, that the lens is well adapted for quick work. Of course, the smaller the stop used the longer must be the exposure, but, at the same time, the greater will be the "depth of focus." It is, of course, quite possible to get good enlargements from hand-camera negatives, provided they are sharp. If they are not sharp, we have little hesitation in saying that it is not the fault of the lens in question.

GERMAN PHOTOGRAPHIC PAPERS.—A. O. YARDLEY says: "Can you give me any information respecting advertisements for photographic situations in Germany, whether there are any papers for the purpose? I am desirous of obtaining such a situation as assistant operator, retoucher, and in the reception room."—In reply: We append the names of the principal German photographic papers and the towns of their publication. You must write them for further particulars, their charges, &c., for advertisements, which we are unable to give you. *Photographisches Wochenblatt*, Potsdammer-strasse, 89, Berlin; *Deutsche Photographen Zeitung*, Weimar; *Photographisches Archiv*, Düsseldorf; *Photographische Mittheilungen*, Dessauerstrasse, 46, Berlin.

WOODEN DEVELOPING TRAYS.—H. V. says: "I have had three wooden tanks made for washing bromide prints, but I find they leak very much: so would you kindly inform me of the best means of stopping the leaking?"—In reply: Coat the joins of the trays with melted paraffin by means of a brush; a mixture of melted resin and beeswax also answers.

GRUBB'S RECTANGULAR PRISMATIC STEREOSCOPE.—STEREOSCOPE says: "At the beginning of the ALMANAC for 1895 there is an article on the *By-paths of Stereoscopic Photography*, and in this there is a description of Grubb's rectangular prismatic stereoscope (illustrated). Could you favour me with full particulars as to dimensions, &c., to make one, or can they be bought ready-made? Also, please say the size of the prisms, and if lenses are required as well, and where the prisms can be bought."—In reply: The fullest, and, indeed, the only available, information on the subject is contained in Sir Howard Grubb's original paper on *Some New Forms of Stereoscopes*. This is printed at p. 74 (February 14) of our volume for 1879, to which we must refer our correspondent.

COLOURED TRANSPARENCIES.—C. H. PRICE says: "I saw, some time ago, a method of toning gelatine transparencies. I thought it was in the JOURNAL, but, after looking through the back numbers, I was unable to find it, and suppose it was in some other paper. I shall be greatly obliged if you can assist me. I propose to tone a few transparencies made on the ordinary dry plate, sepia, blue, and green. Will you kindly tell me how to proceed to get these colours, and whether the developer employed would make any difference in the result? I use pyro soda."—In reply: We cannot trace the article referred to. We know of no process of development which, in one transparency, will simultaneously yield sepia, blue, and green tones—for that is what our correspondent appears to want.

COLOUR PHOTOGRAPHY.—W. A. DELLBAR says: "Will you kindly inform me whether Ives's process of colour photography has been made public, and, if so, what it is?"—In reply: Yes; the process referred to has been frequently described in our pages by Mr. Ives and others. We should recommend our correspondent, if he is interested in the subject, to run through the indices of the volumes of this JOURNAL for the past seven or eight years, and read the various articles on colour photography. In the mean while, we may briefly state that the process referred to consists in the main of taking three negatives through three different colour filters, making therefrom transparencies, which are, as it were, exactly superposed behind their respective colour filters, and viewed or projected as a transparency. See this JOURNAL for January 17, 1896, for a fuller description of Mr. Ives's process, camera and photo-chromoscope.

LIGHT WITH LONG AND SHORT-FOCUS LANTERN OBJECTIVES.—BLOW THROUGH says: "I should be greatly obliged if you would give me in your next issue an answer to the following question: Would an illuminant (say, safety jet), which will light a ten-foot disc with a six-inch objective, light equally well a disc of the same size with a nine or twelve-inch objective, the same aperture being used in all cases; or would the greater distance it would be necessary to remove the lantern from the screen with the longer-focus lenses operate prejudicially on the brightness of the light?"—In reply: We quote from an article on the subject that appeared in a former volume of the ALMANAC: "When it is considered that a long-focus objective demands that the light be brought nearer to the condenser, and that an objective of large diameter will grasp and project all the rays, it will be seen that, unless the atmosphere in the hall be thick and absorbent of light, there is no reason why the screen should not be well illuminated."

PHOTOGRAPHS FOR A BAZAAR.—C. W. M. writes: "A curate in our village took some half-plate negatives of the exterior and interior of the church. They were very bad, but he brought them to me to touch up and make the best I could of, and to make several dozen prints from, to sell at a bazaar as his own work as an amateur. The negatives wanted a lot of working upon, and dodging in the printing and like most work of the kind, was more trouble than it was worth. The prints were sold at the bazaar at one-and-sixpence each. I sent in the bill for the prints, mounted on tinted mounts, as six shillings a dozen, and now he refuses to pay because the charge is *exorbitant*, as the mounts only cost so much per dozen and the paper so much a sheet. My name in no way appears on the prints, as they were sold as being taken by the Rev. ——. How shall I act?"—The charges are very reasonable, and we should say, Take out a summons at the County Court, and, no doubt, it will be at once paid by the curate, who takes sole credit for the work.

CARBON TISSUE.—NORMAN asks: "Would you be so good as to give me, in your Answers to Correspondents, a formula for carbon tissue? I want to know the percentage of gelatine required, in the first place, and, secondly, if a 'soft gelatine' is one that will absorb a large quantity of water. *Quantum suff.* of a soft gelatine is the extent of information usually given in text-books."—The manufacturers of carbon tissue do not publish the formulæ they employ therefore we are unable to give those of any of the commercial tissues. This will, however, give a very good tissue: Gelatine (say, Nelson's transparent sheet gelatine), 4 pounds; sugar, ¾ of a pound; water, 15 pints; pigment (whatever is preferred), *quant. suff.* This must only be taken as a rough guide, as gelatine, even of the same brand, varies with different batches, and, in dealing with them, experience is required to obtain the best results. It will be manifest that, in the selection of the pigments to be used, only those must be chosen for the different colours which will be inert on the gelatine, and themselves unaffected by the bichromates—Indian ink or lamp-black, for example. By "soft gelatine" is generally understood a soluble kind, such as those known as "soup gelatines," in contradistinction to the hard kinds, such as Coignet's Gold Medal, and the like.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1902. Vol. XLIII.—OCTOBER 16, 1896.

Contents.

OUR FORTHCOMING ALMANAC.

The British Journal Photographic Almanac for 1897 is now in an advanced state of preparation. A feature of the volume for the past thirty years has been the co-operation of numerous friends and readers of the Journal, and the Editor takes the opportunity to express the hope that the support so kindly placed at the disposal of his predecessors may be continued to him.

We especially invite contributions on topics of practical interest, and should feel obliged if the articles and any accompanying sketches are sent to us at once.

Secretaries of Societies, and especially of those established since the appearance of the last Almanac, will oblige us by forwarding lists of officers and other details for inclusion in the Directory of Photographic Societies, in order that the list may be made as complete as possible.

The Publishers wish us to remind intending advertisers that the announcement pages of the Almanac are filling rapidly, and that, to ensure insertion and good positions, orders and copy should reach them forthwith.

EX CATHEDRÂ.

The Annual Meeting of the Photographic Copyright Union, held on October 8, and that is reported in another part of the Journal, passed off extremely well, barring a slight note of dissatisfaction as regards Rule 23, which fixes the minimum fee to be charged by members at half a guinea. But the Chairman pointed out, as it has been pointed out over and over again, that the minimum fee was decided upon after great deliberation, and having regard to the fact that it was desirable to consult the interests of the greater instead of the lesser number of photographers. We have so recently (August 14) exhaustively reviewed the work of the Union and discussed its prospects, that it is unnecessary for us to traverse the ground again; but we may remark that our continued observation and experience of what we may term the Copyright Conflict, in which photographers are at present engaged, justifies us in again advising them to join the Photographic Copyright Union, which does useful work that benefits the whole photographic profession, and charges its members no subscription whatever!

* * *

In response to our inquiry of last week as to whether some purchaser of the secret method of preventing halation, already referred to in our columns, would tell us if we had been rightly apprised as to its nature, a correspondent sends us a complete copy of the formula, from which it will be seen that our original information was correct: "Plan or method to prevent fog or halation during the photographing of interiors of every description: First place your camera in the proper place and focus, then attach a small piece of wood, or wire, from the front of camera above lens, about eight or nine inches long, so that the end will clear hood of lens; then suspend, by means of very fine wire, a piece of either thin zinc, brown or black paper, cut the size and shape of window or windows, as shown on focussing glass (on which it might be traced from), move it backwards or forwards until you see it exactly to cover the window on focussing glass; this must be done with the diaphragm you intend using. Now, we will presume that the exposure required for interior would be one hour; after exposing remove the adapter from before the lens, and expose the whole from three to four minutes according to the amount of transparent glass. Of course, judgment must be used, in case the time of exposure be more or less."

We are informed that Dr. Eder, of the Imperial High School of Photography, at Vienna, has purchased about thirty reproductions of the pictures now hanging in the Exhibition of the Royal Photographic Society in Pall Mall. This result is directly traceable to the Society's illustrated catalogue.

* * *

Messrs. F. Braby & Co., of Fitzroy Works, 352 to 364, Euston-road, N.W., draw our attention to the fact that, after experiments lasting over three years, they have perfected a solder for aluminium which they find, from severe tests, will not only hold but will make a bright, strong, clean, and neat joint. Messrs. Braby state they do not sell the solder, but they invite manufacturers to send their work to be soldered by them.

* * *

During the sojourn of the Emperor of Russia at Balmoral, two famous photographs of the Royal Scots Greys, published by Messrs. Gregory, of the Strand, were submitted to His Imperial Majesty, who graciously expressed a wish to retain them. One of them shows the entire regiment on parade at the cavalry barracks at Aldershot; the other, a section of four members of the regiment engaged at tent-pegging. This latter photograph is a very remarkable specimen of instantaneous photography. The object the photographer, Mr. F. G. O. Stuart, had in view was to get a picture at the moment that the lances of the horsemen struck the pegs; it was therefore arranged that the camera should be placed immediately in front of the advancing cavalrymen, and about twenty-five yards from the pegs; and, in order not to run down the photographer, it was arranged that, immediately the pegs had been struck, the two left-hand men of the section were to wheel to the left, while the two on the right wheeled to the right. The result was eminently satisfactory, for, by a most extraordinary stroke of good luck, each man caught his peg, and the picture obtained is a perfect representation of four horses at full gallop coming straight at you. The shutter used was the Thornton-Pickard focal plane, and the exposure on this particular occasion was the one five-hundredth part of a second.

* * *

Mr. W. P. Marsh, of Bognor, writes us: "I enclose a cutting from the *Lady* of October 1, 1896, a reprint of which, I think, would amuse many readers of the Journal who may not have seen the *Lady*. If this expert girl photographer would take into partnership an expert boy ditto, what a fortune they might soon make when on their holiday trips! No wonder professional photography is not as of yore. Perhaps the expert young lady could honour the coupons of the celebrated firm of diarists?"

* * *

We append the extract referred to:—

"Itinerant photography as a possible employment for women has its good points, though they will not appeal to the gentle sex when lusty winds do blow, and the rain it raineth every day, as now. However, for next year the idea has its advantages, and should be stored up in the memory-box of those who want 'holiday engagements.' Good accounts reach us of the comfortable little sum made over and above her expenses by an expert girl photographer this summer. She, with her camera, went a trip through some lovely country, and obtained very great success as a portrait-taker, also receiving orders from people for favourite nooks and crannies in their gardens and houses, family groups, and actually pet and agricultural-show animals. Her winter's work will consist in making albums for sale in the districts she has worked, and lantern slides which she will sell to local and district dealers in these now fashionable commodities."

* * *

It is to be hoped that the financial success alleged to have been secured by the young lady referred to will not incite other members of her sex to pass their holidays in a similar manner. "Itinerant photography," as it is here understood, is a precarious method of earning money, unless, as in the few successful cases that we can at this moment call to mind, it is followed up in a systematised business way. We are aware of some photographers who live caravan fashion from April to October, and make a living by travelling photography, but it is hard work. "Itinerant photography," even as a holiday engagement for ladies, looks pretty and poetical on paper; in practice, it would almost certainly be found prosaic and unsatisfactory, especially, we fear, to the amateur young women's patrons!

PANORAMIC PHOTOGRAPHS TAKEN IN SECTIONS.

In concluding the previous article on the above subject (see page 611, *ante*), it was incidentally mentioned that there were other methods by which the junctions of the various sections can be more successfully hidden than is possible by mounting the finished prints in juxtaposition. It is obvious that, if the picture were on one piece of paper, and from a single negative, a better result would be obtained in the end than by printing from the negatives separately, and joining the prints afterwards. This can be done by reproducing the various negatives as a single one. Doing this may seem a formidable undertaking to some, but it really is not so in practice.

Premising that the negatives were taken with the precautions alluded to in the previous article, this is the procedure. We commence by neatly stopping out the sky in all the negatives with black varnish, so that it prints quite white. The next thing is to make transparencies from them in film form. The best way of doing that, for the present work, is to make them on celluloid films. It is scarcely necessary to mention that they must all be of the same density and of the same colour. The exposure, which is best made to artificial light, should be full, so that, when the pictures are developed, there are no really clear portions except the skies. These should be free from tint, or, if tinted at all, the tint should be precisely the same in all of them. It is, however, better to avoid any tinting whatever, either by a liberal use of sulphite in the developer or by the use of one free from staining properties. The transparencies should be made tolerably dense, or a vigorous negative cannot be easily obtained from them. If there should be a difference in any of the transparencies, it will be better at once to replace the faulty ones rather than attempt any after-dodging. No trouble should be spared at this stage of the work, because on the character of the transparencies depends entirely the perfection, or otherwise, of the negative.

A perfect set of transparencies having been secured, we next proceed to combine them in the following manner: Take a sheet of perfectly flat glass—preferably patent plate—large enough to contain them, and place it upon a retouching desk, or prop it up in a sloping position in front of a window, with a piece of white paper behind it to reflect the light through. Now take, say, the centre transparency and secure it, top and

bottom, in position on the glass with strips of gum paper. Then take the next one, and adjust that in position in the same way with gum paper, top and bottom, and the same with the others, the duplicated portions of the subject, when superimposed, serving as accurate guides, as in the method of mounting the prints described in the former article. When all the transparencies are fastened to the glass, the overlapping films are cut through with a sharp penknife and the released portions of films removed; the junctions are then perfect, as the edges butt exactly together. In making the cut a keen edged thin knife should be used, so that both films are cut clean through at one cut; this will require some pressure if the celluloid is thick. Instead of making the cuts in a direct line, it is preferable to take them round some of the darker parts of the subjects when that is practicable.

The transparency may now be retouched if desired. This is easy to do, as it is a representation of what the finished picture will be. Should the junctions happen to be a little chipped in the cutting, they may be touched up with water colour; but, with careful working, that will not be necessary. The sky will, of course, be clear glass, and clouds may be introduced with water colour, or, better still, by coating the back of the glass with matt varnish, and then stumping in the clouds on that with plumbago. It will be advantageous, in introducing the clouds, to put the darker portions of them over the joins. If the sky be left plain, it will, of course, be white when the negative is printed from. Then the clouds, or shading, can be introduced in the print by double printing; but by far the best plan is to put the clouds into the transparency, and thus save the trouble of the double printing. Natural clouds can, if desired, be introduced in the transparency by printing them, or enlarging them, as a transparency, on a celluloid film, and mounting that on the back of the plate.

The transparency being completed, it only now remains to make a negative from it. This may be done on a dry plate, by contact printing, or it may be made on a suitable bromide paper—such as Wellington's special negative paper, for example; it may also be made on some of the print-out papers. If the latter be employed, the printing must be carried much further than for an ordinary print, and should be fixed without toning. If the clouds are put in on the back of the transparency, the exposure for the negative should be to fairly parallel rays. If at the junctions, owing to the unequal lighting given by the lens, there is a little unevenness in the density, a little colour or plumbago applied to the back of the negative will set matters right. We now have a negative of the panorama—taken in sections—in which, provided the work be skilfully done, the various junctions will be quite imperceptible.

Lunar Photograph.—In the current number of *Knowledge* is a photograph of a portion of the moon on a very large scale—forty-four inches to the moon's diameter. It was taken with the great Lick telescope and the Brashear enlarging lens, and represents the ragged surface of the moon with its craters and walled plains with marvellous reality.

The Duration of the Röntgen Radiation at each Spark.—This subject was discussed at the British Association, the other day, by Dr. F. T. Trouton, the results he obtained with a simple apparatus that he described showing that the radiation lasted for a time varying from $\frac{1}{300}$ of a second to $\frac{1}{10000}$. Similar results were obtained with a phosphorescent screen, but the same exactitude was not attainable as with photographs.

The Wet Weather.—If the vaticinations of the prophets who say we are bound to make up our average of wet after the abnormally dry summer be true, there is rain and plenty of slosh to come before that average arrives, for it is not yet reached in many parts of the country. Mr. Sowerby Wallis, writing from Camden-square, says that last September was the first extremely wet month since October, 1880. The total fall registered at Camden-square was 5·51 in., or 3·17 in. more than the average for the month during the thirty-seven years, 1859–95. The Rev. C. Holland, writing from Petworth Rectory, says: "I have registered rain in Sussex for over forty years, but in no year has there been rain on so many days in any one month as in this last September. On all except six days rain has fallen, bringing the total fall up to 7·56 in. Even in October, 1880, when all but 10 in. fell, it came in sixteen days."

New Cinematograph Effects.—A writer in *La Nature* suggests a series of views for use with this popular instrument, which, whatever their practicability may be, are certainly novel, and would be interesting. One of his proposed series is to take, at easily reckoned intervals, negatives of a rose tree from the time when it began to throw out its buds till the fall of its last leaves, then to use the plates for a cinematograph set. We shall thus have the novel effect of a rose tree throwing out leaves and flowers and then gradually withering away. In like manner, a landscape might be taken and shown on the screen, so that in a short space of time we might watch it covered with snow, then quite bare of interest, to be followed by growth of leaves on the trees, harvest in the fields, and so on. It is true that to obtain such effects would involve so many difficulties, such waiting, and such security from disturbance of apparatus for a long period of time, that it might not pay; but it is equally true that, well done, the result would be a great success, and, if the popularity of the instrument is to continue, it will need to be fed with continual novelties.

Explosive Properties of Acetylene.—M. Berthelot, in conjunction with M. Vieille, has carried out a series of experiments upon the explosive conditions of acetylene. They have examined successively the results of pressure and of concussion, and an account of their conclusions was read at the last meeting of the Paris Academy of Sciences. The influence of pressure is remarkable. At ordinary pressures the gas does not detonate: but, in closed vessels, at a pressure of two atmospheres, it needs a duration of ·76 of a second; at six atmospheres, ·066 of a second; at twenty-one atmospheres, ·017 of a second, for detonation to take place. With liquid acetylene, in a metallic vessel of a like capacity which would hold about 300 grammes, explosion takes place when a red-hot platinum wire is inserted, the effect then being exactly equal to the explosion of so-much nitro-glycerine or of gun-cotton. The effects of concussion are, on the contrary, negative. If the bottle was dropped from a height of 6 metres, no explosion took place: but the fall of a piece of metal 286 kilos in weight (about 3 hundredweight) from a height of 2 metres, resulted in the liquid detonating. With regard to the handling of the vessels of liquid acetylene, M. Berthelot recommends care in opening the vessel, and not to do it too hastily for fear of bringing about an elevation of temperature sufficient to cause an accident. Finally, if the water be allowed to reach the calcium carbide drop by drop, it will become red-hot and explode. It is necessary to avoid allowing any portion of the apparatus or its contents to become red hot.

Röntgen Rays at the British Association.—This subject was naturally one of absorbing interest at the meeting of Section A. Herr Lenard was there, and, discussing the nature of the rays, believed that, if Mr. Crookes' tube be continued beyond the window of aluminium he used, and the pressure of air be reduced, the ray travels much farther, and this fact favours the view that the radiations are not due to projected matter, but are of the nature of ether waves.

Sir G. Stokes, as we have before mentioned, maintained the view that the rays are due to projected matter. "The inside of the

aluminium window is bombarded by molecules of gas, or by particles discharged from the electrode. Why should not this bombardment give rise to a corresponding projection of molecules from the outside of the window?"

PROFESSOR RUCKER had examined the transparency of various solids and gases, and, among other things, found that certain kinds of china are almost as transparent as glass, while others in the manufacture of which bone ash is used are almost opaque. He thought this method of examination might be very useful to china and porcelain collectors.

Curious Developments in Röntgen Ray Sciographs.—Mr. Espin, writing to the *English Mechanic*, details some very singular investigations he has been carrying out. On a former occasion he found double images—one positive, one negative—of metallic objects used as obstructors. For a long time he failed to discover an explanation of the mystery, but he writes: "However, at last a gleam of light came, and in a most singular way. I had, before leaving home, been using bits of a half-plate film cut into six. For a week three had been left in the box. Here they lay on the top of each other, and, as it happened, crossways. On using the top one, nothing was found save the ordinary position of a ring; but the second and third each showed clearly the impress of the film lying above it. My suspicions were at once aroused: but, unfortunately, in came a medical case and prevented my being positively sure; but I think it will probably be found that, if a metal, or perhaps other object, be allowed to lie upon a sensitised film for a few moments, and then moved to another spot, after exposure to the X rays the first will yield a negative and the second a positive of the object. If this be correct, then the mystery over which I have spent so much time will at last be elucidated. Once I had a film that would not lie flat, and I had to take off the objects to straighten it: on developing it, I found a confusion of positives and negatives, quite inexplicable. Sometimes, too, the rings may have moved in carrying them from the dark room to the apparatus. Here, then, there is the possibility of the explanation of the double images; but even then the result is very difficult to understand. Why, for instance, should it happen that an object placed for a few moments in contact with a film can neutralise the action of X rays, and the same object, if left in that position, increase their action? And there is a further consideration, Does this arise through heat? If so, one can understand how taking up the ring with the fingers throws it into molecular vibration, and that this is communicated to the film, and in some mysterious way neutralises the action of the X rays. If this is so with a ring, is it not possible to conceive that, if an image of the sun is formed on a thin brass or copper foil, and a sensitised plate placed behind, the surface would be affected, and Mr. Packer's results be explained?"

ON COLOURED SCREENS FOR ORTHOCHROMATIC AND THREE-COLOUR WORK.

IN the current number of the *Photographische Correspondenz* Dr. J. M. Eder considers the question of the plates and light filters for ordinary and three-colour work, and points out that, although well-made commercial orthochromatic plates can be obtained, yet there is no great difficulty in sensitising plates by bathing them, and states that collodio-bromide plates, sensitised with fluorescine or acridine yellow, are the best; for orange yellow, rose bengal; for orange red, cyanine; whilst an ordinary wet plate should be used for the blue violet.

The light filters must be spectroscopically adjusted to each plate, and they may be prepared in three different ways, either by using glass coated with coloured collodion, or with gelatine, or else solutions may be used in cells. Collodion is, of course, most convenient for spirit-soluble dyes, gelatine being more suitable for the water-soluble dyes.

Eder recommends the coating of glass plates with a filtered solution of gelatine, about the same strength as is used for emulsions, to which a little acetic acid is added. The plates, when dry, are soaked in aqueous solutions of the dyes, and then rinsed and dried.

For bright yellow screens picric acid should be used, for golden-yellow screens Martin's yellow, which absorbs more of the blue-green than picric acid, for orange-yellow screens β-naphthol orange, and for reddish orange erythrosine. To cut out the whole of the blue-violet and bright blue a gelatinised plate should be bathed in picric acid, then in Martin's yellow, and then in β-naphthol orange, and with an eosine or erythrosine plate such a screen gives the yellow-green, with a fluorescine or acridine-yellow only the green.

Eder points out the possible failure from using too thin glasses, which may bend when cemented together, and affect not only the definition but the focal length of the lens, and states that, when using a lens of sixty cm. focus, and focussing same size, he found the focus shortened by 1·3 cm.

He strongly recommends the use of liquid filters, and states that several very fine reproductions of difficult subjects have been produced at the Vienna Institute by means of them. With cells the same trouble of alteration of focus may occur, and therefore he suggests the use of one cell only, which should be filled with water for focussing.

Green light filters are, says Eder, quite unnecessary if a plate sensitive to green and insensitive to red be used with a yellow screen, and a blue or violet filter is unnecessary if plates only sensitive to blue violet are used.

FOREIGN NEWS AND NOTES.

Ultra-violet Light.—M. Zeuger in a recent communication to the Société Française, detailed some experiments he had been making with ultra-violet light, and he states that, if an ordinary dry plate be fixed without exposure to light, well washed, and whilst still damp powdered with the double sulphate of ammonium and uranium, a fluorescent screen of perfect surface will be obtained when dry, and that, if the direct sunlight be concentrated by means of a quartz lens, and the hand, a fish, or some similar object, be placed on the glass of the fluorescent screen, it is quite possible to see distinctly the bones, or rather their shadow, as with the X rays.

Iron-Printing.—Ardut & Troost, of Franckfort, have found that, if a sheet of paper free from chlorides be floated on a mixture of—

Ammonio-citrate of iron	96 grains,
Silver nitrate	20 „
Tartaric acid	20 „
Gelatine	15 „
Water	2 ounces,

and then dried, it gives a printing paper which is five times as sensitive as ferro-prussiate, and that it will keep for several months, and gives, on washing with water after exposure, a dark brown image.

Made in Germany.—It has generally been considered, even on the Continent, that English amateur photographers were a long way ahead of all their brethren, but now we learn, from the report in a German contemporary of the Berlin Exhibition, that we have at last found our rivals in this particular branch of photography in our German brethren.

Waterproofing Dishes.—Although the recent introduction of enamelled steel dishes will, for large work at least, replace, to some extent, porcelain dishes, yet there may be some who wish to construct wooden dishes, and to render these and wooden sinks, &c., watertight, Hugo Müller recommends an indiarubber varnish made by melting two parts of common resin till fumes are given off, then adding one part of finely shredded indiarubber, not vulcanised, and stirring till it has dissolved. The vessel must now be taken from the fire, and two parts of linseed oil added, and stirred till it sets. It requires melting by a gentle heat before use, but will be found very efficient.

Elimination of Hypo.—Ommeganck suggests, as a hypo eliminator, a two per cent. solution of borax, which has no chemical action, but merely displaces the hypo. In the discussion upon Mr. Haddon's paper at the Convention a somewhat similar method was suggested by one of the speakers, and considerable doubt as to the efficacy of the treatment or the correctness of the reasoning was

expressed both by Mr. Bothamley and Mr. Haddon, and probably the latter has proved that water is the best hypo eliminator after all.

Magnetised X Rays.—One of the essential differences between the cathode rays and X rays is that the former are deflected by a magnet, whilst the latter are not. Lafay has, however, now shown that, if the X rays are passed through a silver leaf which is connected with the positive or negative pole of an electrical machine, the rays are sensitive to the magnet, and the reflection is different when the silver leaf is connected to the positive to what it is when it is connected to the negative.

Discovery of Platinum.—Some earths have been found at Refflinghausen, near Iserlohn in Prussia, which contain platinum, gold, and sulphur, but it is doubtful at present whether it will pay to work them, the necessary analyses of the yield of platinum and gold not being yet published.

A New Element.—M. Barrière, in his researches on monazite sand, from which most of the rare earths are obtained which are used for making the Welsbach mantles, has discovered what is considered to be a new element, which he has named Sucium, and which he proposes to use for the production of an incandescent gas light in opposition to the Welsbach, which is, of course, possible, as the existing patents could hardly cover an undiscovered element.

Two New Papers.—Two new papers have just been placed on the Continental market, the one a collodio-bromide, the other a baryta-albumen paper. This latter seems to be nothing more than the ordinary baryta papier coated with albumen and then sensitised. It is stated that the surface is much finer than with any ordinary albumen paper.

Yellowing of Platinotypes.—Ommeganck points out that the yellowing of platinotype prints is most probably due to traces of iron, which, notwithstanding treatment with hydrochloric acid, are very difficult to remove. He states that, if the prints are treated with a solution of ammonium tartrate and then well washed, the whole of the iron can then be removed. The ammonium tartrate solution can be prepared, adding sufficient ammonia to a five per cent. solution of tartaric acid to make it smell fairly strongly.

ROYAL PHOTOGRAPHIC SOCIETY.

President's Annual Address.

One of the labours of your President to which he does not look forward with any great amount of satisfaction is his Annual Address, more particularly when there is no particular epoch-marking advance either in photography or in the status of the Society. And yet an address of some kind has to be given. If we refer back to the past session, we can see nothing of any particular interest on which to discourse. Photography, like the financial wealth of the Empire, is making a steady progress. But there are no such leaps and bounds as once distinguished it. I am purposely excluding photography by the X rays as being anything belonging to an advance in photography. It is not a new photography, but the old kind, and its claim to novelty belongs more to electrical than photographic science. We may just as well talk of "new vision" as of "new photography." The Society has got its royal prefix to it, and its fellowships, which together have increased its popularity and added to its dignity, but beyond that it traces out its work in a strictly orthodox way. It flourishes, and much of its success is due to the energy shown by the Secretary and its Assistant Secretary, whose devotion to its work no one who has not seen what it entails can fully appreciate. But, even so, an annual address cannot well be written on their merits.

With this lack of ordinary topics for an address, I am forced to look elsewhere for material with which to fulfil my duty as President, and I have thought we might turn to some experimental facts which have been brought forward during the last two or three years, and endeavour to account for them theoretically. I am now alluding to the experiments which have been made by myself on the failure of what used to be accepted as a law in photography, viz., that, given a certain constant exposure consisting of time and intensity of light, the resulting chemical action would always be the same, no matter whether the intensity of light was small or great, if the time of its action varied in inverse proportion to its magnitude. And here let me point out a great difficulty that arises in expressing what one wishes to say; as I have already pointed out in a photographic periodical: Exposure may mean time and intensity, or it may mean time alone, and it is this double meaning to the term "exposure" which creates the difficulty. I have proposed that we should have a word to express time and intensity, and suggested that an exposure of a unit intensity for a unit of time should be called a Talbot.

This has, I think, in Bunsen and Roscoe's work, been called "Insolation," but the word is not satisfactory. I should prefer myself rather to unite the two initials of intensity and time and call it an It. For my purpose to-day, I shall adopt this provisional term: the precise unit of It not being necessary, I will not discuss it, though I think it ought to be referred to some wave-length in the spectrum of some optical value, whilst the unit of time would naturally be a second.

Coming to the experiments referred to, the first set which led to the others was the result that with intermittent exposures the same amount of chemical energy was not expended on a sensitive plate as did the same length but of unbroken exposure. The intermittent exposures always gave less chemical action. This, it appears to me, can be readily accounted for by picturing to ourselves the ultimate structure of the chemical compound. Supposing it to be silver bromide with which we are dealing, the ultimate arrangement would be a series of molecules consisting of at least two atoms of silver and two of bromine. We are apt, in thinking of a molecule, to picture the atoms as tied together with string, very much after the fashion that chemists show the supposed structure of more complex ones. We must, however, recollect that there are no bonds, strictly speaking, which tie the atoms together. They are held in their relative positions by mutual attractions, in space and not in a plane, and each one has a motion of its own, more or less simple. I have on several occasions taken the motion of a pendulum as a picture of the motion of an atom, and, as with the latter a series of regular synchronous impulses given to it will increase the swing, so also would they increase the extent of swing of the atoms, and that, when the impulses cease to act, they each will gradually fall back to rest. Owing to the fact that energy of radiation is always falling on the molecules, there is a swing of the atoms below which they will not drop until the temperature induced by it falls. We thus picture to ourselves at ordinary temperatures the atoms of silver and bromine vibrating amongst themselves, but never going beyond a certain boundary. If, however, we allow waves of light to fall on the molecule, the motion of the waves and that of the bromine atoms being in tune, or nearly so, the new impulses given will be sufficient to cause, at all events, one of the bromine atoms to pass the space where the attraction of the other atoms is omnipotent, and, particularly if there be another foreign molecule close at hand which will annex the atom, it will more readily pass from the mother molecule to the foreign one. The closer these two molecules are together, the more readily will the transfer be effected, and this may be the reason of the increase in sensitiveness induced by heating an emulsion or by other means. When the one atom of bromine is taken away from the molecule of silver bromide, the remaining three atoms, two of silver and one of bromine, have to rearrange themselves, and their position becomes more unstable. This idea clears the ground for the explanation of the results of the experiments alluded to. Suppose it takes a hundred wave impulses, one after another, in unbroken succession, to oust the bromine atom from the group. What would happen if we allowed between each impulse a time to elapse before another was applied? Say one impulse was given and then an interval of no impulse for the time during which ten more impulses would have been given. As the one impulse would not be sufficient to send the atom out of the molecule during that interval, the increased swing would gradually diminish, and the next impulse given it would have to start, not quite *de novo* perhaps, but it would not give the atom such an increased swing as it would have done had the two followed each other without intermission. Evidently, then, if we make the assumption indicated, the sum of a number of intermittent exposures ought not to give the same effect as a single exposure given for the same total time.

Let us now endeavour to account for the results of the experiments made with varying temperature of the sensitive salt. It was found that heat increased the sensitiveness, and that cold diminished it; that is to say, the chemical action was greater in the one case than in the other, as shown by the opacity of the deposit on development. We have already said that the atoms vibrate with a fixed amplitude or swing at a given temperature. Now, increase in temperature means an increase in molecular motion, and hence we may take it that the increased molecular motion means increased atomic swing as well. This being so, it is easy to see that, when the sensitive salt is heated, the impulses necessary to expel the bromine atom will be less than when the sensitive body is

colder. The limit of the sphere of attraction must be sooner reached in the one case than in the other. Apart from that, or rather as well as that if there be a foreign molecule present, its constituent atoms will also oscillate further from its centre, and, in the excursion of its atoms, the bromine atom will more quickly be annexed. This seems to me to be an explanation of the phenomena which were observed and measured.

We have been able to trace with a fair amount of ease the reason of the behaviour of sensitive material when heated, and also when the exposure is intermittent; but it is not quite so easy to account for the fact that the material in slow plates is less susceptible of chemical decomposition in feeble light, that is to say, that, "It" being kept constant throughout, a slow plate shows less energy expended on it when the light is feeble than when it is bright. We may suppose that a series of waves falls upon a particle, which is, of course, composed of an enormous number of molecules. Let us suppose that one wave is just sufficient to cause the swing of an atom of bromine to leave some one molecule when the light is fairly intense, then this molecule would be decomposed. We might suppose that with light of one-half the intensity two blows would be sufficient to cause the same expulsion of the atom. Let us look, however, a little closer into the matter. We do not know the exact motion of the atom, we only know that it swings rhythmically, and it by no means follows that the atom would be in that position of its swing that the energy of the second wave applied would increase the swing to the same amount as the first swing; or it might be that the same atom did not receive the blow at all. If either of these results took place, we can see that the two blows of half strength would not be as effective as one blow of full strength. Of course, in the most rapid exposures a large number of waves have time to travel across the path of the molecule, but the average blow in the two cases would follow the same reasoning. We are not, however, bound by this line of thought alone. We can take and annex to it that which Helmholtz followed when explaining mathematically the conditions necessary to explain anomalous dispersion. To arrive at a satisfactory conclusion of this phenomenen, he found it necessary to allot to the ether in which the wave motion of radiation takes place a certain amount of viscosity or resistance to motion when matter was in contact with it, although when by itself it was frictionless. If these free atomic swings be increased by the motion of the waves in the free ether, there would, nevertheless, be a retardation from the full effect owing to what we may call the inertia of the ether in contact with the atom being present. In fact, it might take a very large number of very small blows to perceptibly increase the swing, though the energy of the same concentrated into fewer blows might be sufficient for the purpose in view. But we have at the same time to account for precisely the reverse phenomenon being apparent when the intensity of the light is excessively strong, for in this case we find that the chemical action is less than it is when the same "It" is used with a less intense light. Thus the light of an electric spark at two feet distance from a plate causes much less chemical action than does the light of sixteen similar sparks when eight feet away from it. This appears to be directly contrary to the views just expressed. This may, however, be reconciled if the resistance to motion of the ether in contact with the atom increased as the energy of the wave increased. If we suppose that a comparatively heavy blow given to an atom will not give the full swing to it that it would take supposing there were no resistance, we can conceive that on a still heavier blow the resistance would be further increased (somewhat in the same way that atmospheric resistance to the passage of a body increases more rapidly than the impressed velocity increases), and the length of the swing would be proportionately curtailed. Thus, if an atom received two heavy blows, one double the energy of the other, it is possible that the blow of double energy would not increase the swing of the atom to the extent it would reach from the blows of the other. With feeble intensities the change in the factor of viscosity would not materially change, but, as the intensities increased, the alteration would become rapidly felt, as is the case with the atmospheric resistance. This being so, there would be, as I have already found, some one energy of wave which would have the greatest effect. The deviation from the maximum chemical effect caused by a constant "It," where the intensities are feeble, is found greatest in slow plates, whereas the deviation in the opposite direction, where the intensities of light are large, is much greater in a rapid plate. It follows from this that the maximum effective energy on a slow plate is when the intensity of light acting is great, and on a rapid plate when it is comparatively feeble. As our camera exposures made on the same subject may vary betwen $\frac{1}{100}$ of a second to five seconds, we have an ample margin for these different maxima to be practically taken into account. The rapid plate will give a less rapid gradation in a snap-shot picture on this account.

That some such action as that indicated must take place is borne out by the fact that there are exposures which apparently have no effect on the sensitive salt. The series of curves of gradation which have from time to time been published tell us this. At the place where the energy acting is small, the reduction of silver is below what it should be if there were no retardation of motion. Of course it must be borne in mind that the effect of development has been considered as giving the full value of the chemical decomposition. This may or may not be the case; but it will not affect the general argument. I am inclined to think that a close attention to the curves of gradation will enable a quantitative estimate of the condensation of the ether to be found, and, if so, it will be a valuable addition to molecular physics and the energy of radiation, for it must be recollected that the It is nothing more nor less than the energy of radiation lasting for a certain time.

This address has been one which has not followed the line of previous addresses, and I trust that I may be forgiven in breaking through the traditional review that is usually taken of the Society's proceedings.

CAPTAIN W. DE W. ABNEY, C.B., R.E., F.R.S.

ARTISTIC ARCHITECTURAL PHOTOGRAPHY.*

[Photographic Scraps.]

I DO not know whether the doors of the Photographic Salon would be opened to an architectural subject, however impressionistic its treatment; but, be that as it may, architectural photography, both interior and exterior, should afford the artistically minded photographer a wealth of picture-making material, and that, too, of a decidedly unconventional character. Architectural photographs, from the treatment which is usually accorded them, certainly partake more of the topographical than the artistic, but that such subjects are capable of a really pictorial rendering by means of photography cannot admit of doubt. Little, however, has yet been done in this direction. Will not some of our readers endeavour to make a name and fame for themselves by giving us, for example, a series of photographic *pictures* of our ruined cathedrals? In making this suggestion I do not in the least wish to be understood as giving utterance to an expression of opinion in any way adverse to the ordinary topographical architectural photograph, for such are not only of genuine interest, but of great educational value. I do, however, deplore the fact that, comparatively speaking, so few of our clever men—or rather of our artistically minded men (these cant phrases will obtrude themselves no matter how desirous one may be of avoiding them) have taken advantage of the opportunities which such subjects undoubtedly afford for really pictorial work.

Architectural subjects, notably cathedral interiors, have long been favourite subjects with painters, and their nature is such that wonderful effects of light, shade, and atmosphere are obtainable. Many of these effects should be within the power of photographers to reproduce. In this connexion it may be pointed out that the photographer is often at a disadvantage as compared with the painter, particularly in regard to the amount of subject included. In many paintings of interiors an angle of view is included by the artist which could never be embraced by the widest of wide-angle lenses, and, even were the optical difficulties surmounted, the violent perspective produced would quite destroy pictorial effect. In this respect the painter has a decided advantage over the photographer, for, by changing his point of view from time to time as each portion of his picture is painted, he is enabled to give us a result which, however untrue it may be from the point of view of geometrical perspective, yet succeeds in producing a pleasing impression on the mind of the observer. I only refer to this matter in order to direct attention to one of the limitations placed upon the photographer by his materials, and to show him that in the direction of angle of view he cannot hope to compete successfully with the painter. A wide-angled lens should rarely, if ever, be employed for architectural work when the aim is purely pictorial, and not merely topographical or technical, in which circumstances, of course, different considerations arise. Indeed, in many cases, a lens of decidedly long focus will often be found to be more useful, and will give a truer rendering, than the more commonly used wide-angle. Generally speaking a small angle of view will produce a more pleasing result from a pictorial point of view than the inclusion of a very large amount of subject. Indeed, the indiscriminate employment of wide-angle lenses has largely contributed to the disfavour with which architectural photographs are regarded by artists. In using a wide-angle lens, unless the greatest possible care is exercised (and sometimes all the care in the world will not avoid the evil), a very painful effect is produced by the undue dimensions given to objects in the foreground or near the camera, and the relatively insignificant appearance of those which are more distant. Although lenses of so wide an angle as 70° to 90° are frequently recommended, and used, for architectural work, I consider that such should only be employed in the greatest emergency, and that, as a general rule, an angle of 50° should not be exceeded. Indeed, in many cases, the angle may with advantage be considerably less even than this, and a lens giving an angle so small as 30° to 40° will often be found invaluable. The type of lens used does not much matter when the angle

* [We have seen an architectural photograph at the Salon.—EDS. B.J.P.]

included is small, so long as it well covers the plate; indeed for very narrow angles single lenses answer well. There is another advantage in using narrow-angle lenses in architectural work, in that such will usually cover very much larger plates, and thus they permit of the front of the camera being raised or lowered to a considerable extent without cutting off the corners, and enable the photographer to place the subject properly on the plate without tilting the camera or having recourse to the swing back.

In the short limits of the present article I cannot, of course, attempt to deal with all the many details of procedure pertaining to the practice of architectural photography, and I am only endeavouring to indicate how, by less conventional treatment of such subjects than is usually accorded them, results of a more pictorial character may be obtained.

Pictorial effect will depend to a large extent upon the selection of subject and point of view chosen, but here unfortunately it is difficult to convey useful advice, and the photographer must perforce be left to the guidance of his own innate artistic perceptions or instincts, and to whatever art training it may have been his good fortune to possess. I can, however, point out where, regarded from a purely artistic standpoint, architectural photography, however good technically, frequently signally fails, and that is in the general spotty appearance, the uneven distribution of light and shade without regard to massing, and the often painfully minute definition of the entire subject. The two important, nay essential points to bear in mind are, first: to avoid too much definition; and, second, to mass the light and shadow, and not permit your picture to be dotted chess-board fashion with confused patches of light and shade. In architectural photography it should not be difficult to follow this latter advice. Study your subject well before you attempt to make an exposure. Select your point of view, and then watch and study it at all times of the day and under varying conditions of light. Such a plan, to those to whom the suggestion may be new, will be found very helpful and educational, and much surprise will be felt at the widely different renderings of a particular subject which are obtainable at different times of the day. Strive for a broader treatment than is usually accorded to such subjects, study your lighting, and get your lights and shadows well massed. Avoid the use of small stops and consequent microscopic definition, and, above all, beware of the allurements of the wide-angle lens.

Speaking of definition, it is usually recommended, when taking architectural views, to use a very small stop and give a prolonged exposure. From the topographical point of view the advice, no doubt, is sound, but it is not by following such methods that success in the direction we are now considering is likely to reward our efforts. A full exposure it is always well to give, whatever the size of the stop employed, but with large apertures the inordinately long exposures sometimes necessary with small stops need not, of course, be given. *F*-11 or *f*-16 should afford sufficient, and more than sufficient, definition for pictorial effect, unless lenses of extremely long focus (and consequently small depth of definition) are used, in which case it may be necessary to further reduce the aperture. But even with large stops it will often be found that some portion of the picture is unduly sharp, in which case the simple expedient of printing through one or more thicknesses of celluloid will destroy the offensive wiry definition, and produce a softer and more pleasing result.

It must not, from the foregoing remarks, be inferred that I am an advocate of blurred, fuzzy, "out-of-focus" definition. In all cases the effect aimed at, and the nature of the subject must be one's guide, but, in ninety-nine cases out of a hundred, a better *pictorial* rendering will be secured by gently subduing the intense sharpness of the image produced by the lens. This may be done (without producing any "impressionistic" result) by the use of celluloid in printing; the amount of softness necessary must in every case be decided by the reader himself.

For architectural work of any kind, whether it be interior or exterior, the plates should be backed. Probably the most effective preparation for the purpose is the well-known mixture of caramel and burnt sienna, but, unless one has seen the mixture made by an expert, it is not quite easy to prepare it by merely following written or verbal instructions. A fairly effective substitute will be found in the moist water-colour tubes of yellow ochre procurable at the artist colourman's, or the ordinary moist yellow ochre of the oil shop, when mixed with a little glycerine and gum water, may be employed instead. The mixture should be applied to the back of the plates with a fairly large mop-shaped camel's-hair brush; the work can be very quickly done, it being by no means necessary to apply the paint smoothly, although care should be taken to leave no portion of the glass uncovered. If the plates are reared up against the wall of the dark room, backed side outwards, they will dry in a few minutes. Several dozen can in this way be backed and dried in the course of an hour. If they are to be carried about on tour, it is advisable to pack them in grooved boxes; if packed flat, pure paper must be placed between each film, to avoid the paint rubbing off and causing spots. In any case the plates should be well dusted before putting into the slides, and again before development.

By adopting this very simple plan of backing the plates, that great bugbear of the architectural photographer, halation, will be avoided, at any rate to a very large extent. Halation will also be reduced, though not prevented, by using films instead of plates. A film backed by the foregoing method gives very perfect results as regards absence of halation. Personally, for interior work of all kinds, I prefer an isochromatic plate of moderate rapidity to any ordinary plate. It has been stated that they rather favour halation than otherwise, but a very extended experience in their use, and a careful comparison of the results obtainable from them, and also upon ordinary plates exposed under similar conditions, lead me to take the opposite view. I therefore have no hesitation in advising their employment for all kinds of architectural work. A very striking illustration of their advantages occurred to me when engaged in photographing the ruins of Furness and Calder Abbeys a few years ago, both of which are built of the bright red sandstone characteristic of the district. On each occasion ordinary and isochromatic plates were employed, and in *every* instance the latter yielded an incomparably better result, *Verbum sapientum*.

JOHN A. HODGES, F.R.P.S.

PHOTOGRAPHIC COPYRIGHT UNION.

THE Annual General Meeting of the Photographic Copyright Union was held on Thursday, October 8, 1896, at St. James's Hall, Mr. Frank Bishop (President) in the chair. There were present, amongst others, Mr. Alfred Ellis, Mr. J. Lillie Mitchell (Hon. Secretary), Mr. H. Grove (Treasurer), Mr. Bulmer Howell, Mr. W. Downey, Mr. H. S. Mendelssohn, Mr. H. H. H. Cameron, Mr. T. Birtles, Mr. Warwick Brookes, Mr. Thomson, jun., Mr. F. G. O. Stuart, Mr. T. Bedding, Mr. Snowden Ward, &c.

The Chairman, having read letters and telegrams of regret from Mr. J. J. Elliott (Vice-President) and several others, spoke as follows:—

"According to the rules of our Association, we have to render an annual account of our proceedings during the last twelve months. I am pleased that this rule gives us an opportunity of meeting many of our members and others interested in copyright subjects. I think we may be fairly satisfied with our progress, though, for my part, I confess that our members are not numerous enough—we ought to number 2000—considering what we offer to members, I cannot conceive why we have not reached this figure, and can only put it down to misconception, or some want of perception as to the importance of our movement. As to misconception, I know there has been a general idea that the Union was formed solely for the protection of London interests. It is true that some London photographers, especially Mr. Elliott, Mr. Downey, and Mr. Ellis, were the first to move and to advocate the necessity of a copyright union, and through their exertions, and with the help of others, it was formed; but never with the idea of it becoming merely a London clique. I can testify that from the first the members of the committee have been most anxious that all provincial business should meet with great attention.

"Perhaps many here will be surprised to learn that, at present, four-fifths of the business done by the Union is for provincial members. I trust that from this time forth all photographers will believe that the Photographic Copyright Union is formed for, and works for, the interest of all, quite regardless whether the member resides in London or the provinces.

"There is another what I will venture to call misconception. It is with regard to our Rule 23. This rule states that no member shall allow any of his copyright photographs to be reproduced without a charge for the same of a sum not less than 10*s*. 6*d*. Now, there are many photographers to whom this rule is a stumbling-block; they say, if I were to adhere to this, I should lose my advertisements in the local papers, which my rivals, who don't charge, would get. Is this true? I think not. Your newspaper proprietor does not reproduce your view or your portrait to oblige any of you. He does it for his own interest, because he thinks the subject will be interesting to his readers and do credit to his paper. Does any one mean to say that 10*s*. 6*d*. is going to stop him from introducing an interesting subject? I can well imagine that the Rule 23 may be of considerable service sometimes, when begging friends wish to reproduce the photographer's property without paying. I am firmly convinced that Rule 23 operates, in the long run, entirely in the interest of the profession.

"With regard to the advantages offered by the Union:—

"1. Any member can write for guidance or information; and it must be borne in mind the advice tendered is from experts.

"2. Before litigation ensues the Union, through their solicitors, carefully examine all facts.

"3. In case of unsuccessful litigation, half the expenses are borne by the Union.

"4. The Union's forms as to assignment of copyright, also the permission to reproduce.

"Several cases have recently come under our notice, showing the necessity of using proper forms for permission to reproduce. If permission to reproduce on the payment of the fee be granted, and there are no restrictive clauses, the purchaser has the legal right to use it in various papers and many times over.

"Lastly, I would ask photographers to seriously reflect that the time for selling large numbers of silver prints from their negatives is past. The half-tone process, the collotype, and other mechanical processes step in to replace the silver or carbon print. Therefore, if the photographer be not careful to protect himself, the fruits of his labour will be taken from him. On the other hand, if he registers his copyrights, he will find, mainly through the action of our Union, he has a valuable asset. The ever-increasing use of reproductions from photography ought to be a

source of income, and some compensation for loss of business in other ways."

At the conclusion the President called on the Hon. Secretary to read the Committee's report, the adoption of which was moved by Mr. H. H. H. Cameron and seconded by Mr. Mendelssohn, and carried without dissent.

COMMITTEE'S REPORT.

To the members of the Photographic Copyright Union:

In presenting their second annual report at the expiration of the third year of their existence, your Committee feel that they have good reason to congratulate the members on the successful progress of the Union, on the remarkable ease with which the business of the Union has progressed during the current year, and on the absence of anything like important litigation in the maintenance of its principles, which it is gratifying to report are now almost universally recognised by the users of photographic copyrights.

It will be in your remembrance that at the last General Meeting certain rules were amended, in particular that relating to the membership fees, which were then abolished. So far the Committee are satisfied that this decision was a wise one, as the membership has considerably increased, and the voluntary donations show a satisfactory result.

From the Secretary's diary of correspondence and replies thereto the Committee are pleased to observe that by far the larger number of letters are from provincial members, and, as showing the general interest taken in the Copyright Union, the Secretary reports communications as to membership having been received from America, France, Germany, India, South Africa, and other parts of the world.

So great has been the increase in the business that your Committee, whilst making provision for the daily attention to important letters, have found it necessary to meet regularly once a month, instead of quarterly as formerly.

The financial position of the Union is satisfactory. All debts have been paid, there is a small working balance, and the reserve fund remains intact.

In accordance with Rule 9, the two members of the Committee who have retired by rotation and ballot are Mr. Alfred Ellis and Mr. J. Lillie Mitchell. These gentlemen offer themselves for re-election.

(For the Committee) HENRY GOWER,
Secretary.

TREASURER'S REPORT.

The following statement of accounts has been submitted to the Committee and meets with their approval:—

DONATION FUND.
Year ending September 30, 1896.

Dr.	*Receipts.*	£	*s.*	*d.*
To Balance of cash in hand as per last account		3	15	11
,, Donations received during year		196	9	6
,, Registration fees received and forms sold...		8	7	0
		£208	12	5

Cr.	*Expenditure.*	£	*s.*	*d.*
By Secretary's salary (November to August inclusive)		30	0	0
,, Solicitor's charges and Counsel's fees		36	5	11
,, Stationery and printing		23	4	4
,, Postages		11	7	3
,, Advertisements		10	18	6
Subscription to London Chamber of Commerce...		10	10	0
Cash at bankers'		85	11	5
Cash in hand		0	15	0
		£208	12	5

(Signed) WM. GROVE, *Treasurer.*

Audited and found correct. (Signed) H. H. H. CAMERON,
October 9, 1896. THOMAS BEDDING.

The reserve fund remains intact, and has been increased by the sum of 16*l.* 14*s.* 10*d.*, received as proportion of fees recovered by solicitors.

Some conversation and discussion having taken place on a question raised by Mr. Mackie, Mr. Mendelssohn moved, and Mr. Cameron seconded, that Mr. Alfred Ellis and Mr. J. Lillie Mitchell be re-elected on the Committee, they having retired by rotation and ballot.

The Chairman having spoken as to the importance of these two gentlemen being re-elected, it being most desirable in the interests of the Union, the vote was put to the meeting, and carried unanimously.

It was felt desirable by the Committee that their number should be added to so as to more fully represent the provincial photographers.

Mr. Winter (Mawson & Swan's) moved, and Mr. Thomson, junr. (London) seconded—that Mr. F. M. Sutcliffe, of Whitby, and Mr. McGrath (of Grey & Co.), Cork and Limerick, be elected. This was put to the meeting and carried unanimously.

Mr. A. Ellis proposed a further addition—that Mr. Warwick Brooks (Manchester) be added to the Committee. Mr. T. Birtles (Warrington), having seconded this, it was also carried unanimously.

Mr. H. S Mendelssohn suggested that every President of local Photographic Societies in the provinces, should be asked to join the Committee. This, the Chairman promised, should have the consideration of the Committee.

Mr. Warwick Brooks thought it would be an advantage if the Annual Meeting of the Union was held in close proximity to the Meeting of the National Association of Professional Photographers, and the opening of the Royal Photographic Society's Exhibition. This, it was promised, should be observed next year.

The Treasurer was called upon to read his report as above—the adoption of which was moved by Mr. H. N. King, and seconded by Mr. Caswell Smith (London), and carried unanimously.

The Chairman moved a vote of thanks to the London Illustrated press, who had treated photographers in a fair way by paying a fair amount for value received. Mr. H. S. Mendelssohn seconded, and it was carried unanimously.

Mr. Alfred Ellis moved, and Mr. Thomson, jun., seconded, a vote of thanks to the photographic press—and which was supported by the Chairman—for what they had done in furthering the principles of the Union. This was carried.

Mr. Bedding replied to this vote of thanks, and, in the course of his remarks, refuted the statement made by some, that the Union worked for the benefit of a few London photographers. His position, as an auditor of the Union, gave him opportunities of seeing that London photographers were the least to profit, financially, through the Union.

Mr. Snowden Ward, in the course of his remarks, thought that Rule 23 was a mistake, and stated that it was impossible for him as a photographer (not as a journalist), owing to this rule, to become a member, but thought those outside should give their moral support to the Union.

The Chairman moved that a vote of thanks be passed to the Auditors for their work during the past two years, and thought the best way of showing appreciation of their services was to ask them to serve for another year. This was seconded by Mr. Mendelssohn, and carried unanimously.

A vote of thanks to the Chairman, as President of the Union, and also to all the Committee, was moved and carried unanimously, for the interest and work they had done to further the interests of the photographers in their copyright rights.

BRIXTON AND CLAPHAM CAMERA CLUB EXHIBITION.

THE Sixth Annual Exhibition of the Brixton and Clapham Camera Club was held last week, and was unquestionably the best we have seen promoted by this flourishing South London association, which includes among its members some of the foremost workers of the day.

The Judges were Messrs. Cembrano, Gale, and Wall, and they gave their awards as follows:—

Class A (Prints by Members).—Silver medal for best collective exhibit (Nos. 1–18), John Gunston; bronze medal for collective exhibit (Nos. 86–93), G. W. Welham; bronze medal for No. 104, C. F. Archer; bronze medal for No. 34, F. W. Levett.

Class B (Junior Members' Work).—Bronze medal for No. 153, L. E. Cotterell.

Class C (Lantern Slides by Members).—Bronze medal, John Gunston.

Class D (Prints—Open Competition).—Bronze medal for No. 225, A. J. Jeffreys.

Class E (Lantern Slides—Open Competition).—Silver medal for No. 316, E. Dockree; bronze medal for No. 305, A. Brooker.

Pressure on our space obliges us to be very brief in referring to the Exhibition, but we may say that, in addition to the medalled work, great credit, in our opinion, was due to the productions of Mr. W. H. Whittard, who, in Class A, showed some cleverly rendered figure studies. Some excellent landscape work, by Mr. C. F. Archer and Mr. A. Whittaker, and architectural interiors, by Mr. F. P. Smith, also attracted our attention. In Class D Mr. E. C. Hertslet ran the successful exhibitor, Mr. Jeffreys, close with a beautiful view, *Tranquil Rye*, and a composition study, *Waiting for Father's Return*. Mr. P. S. Lankester had a charming portrait study and a study of a head, a line of work in which he excels, which were certainly the best of the kind exhibited. A loan collection included choice examples by past conquerors at this Exhibition —Mr. E. Dockree and Mr. Thomas.

Animated photographs were shown by Messrs. Banks & Greaves each evening, and there was an exhibition of apparatus by the Prosser Roberts Company, Messrs. Beck, and other firms, as well as demonstrations of radiography.

A PATENT COURT.

FOR long past we have experienced a growing conviction that there should be a special court for the trial of actions affecting the validity of patents and the rights of inventors. That conviction strengthened as it grew, says our contemporary *Invention*, and has at length become a settled one—a fixed and unalterable opinion. This opinion is the outcome of a somewhat lengthy experience of patent cases in connexion with expert evidence, and is based upon personal observation of the unmistakable, though unexpressed, views entertained by some of the Judges

before whom we have had to appear. We have more than once noted the anxiety depicted upon the face of a Judge in his earnest endeavour to grasp the details of some involved and complex mechanical or chemical question; and we have also seen the look of relief when the hour of adjournment arrived. We have, moreover, listened to judgments which have passed over several important technical considerations and steered clear of the common-sense aspect of the case. Not that common-sense should always, or even generally, guide or influence a decision; but it may occasionally prove a useful factor in a judgment. On the other hand, a common-sense view may sometimes be neglected with advantage. In a case in which we were recently engaged, and which involved a close legal argument, Counsel, when his armoury had been depleted, appealed to the Judge on the ground of common sense. His Lordship remarked that he had often heard common sense appealed to as a last resource of defeated argument.

But to return. The inadequacy of some Judges to deal equally well with others with abstruse technical questions arises from an unavoidable want of sympathy on their part with the subject. This sympathy, while it is absent from some minds, is present in others in a marked degree, and enables them to readily assimilate that mental pabulum which to others is very difficult of digestion. Some will almost instinctively apprehend that which others comprehend but slowly. This inadequacy is not the fault of the Judge, but his misfortune. His judicial duties oblige him to undertake a task which the natural constitution of his mind renders, in certain respects, difficult of performance because of its uncongeniality. Professional training has somewhat to answer for in this connexion. That of one Judge may have differed from that of another in that, for want of inclination, or, in other words, of natural aptitude, his studies have not included subjects which would enable him to regard scientific cases or to construe a patent specification otherwise than from a purely legal point of view. The unfamiliarity of some of our most eminent Judges with technical matters is not infrequently exhibited in court. We well remember how upon one occasion, at the close of an hour's cross-examination by an eminent Q.C., we were asked by the Judge to explain a simple mechanical principle about which we had been contending with the Q.C., and upon which the case mainly hung; on the other hand, with what avidity and evident zest some of our Judges tackle the most difficult cases! Those are they whose minds are in thorough sympathy with scientific subjects, and who take up point after point with the readiness and familiarity of a practised expert, sometimes to the discomfiture of counsel and witness.

GLASS SUBSTITUTES IN GERMANY.

There are several substitutes for glass in use in Germany, the chief among them being tectorium, *fensterpappe*, and *hornglas*. Tectorium is a sheet of tough, insoluble gum—said to be bichromated gelatine—about one-sixteenth of an inch in thickness, overlying on both sides a web or network of galvanised iron or steel wire, the meshes of which are generally about one-eighth of an inch square. The United States Consul-General at Frankfort says that both surfaces of the tectorium in ordinary use are apparently covered with a varnish of boiled linseed oil, and it feels and smells similar to the oiled silk that is used in surgery and for sweat bands in summer hats. It is lighter than glass of equal thickness, is tough, pliant, and practically indestructible by exposure to rain, wind, hail, or any shock or blow which does not pierce or break the wire web by a violent thrust. It may be bent in any desired form, and fastened in position by crimping, nailing, or with putty like ordinary glass, and when punctured it may be easily repaired. Its translucence is about the same as that of opal glass; its colour a greenish amber yellow, which fades gradually to white from exposure to the sun, so that, while arresting the direct rays of sunshine, it transmits a soft, modulated light, which is said to be well adapted to hot-houses and conservatories. It is a poor conductor of heat and cold, and thus preserves a more equable temperature than glass in rooms containing growing plants. Its surface is well adapted for painting in oil colours, and it is used for illuminated windows, signs, and transparencies, in which strength, lightness, and immunity from breakage are essential, especially in arched, curved, or irregular surfaces. The only objections that can be urged against tectorium are that it is more or less inflammable, and that in very warm weather the outside surface is sometimes softened until dust will adhere to it, but this may be removed by wiping or washing, a service that is usually performed by the rain in exposed situations. Tectorium is an English invention, and Consul-General Mason says that, as far as can be ascertained, it is not patented in Germany. It is claimed for it that it has effected an important economy through its immunity from breakage, which, in case of large roofs of glass, are so frequent and so expensive to repair. For ordinary hotbeds and forcing houses, such as are used by most florists and market gardeners, the Germans have another and cheaper substitute for glass in the so-called *fensterpappe*, which is a tough, strong manila paper, that may be stretched on large sashes or frames, and saturated by painting the exposed surface with boiled linseed oil until it becomes translucent and impervious to water. The paper costs wholesale in Germany about 19*s*. 10*d*. per roll, 100 metres in length by one metre in width, equal to 1220 square feet in each roll. There is no difficulty or secret about its preparation or use. Light wooden frames about forty inches in width, and of any desired length, are provided, and covered with the paper, which is fastened by nailing at the edges, and then painted with ordinary boiled linseed oil, until the paper is so saturated that the last coat of oil forms a smooth, glistening surface like varnish. As soon as dry, the frame is ready for use. It admits sufficient light for growing plants, does not require to be shaded in hot sunshine, is light, durable, secure against breakage by hail or ordinary accident, and, taking everything into account, is said to be about one hundred times cheaper than glass. It is largely used by florists and market gardeners in the district of Frankfort, and their general verdict is strongly in its favour, although for handsome conservatories, skylights, &c., it possesses less durability, and none of the neatness and elegance of tectorium. Finally, there is a new product, called *hornglas*, which has been recently patented and placed on the German market. *Hornglas* resembles tectorium in appearance, with the difference that it is thinner, and consequently lighter in weight, and the insoluble gelatine with which the wire gauze is covered is whiter, and more nearly transparent, than tectorium, although it may be coloured red, green, blue, or any other tint that may be desired for special purposes. It is manufactured in two qualities, one being of heavier wire and with larger meshes than the other. It is cut into lengths of about twenty-three feet by forty-seven inches in width, and is sold wholesale for about 5*s*. 4*d*. per square metre, or rather more than 5*d*. per square foot. The special advantage claimed for *hornglas* is that it does not soften under sun heat, and is therefore adapted to use in any climate without the danger of becoming so soft and adhesive as to retain dust and dirt. Its uses and general characteristics are similar to those of tectorium.

A PHOTOGRAPHER SUMMONED FOR INFRINGING BUILDING BY-LAWS.

At the Portsmouth Police-court, on October 5, before Mr. T. Cousins and Captain Bamber, Ernest Charles Hopkins, of 23, Landport-terrace, Southsea, a photographer, was summoned by the Corporation for unlawfully, and without the written consent of the Urban Sanitary Authority of the borough, erecting a wooden building, with glass front and sides, beyond the front main wall of his residence in Landport-terrace, and continuing the offence from June 10 to September 22, although he had received notice to pull down and remove the same.—Mr. G. H. King prosecuted on behalf of the Authority, and Mr. Bell, of Southampton, appeared for the defendant.

Defendant was previously summoned for the same offence, and the information had then been dismissed on technical grounds.

Mr. W. Coish, Private Improvement Clerk to the Portsmouth Corporation, produced the notice from the Urban Authority, a copy of which he had served on defendant. He also produced a resolution passed by the Roads and Works Committee on May 4, to the effect that notice should be served on defendant to move the structure. This resolution was confirmed by the Town Council on June 9.

Mr. Bell: That is exactly sixteen days after the service of the summons.

Mr. Philip Murch, Borough Engineer, was called. He said he had not closely examined the structure in question, but he had seen it. It was built of wood and glass, and stood in the garden in front of defendant's house. It was used by defendant for the exposure of photographs.

Mr. Bell: Do you produce any written resolution authorising you to serve any notice upon defendant? Witness: No.

Mr. Richard James Jenkins, building and house drainage surveyor, employed by the Corporation, said that he had examined the structure in question. It stood upon wheels, which ran on rails, and could be moved backwards and forwards about three feet six inches. The erection was first made on April 2, and was still standing.

A minute detailing the duties of the Borough Surveyor was produced, in which it was stated that the officer should perform all duties necessary for the proper carrying out of the provisions of the Public Health Act.

Mr. Bell submitted that he had no case to answer. His objection to the proceedings was that the notice, which was the foundation on which the proceedings must stand or fall, was a bad notice. The notice under which the information was laid stated that any person offending against the enactment would be liable after written notice from the Urban Authority. The evidence with reference to the notice was that a Committee had passed a resolution to the effect that such a notice should be served, and that resolution had to be confirmed by the Town Council. The Committee had done very foolishly in serving the notice on May 23, when the Council did not confirm their resolution until June 9. A second point was that there was no evidence before the Court that defendant erected the building in question. Further, Mr. Bell contended that the erection was not a building, but merely a box on wheels, which could be conveyed to any part of the town or the world.

The Court decided, as a matter of fact, that defendant did erect the building in question.

After a lengthy consultation in private, the magistrates decided that the erection in question was a building, and was a very flagrant violation of the statute, and must be a great nuisance to people living in the neighbourhood. They inflicted a fine of 2*s*. 6*d*. for each of the 102 days the erection remained after service of the notice, amounting in all to 12*l*. 15*s*.,

and costs 9*s.* 6*d.* They had power to alter the penalty during the sitting of the Court, and, if defendant was prepared to have the building removed within a reasonable time, they were prepared to reconsider their decision as to the amount of the penalty.

Mr. Bell, on behalf of defendant, agreed to remove the structure within seven days and to accept the magistrates' judgment, and the penalty was thereupon reduced to 2*l.* 11*s.* (sixpence a day). Defendant was not called upon to pay costs.

The Inquirer.

*** *In this column we from time to time print questions that may be addressed to individual contributors to our pages, or such as are sent to us with the view of eliciting information from a variety of sources. We invite the co-operation of our readers in rendering this feature of the* JOURNAL *useful and instructive.*

COLOURED TRANSPARENCIES BY DEVELOPMENT.—C. H. PRICE inquires for a method of making, by development, transparencies (separate) in sepia, blue and green colours.—Perhaps some reader can supply the desired information.

STUDIO ARCHITECTS.—N. P. says: "Could you inform me of an architect who makes photographic studios a speciality? I am building a new one, and should like to have expert advice, and also learn the name of designer specially qualified for the work."—Perhaps some reader can supply the desired information.

RETOUCHING SURFACE (To "Japhet").—COUNTRY PROFESSIONAL writes: "I do not know exactly how much lead you want to get on to the negative; but, if you cannot get enough by careful variation of the formula I gave, it is certainly not the right one for you. Perhaps, if you dust the surface, while wet, with flour emery, it might give a sufficient 'tooth' to suit your touch."

SPIRIT LEVEL DEFECTIVE.—W. J. C. says: "I have one of the circular spirit levels ordinarily employed for levelling the camera out of doors; but it is of very little use, as, owing to leakage, the bead or bubble occupies more than half the area of the circle. The liquid is introduced by means of an aperture on the under side, closed by a screw which, after considerable trouble, I succeeded in removing; but I have entirely failed in all my attempts to get any more liquid into the level. Can any of your readers help me? What is the proper liquid to employ? Alcohol, I believe."

MAGNESIUM FLASH PAPER.—P. STOW says: "In the JOURNAL for May 8 last there is a note, on p. 291, on magnesium flash paper. I have tried to make it, but failed to get any satisfactory result. Could you give me any further particulars, I should be much obliged. I used plain thin white paper, soaking it in a saturated solution of potassium chlorate, and drying when it appeared to be covered in small crystals; is this the best way? I don't know how much powder to put on, but in my experiment I sprayed as much as the paste would hold on when the paper was held perpendicularly. My result simply crackled with an occasional small flare of magnesium."—Perhaps some reader could supply the desired information.

DAMAGED SURFACE OF NEGATIVES.—ALUM says: "In going over a number of negatives taken during the past summer, previous to packing them away, I find several of them suffering from a sort of crystalline surface marking, which I attribute to imperfect washing after using the alum bath. These particular negatives were all taken at a time when I was more than usually busy, and, though they showed no sign of the defect when newly dried, there is little doubt the washing has been 'scamped.' The question now is, Can the markings be removed? I have soaked one of them in water for an hour, but, though on redrying some crystalline matter appears to have been removed, the markings remain. Can I do anything more?"

PURE WATER.—W. FINLAY writes: "Allow me to thank W. C. Holmes for his description of a cheap filter. I have made an experimental one, and it seems to work most efficiently; but the water, when filtered, although beautifully clear and perfectly colourless, has a decidedly 'tarry' or 'burnt' taste, which, I assume, comes from the charcoal. Is this as it should be, and will it pass off in course of time? The material used is animal charcoal, freshly burnt, which may possibly account for the taste." Another correspondent, J. E. JOHNSON, writing on the same subject, says: "I have tried W. C. Holmes's cheap filter, which seems to be all right in theory, if you can only get proper sand. He speaks of 'well-washed silver sand.' I have taken silver sand as obtained from the oil shop and soaked and washed it for a day, and still the water comes through like the drainage of a gravel pit, in fact a good deal worse than it goes in. How long should it take to well wash a peck of sand?"

BISULPHITE OF SODA.—ECONOMY writes: "I have a quantity of bisulphite of soda which I wish to utilise for developing purposes. I have employed it in solution, instead of the neutral sulphite, and, as a matter of course, it forms a much better preservative, especially in the case of pyro; but the excess of acid I find very confusing when adding the alkali for development. Of course, under normal conditions, it is easy to know what quantity of alkali to add; but, if the proportions have to be altered for either under or over-exposure, a somewhat elaborate calculation is needful. I wish, therefore, to convert the acid into the neutral sulphite, but cannot tell how much carbonate or hydrate of soda to add to bring about the exact conversion. In separate small quantities, operated upon experimentally, the quantities of alkali used vary so widely that I think something must be wrong, and I find it very difficult with litmus as the indicator to judge the colour. Will any one give me the relative proportions of bisulphite and alkali?"

SPOTTING PRINTS AND NEGATIVES.—COLOURIST writes: "With regard to this question, 'Spotter' is quite right in saying that proper materials are an essential to success, and this is especially the case in the matter of the medium. I have for years past adopted the following plan, and, although it entails some little trouble at the start, it is well repaid, and a small quantity of the preparation will last a long time. In spotting or retouching (with the brush) negatives, I take any quantity of old negative film, removed from the glass and boiled in a porcelain or earthenware jar with a little dilute acetic acid, until reduced to a permanent liquid state. I do not find any need to do anything more to this preparation beyond simply evaporating it to a suitable consistency, in which condition it keeps ready for immediate use for any period; should it exhibit a tendency to dry up, however, a little glycerine may be added. For prints, I take the trimmings and clippings of toned gelatino-chloride prints and treat them in the same way, only omitting the acetic acid. The trimmings are boiled in water until all the gelatine and silver are dissolved off, the paper is then removed and the liquid concentrated as before. The colour of the deposited matter will be much redder than that of the prints operated upon, but it may be considerably modified, in fact brought to any desired tone, either by intentionally over-toning a portion of the cuttings, or by treating the deposit obtained with a little chloride of gold while boiling."

Our Editorial Table.

THE COOKE LENS.

MESSRS. TAYLOR, TAYLOR, & HOBSON, of Slate-street Works, Leicester, send us a neatly got-up booklet, which is devoted to briefly describing the defects of curvature of field and astigmatism in lenses, and the influence of those aberrations on the character of the image. Lenses so characterised are compared with others of modern construction, of which the Cooke is taken as a type. We are asked to recommend the pamphlet to our readers, and have pleasure in doing so.

FIRST AID IN PHOTOGRAPHY.

By J. R. COURTENAY GALE and J. CADETT. Ashtead: Cadett & Neall.

THIS, a beginner's book, is No. 1 of the Cadett Photographic Handbooks, and is perhaps more like a photographic Mavor than any other elementary book we have seen. It appeals to the aspirant who knows nothing of photography. Persons of this kind are hard to write for, on account of the difficulty of authors to let themselves down to the level required. In this task Messrs. Gale & Cadett have succeeded very well, and the book is a collection of tersely expressed instructions in elementary photography, through which the ignoramus may pass to a very fair knowledge of his subject. It includes a celluloid negative and sells at 1*s.*

ECCLESIASTICAL BUILDINGS IN SHREWSBURY.

Shrewsbury: Adnitt & Naunton.

THERE were very few visitors to the Shrewsbury Convention who did not avail themselves of the excellent photographic guide to the

town issued by Messrs. Adnitt & Naunton, of the Square, Shrewsbury. The same firm also issued an exeellent album of collotype views—"Picturesque Shrewsbury"—which was greatly appreciated. "Ecclesiastical Buildings in Shrewsbury" is the latest pictorial publication of the firm, who took advantage of the Church Congress, a fortnight ago, to issue the volume. It is an elegantly got-up album, full of capital photographs of the Shrewsbury churches by Mr. W. W. Naunton, who is personally known to many of our readers. The volume sells at 2*s.*, and it is one that possibly many who read this parsgraph will be glad to possess. It will app-al to them, as it does to us, as another reminder of the memorable Shrewsbury Convention.

News and Notes.

ROYAL PHOTOGRAPHIC SOCIETY.—Photo-mechanical meeting, Tuesday, October 20, at the Gallery, 5A, Pall Mall East, at eight p.m. *Half-tone Direct from Nature*, by Mr. William Gamble.

PHOTOGRAPHIC CLUB.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock on Wednesday evening, October 21. Members' Open Night.

THE BRISTOL EXHIBITION.—Messrs. Bernard Alfieri, Valentine Blanchard, Payne Jennings, H. A. Hood Daniel, and Reginald Smith have kindly consented to act as Judges at the Bristol Exhibition, to be opened in December.

ERRATUM.—By a typographical error we were made last week to say that the British Photo-print Company, of 22, Southampton-buildings, Chancery-lane, had purchased the business of the Richmond College Company. For "College" read "Collotype."

THINGS THEY MANAGE BETTER IN AMERICA.—The late Dr. Brown Goode made the following comparison in a report of the United States National Museum: "There is not a department of the British Government to which a citizen has a right to apply for information upon a scientific question. This seems hard to believe, for I cannot think of any scientific subject regarding which a letter, if addressed to the scientific bureaux in Washington, would not receive a full and practical reply. It is estimated that not less than 20,000 such letters are received each year. The Smithsonian Institution and National Museum alone receive about 6000, and the proportion of these from the new States and Territories which have not yet developed institutions of learning of their own is the largest. An intelligent question from a farmer of the frontier receives as much attention as a communication from a royal academy of sciencea, and often takes more time for the preparation of the reply."

ROBERT LOUIS STEVENSON AS A DRAUGHTSMAN.—A special winter number of the *Studio* will shortly appear, in which will be published for the first time an account by the late Robert Louis Stevenson of his stay at Monastier in the autumn of 1878. This article was originally intended to serve as the opening chapter of his well-known volume, *Travels with a Donkey in the Cevennes*, but the intention was abandoned in favour of a more abrupt beginning. The story will be illustrated with sketches by the author which have never previously been published, while reproductioos will also be given of the humorous woodcuts executed by Stevenson and printed by his young stepson, Lloyd Osbourne, at Davos, in the Engadine, during the winter of 1880-81. This number will also contain "The Ideal Life of a Landscape Painter," by James Stanley Little; "Some Famous Paris Studios," by Gabriel Mourey; an article upon Old Samplers, by Gleeson White; and contributions from the pens of Joseph Pennell, Norman Garstin, Margaret Armour, and others. A sketch in colours by G. H. Boughton, R.A., will be included among the supplemental illustrations.

SYMPSYCHOGRAPHY is a portentous word, and so it should be to sum up worthily the phenomena with which it is concerned. The world knows something already of the remarkable photographic experiences of Mr. Ingles Rogers, who professes to have obtained pictorial images of certain mental processes. Mr. Rogers alleged that, after contemplating fixedly for a time so simple a work of art as a British postage stamp, he then placed himself before the lens of a camera in a dark room, and was rewarded by finding that the sensitised plate reproduced a shadowy portrait of our gracious Sovereign, with the words "One penny" on the rim. Mr. D. S. Jordan, however, a gentleman holding a distinguished university position on the other side of the Atlantic, has now contrived to go one better than his predecessor in this branch of occult science. He gets together six persons of suitable capacity, and bids them concentrate their minds upon the harmless, necessary cat—in the abstract, of course—without reference to any individual of the species. Each then projects this mental image into a separate lens, all the invisible rays being focussed upon a single plate, and the result is a representation of the ideal cat. Mr. Jordan hopes very soon to be able to reverse the process, and to extract from the feline brain a true picture of the ideal man. But here a difficulty comes in, the cat may refuse to take the matter seriously, and may laugh at the philosopher.—*Daily Chronicle.*

AN INJURY WITHOUT A REMEDY.—At the Sheffield County Court on Friday, the 2od instant, an interesting action was tried involving a question as to the person liable for damage to a parcel of photographic plates sent by passenger train. The plaintiff in the case was Frank Mottershaw, trading as the Sheffield Photographic Company at Norfolk-street, Sheffield, and the claim was for 10*s.* 9*d.* for goods sold (photographic plates) by him to Mr. F. Whaley, the well-known photographer and artist at Doncaster, who resisted the claim on the ground that, upon receipt of the goods, the plates were broken into hundreds of pieces, and that such breakage was caused by the negligence of Mottershaw, firstly, in not affixing a board on the top as well as underneath the plates, and, secondly, in not labelling the parcel, which was sent by a passenger train from Sheffield to Worksop, "Glass" in the usual way in the trade of these kind of goods. Plaintiff had absolutely refused to make the damage good by supplying others in the place of the damaged plates, and the defendant was unable to obtain compensation from the railway company in consequence of Mottershaw omitting to label the parcel "Glass." After the evidence was taken, and the legal argument on both sides heard, the Judge considered an important point was raised in the case, and, although he gave judgment for the amount claimed, he gave Mr. Whaley leave to commence an action for damages against Mottershaw or the railway company for the breakage as he may be advised, he (Mr. Whaley) having received nothing of any value for his money.

THE Hackney Photographic Society's Annual Exhibition will be held at Morley Hall, Triangle, Mare-street, Hackney, on Tuesday, Wednesday, Thursday, and Friday, November 17, 18, 19, and 20, 1896. The Exhibition will be opened on November 17, at half-past seven, the succeeding days at twelve (noon) till ten p.m. The prices of admission each day will be, between twelve and six, 6*d.*, afterwards, 1*s.*; and arrangements will be made for continued instrumental concerts of a high-class character, lantern displays, &c. The Judges are Mr. F. Hollyer, the Rev. F. C. Lambert, and Mr. E. J. Wall. The Hanging Judge is Mr. Alexander Mackie. The classes are: (Members') Class A, Any picture taken since last Exhibition; Class B, Pictures taken during Membership; Class C, Best Picture taken in Hand Camera (enlargements permitted); Class D, Stereoscopic, set of six (prints or transparencies); Class E, Set of four alides; Special Class for greatest novelty, home-made or otherwise. The Open Classes are (entries in these classes may be priced for sale at the option of the exhibitor): Class F, For any picture not previously having received an award; Class G, For Portraiture and *Genre* (in this class the work may be that of a firm, and need not be that of the exhibitor alone); Class H, Champion Class, for pictures which *have* previously received awards; Class I, For four Lantern Slides *not* having previously received awards. Awards (Members'): Classes A, B, C, D, and E, silver and bronze medals in each; Members' Novelty Class, silver medal; for best picture in Members' Classes, gold medal, presented by F. Houghton, Esq. The medals in Classes C and E are presented by L. S. Wilks, Esq., and Major Woolmer-Williams respectively. The President (Mr Bedding) has also notified his intention of presenting a special prize in Class D. Open Classes: Classes F, G, and I, silver and bronze medals in each; Champion Class, gold and silver medals; Trade Section, silver medal. Certificates will be awarded at Judges' discretion. Extra entry forms and all further information respecting Exhibition can be obtained from W. Fenton-Jones, Hon. Secretary, 12, King Edward-road, Hackney, N.E.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

October.	Name of Society.	Subject.
19.....	Bradford	*Church Notes from Various Counties.* S. Margerison.
19.....	Camera Club	*Transparency of Glass and Porcelain to the X Rays.* Professor A. W. Rücker.
19.....	North Middlesex	*The Silver Sensitising Bath.* W. J. Simpson.
19.....	Richmond	*At Home Subjects.* W. Thomas, F.R.P.S.
20.....	Birmingham Photo. Society ...	*Westminster Abbey: its Monuments and Historical Associations.* Sir J. Benjamin Stone, M.P.
20.....	Brixton and Clapham	*Pictorial Photography.* A. Horsley Hinton.
20.....	Gospel Oak	Developing, Toning, and Mounting.
20.....	Hackney	*Intensification and Reduction.* E. J. Wall.
20.....	Leeds Photo. Society	*Elementary Lantern Manipulation for Beginners.* S. A. Warburton.—Lantern Slides on Sandell Plates from J. T. Sandell.
20.....	Lewisham	Lantern Evening.
20.....	Royal Photographic Society ...	*Half-tone Direct from Nature.* William Gamble.
21.....	Croydon Camera Club	*At Home Photography.* W. Thomas, F.R.P.S.

22.....	Ashton-under-Lyne.....	*Print Enamelling.* Samuel Woolley.
22.....	Camera Club.....	*The Chemistry of some of the more Common Processes of Photography.* H. C. L. Bloxam, F.C.S., &c.
22.....	Ireland	Practical Demonstration in Enlarging by R. M. Inglis.
22.....	Liverpool Amateur.....	*The Art of Sculpture, with Practical Demonstrations from Photographs.* George Holding.
22.....	Nottingham	Annual Meeting.
22.....	West Surrey	Discussion: *What is the Best Camera for Beginners?*
23.....	Croydon Microscopical	Trial Night, Members' Slides.
24.....	Leytonstone	Open Social Meeting.

ROYAL PHOTOGRAPHIC SOCIETY.

OCTOBER 13,—Ordinary Meeting,—Captain W. de W. Abney, C.B., R.E., F.R.S. (President), in the chair.

THE LATE MR. WILLIAM ENGLAND.

The PRESIDENT referred, in sympathetic terms, to the death of Mr. William England, who was for many years intimately connected with the Society, and stated that the Council had passed a vote of condolence with the family of the deceased, in which vote he was sure the members generally would wish to be associated. It was agreed that a letter should be addressed to Mr. England s-

relatives, expressing the sympathy and condolence of the Society with them in their bereavement.

NEW MEMBERS.

Applications were read from some thirty candidates for membership, and Mr. S. J. Beckett, of Hackney, and Colonel Edward Mockler, H.M. Consul-General at Bagdad, were duly elected.

ELECTORAL REFORM.

The PRESIDENT announced that the question of the modification of the Articles of Association relating to the election of the Council would shortly be considered by a Committee of the whole of that body.

PRESENTATION OF AWARDS.

The PRESIDENT presented the medals awarded by the Judges at the Exhibition to Mr. Wilson Noble, Mr. Paul Martin, Mr. C. F. Inston, Messrs. Bulbeck & Co., and Mr. W. Thomas, addressing to each a few words of congratulation and encouragement. It was arranged that the medals awarded to the following gentlemen, who were not present, should be forwarded to them, viz., Mr. P. von Schoeller (Austria), Mr. A. Stieglitz (New York), Mr. J. Bushby (Liverpool), and Dr. Macdonald.

COMPLIMENTARY.

The thanks of the Society were accorded to the Hanging and Selecting Committees, and also to the Judges, for their services in connexion with the Exhibition.

PRESIDENT'S ADDRESS.

The PRESIDENT then delivered his annual address [see p. 661.]

Mr. J. W. SWAN, M.A., F.R.S., moved that a cordial vote of thanks be given to Captain Abney for his exceedingly interesting address, and the motion was seconded by Mr. W. E. DEBENHAM.

Mr. JOHN SPILLER, in supporting, wished that some better term than I T could have been selected to express *time* and *intensity*, and would have preferred the name of Talbot to have been used, in the same manner as Ampère, Ohm, and Watt had been applied in electricity.

The motion having been carried by acclamation,

The PRESIDENT, in acknowledging the vote, said that, if the name "Talbot" were chosen, it would be the only instance in photography in which the name of a distinguished man was so employed, and he did not think any difficulty would be found in making the printers use capitals for I T.

THE FINANCE OF THE EXHIBITION.

Mr. G. SCAMELL (Hon. Treasurer) stated that the receipts at the Exhibition during the first thirteen days showed an increase of nearly 38*l.* over the corresponding period last year.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

OCTOBER 8,—Mr. R. Beckett in the chair.

Messrs. G. H. James and Paul Martin were elected members, and Mr. A. E. Allen proposed for membership.

Mr. Kellow brought up a print of which he was desirous to know the printing process and maker. To all appearances it was some kind of bromide print.

The CHAIRMAN believed that the process was originally brought out by Friese Greene.

Mr. EVERITT said it was a question whether the print had not been mounted on the card after development, and the card then trimmed down. The card presented the appearance that a mounted print gives to it by a slight bend it possessed.

Mr. A. L. HENDERSON gave his promised lantern display on *Sicily*, which places he visited this year. Starting at Palermo, and thence to Taormine, Gergenti, Catania, Syracuse, and Messina, Mr. Henderson showed a large number of slides, chiefly of panoramic views, including cathedrals, royal residences, ancient and ruined temples, and types of the different architectures, besides the ordinary town and country scenery.

Mr. Cole projected on the screen a stereoscopic slide from a negative of the last (or one of the last) Flemish mills in this country, which exhibited, on development, three peculiar markings. One was a plainly outlined head, surmounted by a helmet; another was shaped like the head of a hound; and the third closely resembled the head of a boy wearing a cap. No explanation forthcoming, the subject dropped.

PHOTOGRAPHIC CLUB.

OCTOBER 7,—Mr. A. Mackie in the chair.

Captain Hayes was unanimously elected a member of the Club.

Messrs. Bedding and Carter were elected as Auditors of the Club's accounts for the current year.

A large number of members and friends (about seventy in all) attended to hear a lecture upon

PICTORIAL PHOTOGRAPHY,

by Mr. A. HORSLEY HINTON. Pictorial photography, said Mr. Hinton, is mainly emotional. It is a means of communication between the creator and the spectator, and the response of the latter is the measure of its success. A picture may be accepted by the world without its true merits being appreciated; on the other hand, its meaning may be grasped by the few, and their approval may be worth as much as the praise of the many. The two London Exhibitions constitute the culminating point of the photographic year; they are the something definite to be worked for. A man is not fitted to judge his own work. Knowing what his ideal was, he sees his picture rather as it was intended to be than as it is. One is apt to be too easily satisfied and too lenient to small faults. After seeing both photographic Exhibitions, he felt momentarily despondent for the future of pictorial photography. Is the practitioner unskilful? said Mr. Hinton. Before photography came, was the want of pictorial photography felt? Is there any pleasurable impression, any fine idea, any subtle feeling expressed that has not been as well or better done by other and more recognised methods? Has it brought any new interpretation to art? or, were it obliterated, would the world be poorer? He would fain check the aggressive tendency of those whose self-satisfaction and contentment made photography's position in art hopeless. After all, the answers to the questions he had raised must be according to one's own convictions. Mere picture-making is not synonymous with art, and the phrase "pictorial photography" as a title would provide greater safety and greater freedom than the claim of art permitted. The making of a pleasing picture is the most popular phase to photography, and, as landscape can be more easily portrayed than figure subjects, it had the greatest number of votaries. Only those photographs are pictorial whose interest is in themselves. Expression and composition are the two elements of a picture.

Mr. Hinton's lecture, as will be seen by the above brief extracts, consisted mainly of a series of aphorisms. He interspersed his remarks with many of a lighter character. He instanced how, in one case, he had composed a picture which he called *By Weedy Bank*, but ultimately rechristened *The Road to the Farm*, kindly critics having suggested that the shallow stream of winding water was more suggestive of a dusty road. He compared what he called a technical, topographical photograph, which included a view of five counties and 500 churches, with another of a specimen of *Pulex irritans*. Both, said Mr. Hinton, are obvious physical facts. As for a glossy surface and fine definition, he said that such photographs are to be wondered at for their marvellous perfection, but not for the emotions which they arouse. Mr. Hinton illustrated his lecture with a series of lantern slides and diagrams, in which latter he showed the salient points of the composition of the former.

Mr. MASKELL said that, if he made any remarks at all, it would be to compliment Mr. Hinton upon his admirable lecture. He suggested the advisability of such papers being printed and put into the hands of the Society before they were read, as it was impossible to analyse them in a few impromptu words. The lecture was a series of truisms well expressed. As to whether pictorial photography is needed, the answer was instinctive, We feel it is. The pleasure shown by visitors to exhibitions also demonstrated its need. When he was told that a painter could, with a few masterly strokes, produce better results than a photographer, and that he could do it in five minutes, he (Mr. Maskell) replied, Then let me see it. As a matter of fact, painters cannot do it. We practise photography because we are able to produce results by it which we cannot do by other means; we take refuge in our photographic art because it gives us a new method of expression. His feeling was one of gratitude for a very able paper.

Mr. W. THOMAS agreed that the paper required time for assimilation. He thought that that meeting was a justification of the Affiliation scheme, and he took the opportunity of explaining that the reason a series of lectures were given on consecutive nights was that the rooms were only available if that course were adopted.

Mr. MUMMERY disagreed with the lecturer, who had stated that pictorial photography was impossible with lantern slides.

Mr. EVERITT raised the point that the claim for photography to be an art was a modest but a true one. He said that an engraver was admitted to be an artist, although he but produced another man's picture. There had been great improvements in photography, and it possessed a power of reproduction which the engraver could certainly not excel, even if he could do as well. A painter, however, had advantages over a photographer in that he could take liberties with his subject in a more easy way than could the photographer.

Mr. MORLEY BROOK said he did not know why lantern slides should not be satisfactory in a pictorial sense; their size should not be a great disadvantage. As to the technical defects in production, they could be overcome.

Mr. SNOWDEN WARD said that the lecturer had spoken as if all manipulative work should be done upon the print; he thought much could be done on the negative. With regard to lantern slides, we do not look at the slide, but at the screen, and the statement that we had to look through them, and not at them, must therefore fall through.

Mr. WELFORD said that he was struck with the lecturer's denunciation of lantern slides, but, if the slides shown by Mr. Hinton were to influence the argument, he should agree with him. He thought that Mr. Hinton, as an editor, could have availed himself of the slides which he (Mr. Welford) knew had passed through his hands at one time or another, and which were excellent. Lantern slides could be pictorial or otherwise. It depended upon the way they were produced, and it should be remembered that they pleased a very large number of people.

Mr. HINTON, replying, said that he had not anticipated anything in the nature of a discussion, although he welcomed it. With regard to the controversial points raised, he said that reproduction had nothing to do with pictorial photography. As regards lantern slides, he had not seen one yet which satisfied him. They had no claim to art because they pleased many people.

Mr. BEDDING said the Club was to be congratulated at being the first to hear Mr. Hinton's lecture. Most speakers, in discussing art, generally did so with a bias, but the lecturer had treated his subject very fairly. He thought that in its progress through the country it would provide much useful information and matter for discussion. Mr. Hinton appeared before them in the double capacity of a teacher and a worker, and, failing his works, he could not be better represented than by this lecture. He proposed a hearty vote of thanks to Mr. Hinton.

Mr. WALL, in a few humorous observations, seconded the vote of thanks. He made fun of the lecturer's comparative references to boot polish and high gloss. He added that he thought a man had a right to ask whose plate and lens had been used to make a photograph. It was the only chance that some people would have of working upon the same lines as pictorial artists. As for spending hours over a single print, he did not intend to do it, but there was one thing he should do, and that was to most carefully read through Mr. Hinton's lecture, a copy of which he had in his pocket, and from which he anticipated further pleasure.

Mr. HINTON thanked the meeting for what he described as the flattering and far too kind way in which it had received him. He was gratified at the very cordial reception he had received at the Photographic Club.

Croydon Camera Club.—The winter session of this Club was inaugurated on Wednesday, when, according to usual custom, the PRESIDENT (Mr. Hector Maclean, F.R.P.S.) gave a short address, reviewing current matters of photographic interest, and also speaking upon the future arrangements of the Club. Amongst many notable subjects touched upon were the general use of rollable films and the availability of the acetylene light for various photographic purposes. These were followed by a rapid but complete sketch of the comparatively newly adopted Artigue printing process, which was briefly compared with the better-known so-called carbon process. Mr. Maclean showed a copy of M. Philipp Von Schoeller's medalled picture, printed upon Artigue, in illustration of the beauty and general excellence of the process when used by capable hands. In conclusion, he glanced at X-ray work and photographs in motion, and announced that unusually interesting demonstrations by distinguished specialists of the foregoing branches of photography would be given to members. Having referred in some detail to the fixtures and plans for the winter, he appealed to members to maintain the Club's high reputation which it had in past seasons earned for lantern slides. At the termination of the address, Mr. H. E. HOLLAND read a most interesting paper upon

HOW TO MAKE LANTERN SLIDES.

Mr. Holland then proceeded to give a demonstration of his method of working, which was followed with considerable attention by a number of beginners. In the ensuing discussion Messrs. Smith, Costa, Isaac, Richardson, Taylor, and others took part.

Gospel Oak Photographic Society.—On Monday, October 5, the annual Social Evening of this Society was held in the Lecture hall of the Gospel Oak Congregational Church, and was attended by a large number of members and friends. By means of the oxyhydrogen lantern the following members were enabled to exhibit an interesting series of slides, which were much appreciated:—Messrs. Beyer, Hall, Morris, Morton, Palmer, and Pridham. One of the slides exhibited by Mr. Pridham, made from a negative taken by him at the Zoological Gardens, represented a young lady holding a python without apparently any fear. Mr. Pridham stated that this picture had been reproduced in the *Graphic* of September 19. Refreshments having been served, a capital programme was gone through, which included songs by Mrs. Hingston, Miss Lily Sweet, and Messrs. Haywood and Young; also a humorous recitation by Miss M. Brodie, a banjo ditty by Mr. H. Gooding, and a humorous sketch entitled "The Darkie Photographer," in which the characters were taken by Messrs. W. James, H. Gooding, and B. Daly. Miss Randall kindly acted as accompanist during the evening, and also contributed a well-played pianoforte solo. One of the most successful Social Evenings that this Society has had was brought to a termination by singing the National Anthem.

Tooting Camera Club.—On the 9th instant a supper was given to celebrate the return of Mr. J. F. Child (the Club's late Secretary) from the Arctic regions, where he had been engaged as photographer to the Jackson-Harmsworth Expedition. There was a large attendance of members and friends, Mr. J. H. Beckett occupying the chair, and Mr. Joseph Nock the vice-chair. The CHAIRMAN, in proposing Mr. Child's health, mentioned that many friends and acquaintances of the explorer had had grave misgivings as to whether he would be able to withstand the rigours of an Arctic winter, but they had, as events proved, underrated Mr. Child's power of endurance and indomitable pluck, for he had returned, to their great gratification, in the best of health. Mr. CHILD, who was listened to with eager interest, and subjected to many interpolations, spoke at some length, and, in addition to giving his experiences as photographer to the Expedition, graphically depicted the life of the party on Franz Josef Land, and the now historic meeting with Dr. Nansen. He likewise added that Dr. Nansen was an expert photographer, and that during his long journey across the ice, accompanied by Lieutenant Johannsen, the camera was fully utilised. During the evening the toast of "Dr. Nansen" was enthusiastically received, and, at the unanimous request of the members, the Chairman dispatched a telegram to that gentleman, expressing their admiration of his intrepidity, and their best wishes for success in any future explorations he might undertake. The various toasts were interspersed with songs, and altogether the evening was voted an immense success, which was owing in a large measure to the excellent arrangements carried out under the supervision of Messrs. Simmonds and Mayhew (Secretary).

Woolwich Photographic Society.—The annual business meeting was held on Thursday, the 8th inst., in St. John's Schools, Wellington-street, Colonel C. D. Davies presiding. The balance-sheet was read and carried unanimously. The report of the Council was then read, in which it was viewed with satisfaction that, at the close of the year's work, they were able to record the continued advancement of the Society. This was evidenced in the largely increased membership and healthy financial condition. Although the balance in hand was only a small one, it was to be noted that about 5*l.* had been paid during the year to the lantern fund, and property was in hand available for use at future Exhibitions to the value of at least 2*l.* This report was unanimously adopted. Last year the winter session was opened by a series of lectures on photography from a technical point of view; this season it is intended to follow this up by a series of three lectures on the art side of photography, and the Rev. F. C. Lambert has kindly consented to deliver them. It was with deep regret that the meeting heard the announcement that Mr. J. Borthwick Panting would be unable to stand again for the office of Hon. Secretary, his time was so fully occupied in other directions that he felt he would be unable to do the Society or himself justice. Under these circumstances, and taking into consideration the admirable manner in which he had worked for the Society during the last four years, and had pioneered it from a handful of members to its present flourishing condition, with about eighty members, he was not pressed to withdraw his resignation. The officers for the ensuing twelve months were elected as follows:—*President:* Colonel C. D. Davies.—*Vice-Presidents:* Rev. S. E. Chettoe and Messrs. W. H. Dawson, H. H Barker, and J. Borthwick Panting.—*Council:* Messrs. C. Churchill, J. Cregan, J. Desforges, W. R. Dunger, J. Hope, and R. J. Redding.—*Librarian:* Mr. H. J. Maskell.—*Hon. Secretary:* Mr. Frederick W. Machen.—*Hon. Assistant Secretary:* Mr. W. G. Champion. All communications to the Society should in future be addressed to Mr. Frederick W. Machen, 161, Griffin-road, Plumstead.

Leeds Camera Club.—The members of the Leeds Camera Club met on Wednesday evening, September 30, the subject being *Hints to Beginners on the Choice of Apparatus.* It was with deep regret that the members learnt that, owing to severe illness, Mr. C. B. Vevers (who should have given the lecture) would be unable to do so. Mr. J. GARBUTT very kindly undertook the duty, and very ably did he acquit himself of the task. He pointed out the pitfalls which many are apt to fall into by purchasing the cheap and nasty articles that are placed upon the market to catch the unwary, and strongly advised members to give a fair and reasonable price for their outfit, thereby making certain of getting something that would not only be a pleasure to work with, but of fair durability. Useful hints were given also with reference to the use of chemicals, developers, dark rooms, and their appurtenances, and the choice of hand cameras. The whole was a *résumé* of good, sound, practical advice to those about to take up the mysteries and fascinations of the "dark art." The lecture was much appreciated by a large audience, and a very hearty vote of thanks was accorded to Mr. Garbutt for his services.

Plymouth Photographic Society.—The Society opened its winter session on October 9 with a social gathering of members and friends. Nearly a hundred attended. The PRESIDENT (Mr. E. H. Micklewood) welcomed the friends, and announced a very attractive programme for the first half of the winter session. One of the Vice-Presidents (Mr. Aver W. Duncan) kindly provided a choice selection of transparencies, stereoscopes, concave mirrors, and graphoscopes, with some of the best examples of work of the best men. Messrs. Heath & Co., the well-known local opticians, kindly sent a lantern illuminated by the Incanto acetylene gas apparatus. Except some very dense slides, the illumination was excellent, and a set of Mr. Duncan's, of Cotehell House, a local example of one of the best-preserved manor houses in the kingdom, were specially admired. Vocal and instrumental music and the handing round of light refreshments completed the inaugural function of the Plymouth Society.

Rotherham Photographic Society.—Annual Meeting, October 6, Dr. Baldwin (President) in the chair.—The report recorded a satisfactory amount of progress both in regard to the individual work of members, the strength of the Society, and the character of the meetings. The annual Exhibition has yielded a net profit of 5*l.* 9*s.* 7½*d.* The enlarging lantern balance has been paid off. The total sum standing to the Society's credit was 6*l.* 2*s.* 5½*d.* Regret was expressed at the feeble character of the competition for members' work and at the small attendances at the summer excursions. The appointments for the year were as under:—*President:* Dr. F. B. Judge Baldwin.—*Vice-Presidents:* Messrs. E. Isle Hubbard, G. T. M. Rackstraw, and J. Leadbeater.—*Hon. Treasurer:* Mr. A. S. Lyth.—*Hon. Secretary:* Mr. H. C. Hemmingway. These officers with the following members constitute the Council, viz., Messrs. W. Mason, John Clarke, R. H. Law, J. Turner, and C. E. Parkin, jun. The special subject was *Hand Camera Work*, and 112 prints were exhibited by Messrs. Rackstraw, Hubbard, Mason, Parkin, Lyth, and Oldham. It was announced that the season's programme was very complete.

Sheffield Photographic Society.—October 6, Annual Meeting, Mr. B. Nowill occupied the chair.—The Treasurer (Mr. Smith) presented his annual report and balance-sheet, which showed the Society to be in a sound financial position, and was unanimously adopted. The Secretary read his annual report, giving an outline of the work done and meetings held, and making several suggestions for the coming year. Eleven new members have been elected during the year, and six were elected whilst the meeting was in progress. Votes of thanks were passed to the Auditors and retiring officers for past services, and the election of officers for the ensuing year was next proceeded with, and resulted as follows:—*President:* Mr. G. Tomlinson.—*Vice-Presidents:* Messrs. B. Nowill, E. Beck, and T. Firth.—*Council:* Messrs. S. Camp, W. T. Furniss, D. C. Brooks, T. Hibbert, and E. H. Pearce.—*Reporter:* Mr. George W. Blackwell.—*Treasurer:* Mr. Joseph Smith.—*Secretary:* Mr. Herbert Ellis.

Edinburgh Photographic Society.—October 8.—Mr. F. P. MOFFAT (the President), in a short, vigorous address, impressed upon his hearers the necessity of members taking part individually in the discussions and other work of the Society. If members would make a point of asking a question now and again, they would soon find that they were benefiting greatly, and would feel a renewed interest in the affairs of the Society. Besides the usual monthly meetings, it was explained, the Elementary Section under Mr. Lugton, and the Lantern Section in charge of Mr. Souter, held regular meetings. There were, therefore, plenty of opportunities for the acquiring of knowledge on photographic matters. Mr. Moffat has been a member for twenty years, and the interest he takes in the Society is well known. After reviewing the past, he showed that the Society was now in a more flourishing condition than ever. The report of the Treasurer, Mr. G. Cleland, showed the financial affairs to be in a very satisfactory state. Captain W. Morrison, Army Medical Staff, then delivered a lecture on Ceylon; its scenery, temples, and industries. The lecture was most interesting, and profusely illustrated by lantern slides. At the close, Captain Morrison and Mr. Moffat were heartily thanked.

FORTHCOMING EXHIBITIONS.

1896.		
Oct. 16-Nov. 7	.....	Photographic Salon, Dudley Gallery, Piccadilly. **Alfred** Maskell, Dudley Gallery, Piccadilly.
,, 16-Nov. 12	.....	Royal Photographic Society. R. Child Bayley, 12, Hanover-square.
,, 26-31	.....	Southport Social Photographic Club.
November 12	.....	Dulwich Photographic Society.
,, 17-20	.....	Hackney Photographic Society. W. F. Fenton Jones, 12, King Edward Road, Hackney.
December 3, 4	.....	Aintree Photographic Society. E. P. Heron, 2 Tilney-street, Orrell Park, Aintree, Liverpool.
Dec. 1896-Jan. 1897		Bristol International. Hon. Secretary, 20, Berkeley-square, Clifton, Bristol.

Patent News.

THE following applications for Patents were made between September 30 and October 7, 1896:—

APPARATUS.—No. 21,435. "Improvements in Photographic Apparatus." A. C. SMITH.

CAMERAS.—No. 21,475. "Improvements in Photographic Cameras." E. P. SCHOENFELDER and E. KEHLE.

DISHES AND BATHS.—No. 21,495. "Improvements in Dishes or Baths employed in Developing and like Photographic and Chemical operations." W. S. WAIN.

DARK SLIDE.—No. 21,505. "An Improved Photographic Dark Slide." F. E. BROWN and W. EDWARDS.

SCREEN KINETOSCOPY.—No. 21,554. "Improvements in connexion with the Projection of Photographs of Animated Subjects and Methods of taking the said Subjects." J. BONN.

PORTABLE APPARATUS.—No. 21,755. "Improvements in Portable Photographic Apparatus." Complete specification. E. BLOCH.

THE TANNING ACTION OF PYRO ON GELATINE.

To the EDITORS.

GENTLEMEN,—Referring to the discussion on the tanning action of pyro at a recent meeting of the London and Provincial Photographic Association as reported in last week's issue, I think Mr. Warnerke stated the real case some years ago when he first introduced his process now applied to photogravure. If pyro alone, or even pyro in conjunction with alkali, and therefore in a more or less oxidised condition, exercised the tanning action —at any rate in a reasonable time—the Warnerke process would be an impossibility. Mr. Warnerke, if I remember rightly, ascribed the insolubilising action in his process to the combined effect of light and development. If it were dependent on development alone, the whole film would become insoluble instead of only those parts in which there is a deposit of silver.

If any one will take the trouble to add some alkaline pyro to two separate bottles of gelatine emulsion, and, after allowing them both to "set," will expose one of them to light, and then immerse both in hot water, he will come to the conclusion that light has something to do with the tanning. Again, if a piece of ordinary gelatine chloride paper be exposed under an opaque mask, with a clearly cut opening, until a bronzed image of the latter is formed, it will be found that the unexposed portion of the sensitive film is easily dissolved with only moderately warm water, while the exposed part will, for a long time, resist a much higher temperature. Here is the action of light alone without pyro.—I am, yours, &c.,

October 12, 1896. W. B. BOLTON.

GOLD PAINT FOR PHOTOGRAPHIC PURPOSES.

To the EDITORS.

GENTLEMEN,—Seeing in your JOURNAL, issued September 25, 1896, two paragraphs *re* gold bronzing for photographic mounts, I may say I have used a gold paint for this purpose, the best I have ever come across, as it is thoroughly permanent, and weak acids or water have no effect on it whatever. I have heard lately that it is being used in this part of the country for outside work, and is satisfactory.

I do not think it is generally known, as it is practically new. Now, I think, if this article was known of by the photographing fraternity, it would be widely used. I have used some quantity, both of the colours and golds, and believe there are something like forty colours, and six or seven shades of gold. The name of the paint is "The New Electric," manufactured by Hayes & Co., Bristol; there is no other address on the label, but no doubt this will find them by post.

I should advise brother photographers to try this, as I am sure it is worth the trouble of procuring a really good article for a small sum.—I am, yours, &c., A. EVANS.

Tremont, Nottingham-road, Bishopston, Bristol, October 5, 1896.

THE PHOTOGRAPHIC SALON.

To the EDITORS.

GENTLEMEN,—It is not often that the "Rejected" send forth to the world such a bitter wail as that which came from Mr. J. C. Oliver last week, and I must say I feel sorry for him—sorry, not because his works were rejected, but because his disappointment has evidently not had a good effect upon him. If he feels his "sweetness has been wasted on the desert air" on this occasion, it should have stirred him up to gather more, with a determination that next year his sweetness should be so sweet that the Dudley Gallery should be flooded with it.

As I understand the constitution of the Photographic Salon, *all* works sent in for exhibition are submitted to a Committee composed of men who are, above all others, best qualified to judge pictorial photography. To be accepted and hung is an honour, undoubtedly the greatest a pictorial photograph can gain; to be rejected is not, as Mr. J. C. Oliver seems to think, an insult, but should be an incentive to better work next year. If, however, Mr. J. C. Oliver has reached that point (and from his letter I gather he has) where no improvement can possibly be made in his pictures, I should advise him to send them next September to Pall Mall.—I am, yours, &c., CHARLES MOSS.

Coombe-road, Croydon.

THE KINESIGRAPH.

To the EDITORS.

GENTLEMEN,—Your issue of the 9th instant contains a letter signed J. Vincent Elsden, in which it is claimed that the *principle* of the kinesigraph "has been public property for nearly thirty years." This extraordinary contention is supported by showing that, "as early as 1868, M. Roman Talbot brought into notice an optical toy," which he describes, and which turns out to be a wheel of life or zoetrope, in which photographs were substituted for the clumsy little drawings previously used.

Now, sir, this is to entirely misunderstand the principle of the kinesigraph. It is to confound the photography of *motion* with a series of photographs so arranged as to give an appearance of motion, a very different matter.

The zoetrope was a very ingenious toy, but every one remembers the absurd and amusingly unreal movements of the figures. The use of photographs, doubtless, improved their statical accuracy, but it left their dynamical inaccuracy untouched, and, if anything, even more obviously ridiculous.

It is surely one thing to give an apparent and arbitrary motive to a photographed or drawn figure, and quite another thing to photograph the actual movements of the bodies in the field of vision. Mr. Birt Acres avoids this error in his letter of September 18. He says: "Twenty-four years ago I made wheel-of-life pictures, drawn partly from photographs. I tried to make them by photography purely." But he further says: "I do not profess to be the original inventor of animated photography," by which I take him to mean the inventor of the photography of motion.

Since Mr. Birt Acres has probably done more than almost any other man to perfect the practical application of the principle of the kinesigraph, his modest disclaimer is all the more striking. Mr. Elsden would do well to preface his next utterances on the subject with a definition of kinesigraphy, which denotes the *re*presentation of motion—of real, actual motion—and not a mere presentment of arbitrary movements of photographed bodies, which never performed or could perform such movements in nature.—I am, youre, &c., WORDSWORTH DONISTHORPE.

Reigate, October 12, 1896.

THE POISONS ACT.

To the EDITORS.

GENTLEMEN,—"A Pharmaceutical Chemist" accuses me of having employed "malignant abuse" as a form of argument, not a trace of which abuse can I discover in my former letter; and then, again, he as good as tells me that I am a liar, that is, however, a matter of no consequence, for the "anecdotes" to which he refers are, every one of them, absolutely true.

With regard to the chemical education of pharmaceutical chemists, I must refer him to "Dogberry" in your last issue. As to the framing of the Poisons Act, I understand that no person is allowed to sell poisons, unless registered under the Act, and subject to such regulations *as may be prescribed by the Pharmaceutical Society*, with the consent of the Privy Council. Is that correct or not? Unregistered persons are forbidden to assume or use the title "chemist." That is an absurd regulation in view of actual facts; but it is not clear who is responsible for it,

With regard to signing the poison book, the main object of this regulation is to afford means of tracing the purchaser in case the poison is used for criminal purposes; if this regulation does not apply to bichloride of mercury, there is apparently little need for it in the case of other poisons.

There should be stringent regulations with regard to the sale of poisons which by reason of their nature can be conveniently administered to other people; but no such regulations can have any effect in diminishing suicides. Up to the present, though the suicides from scheduled poisons have decreased, nevertheless, the total, if anything, tends to increase; and, if all the known poisons were included in the schedule, the result would be the same. Take away one weapon, another is adopted. I admit that certain regulations are necessary, but such regulations should be complete, rational, and properly adhered to; and they should not be formed so as to put a monopoly into the hands of one class of tradesmen to the exclusion of others, who are equally well qualified to carry them out.

Purchasers who require poisons for legitimate purposes are quite ready to conform to any reasonable regulations, but, under present circumstances, getting the poison at all depends more or less upon luck. Take, for instance, potassium ferricyanide. Personally, I have had more trouble over getting this poison than with any other; sometimes I can get it easily, and sometimes not at all. Pharmaceutical chemists do not

keep it in a sufficiently pure condition to be of any use, yet, strictly speaking, they appear to be the only persons who, under the Act, are qualified to sell it. Pharmaceutical and photographic chemists even do not often keep it "pure." I must go to a manufacturing chemist to ensure getting the right thing, and, unless I go to one who knows me, I probably shall not get it even then—all this vexatious trouble on account of a poison the criminal use of which I have never heard of.

What photographers want is, that, under reasonable regulations, they may be able to obtain their poisons from the same dealers that they buy their other chemicals from, that is, from photographic chemists. Pharmaceutical chemists do not keep chemicals of sufficient purity, and charge outrageous prices for the impure ones they do keep; consequently, as photographers, we prefer not to go to them.

It is all very well to lay the responsibility for the Poisons Act upon the "Law," but this particular law was apparently framed upon the recommendations of the Pharmaceutical Society, that is, by the very people to whom a monopoly of the sale of poisons is valuable. A committee of expert scientific chemists would have drawn up a better schedule, and the regulations would have been fairer if left to men not personally interested in the sale of poisons. To talk about the protection of the public is absurd under the present state of affairs.

With regard to the chemical examination of a pharmaceutical chemist being of equal stringency with the B.Sc. examination, I should like to hear the opinion of a B.Sc. upon the point. I have passed through many examinations myself, and know full well that it is much easier to "get through," or "qualify," by judicious cramming in a subject that you really know little about than it is to secure a high position in a subject that you have considerable knowledge of. The mere fact of having "passed" implies very little. The art of passing examinations has been brought to great perfection, but the art of acquiring knowledge is no more perfect than it was a century ago. I have known many men who failed in examinations, not from want of knowledge, but from want of nerve, while others, who were comparatively ignorant, passed easily. Passing simply means that a minimum amount of knowledge is retained for the time of the examination, nothing more. The possession of knowledge is evinced by what the man does *after* he has passed.—I am, yours, &c.,

NEMO.

October 9, 1896.

To the EDITORS.

GENTLEMEN,—The frantic and bulky communication of the gentle "Nemo" quite perfumes the air, and I am now able to sympathise with the sportsman, who has accidentally hit a wild elephant and is forthwith charged down upon by the screaming and infuriated animal.

A druggist asked him this, a doctor told him that, a friend informed him something else, &c. From his own confessions it is evident that the class of doctors and druggists he knows, or is likely to know, belong to the "residuum" of their respective occupations. If I were to provide your readers with a relation of all the comical incidents I know that have occurred through the vexations, ignorance of so-called photographic dealers, I could fill an entire page or more of the B.J.P. without difficulty, anecdotes of such a character are quite important circumstances in the eyes of "Nemo." Having exhausted his collection of childish tales, he informs us what are "the real points of issue" by the irregular method of asking questions founded upon erroneous assumptions. Let us take them in order to provide him with satisfaction.

Firstly, "Why should I be allowed to appropriate the title of 'chemist?'" Well, why should a medical practitioner be allowed to appropriate the title of "doctor?" "Nemo" with his persistent *suppressio veri et suggestio falsi*, attempts to smother the fact that a stringent examination in chemistry, in addition to *materia medica*, botany, pharmacy, and other subjects, has to be passed by the "chemist;" perhaps "Nemo" will not "try to forget" that in future.

Secondly, "Why should chemists have a monopoly of the sale of poisons? Because the advisers of the State have decided, for the benefit of the State, that the sale of poisons shall be taken away from miscellaneous and irresponsible hucksters, and placed in the hands of a properly educated, regulated, and centrally controlled body of men; and there is nothing whatever to prevent any man, with the average amount of brains, from joining that body if he desires to do so.

Thirdly, "Why don't the 'chemists' take steps to have the schedule of poisons enlarged?" Chemists have no power in the matter, we are an administrative body, not a legislating one. This matter is even now under the consideration of the Privy Council and the Poison Schedules are going to be enlarged; but it is not at all probable that the "chemists'" interest will be taken into consideration. "Nemo" is not satisfied with the schedules as they are, and he will be probably still more dissatisfied with them as they will be.

Fourthly, "Why does the Pharmaceutical Council allow quack medicines containing scheduled poisons to be sold by anybody?" They do not allow it, and they have quite recently prosecuted and fined many vendors of quack medicines for infringing this clause of the Act. "Nemo's" information requires a little readjustment. And, why do we find oxalic acid and spirit of salt in many households, although they are scheduled poisons? Again, either real ignorance, or, in order to mislead, pretended ignorance. There are two poison schedules, one requiring a customer's signature, and another schedule of less dangerous substances, including oxalic acid, which do not require signing for. Spirit of salt has never been scheduled at all yet, so that "Nemo" and his friends can sell it if they please. If "Nemo" has any more questions to ask, he had better ground them upon facts, and not upon a foundation in which ignorance and the "economy of truth" are conspicuous indeed, but not, alas by their absence.—I am, yours, &c.,

PHARMACIAN.

To the EDITORS.

GENTLEMEN,—The "poisons" tirade has now been going on some weeks, and some of the letters are not only extremely irritating and exasperating, but offensive. Nor do they go to the root of the matter, but take side issues. Shall chemists retain the monopoly of selling poisons, or not? At present the law is with the qualified chemist, and so the abuse directed towards him is, in a manner of speaking, cowardly. The virulence, if any is needed, ought to be used against the Pharmaceutical Society, because they carry out their duties more stringently than common sense dictates. It is, perhaps, unlawful for a photographic dealer to sell any sort of poison, but the Pharmaceutical Society might wink at it, and see that the public are not harmed. They take a too selfish trade-unionism view of the matter. But it is not at all likely the Pharmaceutical Society will give way. Their very existence depends, in a measure, upon the Poisons Act. What might be done is to bring pressure upon that body, so as to modify the examination when the poisons are for arts and manufactures. Now, supposing in their modified examination you showed a satisfactory knowledge, and could also produce certificates in qualifying science subjects, such as theoretical and practical chemistry, both inorganic and organic, say on a basis of the advanced, or honours stage, at South Kensington, or of a University, what would, very likely, be the result? There are hundreds who will never be able to pass the Pharmaceutical 'minor' that would get through this. Then we should have grocers, ironmongers, oilmen, and others putting in their windows, "licensed poisoners"—beg pardon, "licensed to sell poisons." Again, supposing you only allowed them to sell poisons for arts and manufactures, and not for any application to living bodies, how is this thin, invisible line to protect the public against wholesale poisoning, either by murder or suicide? Many forms of poisons are too easily got at now. It would be more sensible on the part of the Pharmaceutical Society to use discretion, and not raise a storm of opposition about their ears.—I am, yours, &c.,

S. E. K.

Reading, October 7, 1896.

To the EDITORS.

GENTLEMEN,—Your correspondent, Mr. James Reed, in his letter dated October 1, referring to this Act, says: "It draws up a schedule of poisons which cannot be sold by any but those who have complied with the *educational demands* of the State." Therein is the crucial point of the whole argument. It is not educational attainments at all, but membership of the Pharmaceutical Society, that qualifies the man to sell poisons, and it is the fact, that those whose knowledge of chemistry is far above that required by the Act are still prosecuted for selling, while any one who has "crammed" for his examination (and there are ignorant men among chemists equally as in every other business) has, in common with his fellow-members, the sole right of selling to photographers substances of whose properties he may be thoroughly ignorant, that is responsible for all the outcries against the Poisons Act. It creates a monopoly in favour of one particular class, and to the disadvantage of those who require the materials for their work. Every photographer must, at times, have experienced the great difficulty that exists in obtaining certain substances because they are scheduled poisons, while others almost equally dangerous may be sold without any restriction.—I am, yours, &c.,

HENRY W. BENNETT.

Hastings House, Norfolk-street, W.C. October 13, 1896.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post. Questions are not answered unless the names and addresses of the writers are given.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2, *York-street. Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

Robert William Howes, Dereham.—*Two photographs of Clare Sewell Read, Esq.*

A. Edwards, West End Studio, Morecambe.—*Photograph of high tide at Morecambe, October* 8, 1896.

Richard Hutton Blyth, photographer, Ilfracombe.—*Two photographs of Mrs. Jane Bray, another Ilfracombe Centenarian.*

Albert Rudolph Douglas, 23, Upper Dicconson-street, Wigan.—*Three photographs of Rev. Wm. Medley (Professor), Rawdon College, Bradford.*

John Blair Scott, 18-22, Devonshire-street, Carlisle.—*Photograph of H.R.H. the Duke of Cambridge. Photograph of H.R.H. the Duke of Cambridge, Lord and Lady Hothfield, and party.*

Mark William Thompstone, Allandale, Brooklands, Cheshire.—*Photograph of young lady seated at a table with writing materials before her, pen held by right hand to the lips, and titled, "What Shall I Say?"*

RECEIVED.—J. PIKE; W. D.; FOCUS; F. G. WILLATT; EDGAR SCAMELL; MANCHESTER PHOTOGRAPHIC SOCIETY, and others. In our next.

STAINS.—H. W. The metallic stains on the back of the film, as seen through the glass, are due to a dirty plate before it was coated. The remedy is obvious.

ENAMEL COLOURS FOR ENAMEL PAINTING.—W. NELSON. These colours may be obtained from Lechertier, Barbe, & Co., The Quadrant, Regent-street, W.

SITUATION IN GERMANY.—W. ZEIGER, of St. Tugbert (Pfalz, Germany), writes: "Your correspondent, Mr. A. O. Yardley, who is desirous of obtaining a situation in Germany, may communicate with me."

TRANSFER INK.—R. BIRDSEY. Winstone & Sons, Shoe-lane, make a special ink for photographic transfers. A suitable transfer ink is also, we believe, supplied by Penrose & Co., Amwell-street.

DAMAGE TO STUDIO.—S. W. As you hold the premises on a repairing lease, you cannot compel the landlord to repair the damage done to the studio by the late storms. "The act of God" does not apply in such cases.

THINNING CELLULOID VARNISH.—W. SMITH says: "Will you please tell me what is the best thing for thinning celluloid varnish? If more than one chemical is wanted, please give me the exact proportions."—Dilution with double its bulk of methylated spirit is recommended.

ZINCO BLOCKS.—H. A. MARLEE. Any process worker will undertake these. Surely there are such firms in your town. If not, run through our advertisement pages, or those of the ALMANAC, where several names are given. It is, however, hardly worth your while to send all the way to London.

STEREOSCOPIC PHOTOGRAPHY.—WARMINSTER. Stereoscopic pictures may be taken quite as well, so far as stereoscopic relief is concerned, with a single lens and moving the camera, as with a twin lens camera; but the latter is much to be preferred, and, for moving objects, is imperative.

ANCIENT LIGHT.—W. A. W. If the facts be as stated, you can certainly prevent your neighbour from putting up his building so as to obstruct your light. As your studio has stood for over twenty years, it enjoys the "ancient lights" privilege, which must not be infringed. The remedy is by injunction, and, as we have just said, there is no question as to the result.

THE ANIMATOGRAPH.—AJAX says: "Can you give me the names and addresses of any persons or firms who would undertake to provide and manage an exhibition (for one night only) of the cinematograph or kinetoscope? If so, you would much oblige."—Probably Mr. Birt Acres, the Northern Photographic Works, Salisbury-road, Barnet, would do so. Better write him.

REPRODUCING NEGATIVES.—T. PRATT. The cause of feebleness in the reproduced negatives is unquestionably due to the thin and flat character of the transparencies, that is, if the one sent—which, by the way, arrived, as did the negative, in fragments, owing to insufficient packing—may be taken as a type of the others. For vigorous reproductions vigorous negatives are necessary.

INCREASING ANGLE OF LENS.—A. H. BENN. It is quite correct that by shortening the tube of a rectilinear, so as to bring the glasses closer together, the lens can be made to cover a larger plate, and thus embrace a wider angle of view. But it must be borne in mind that a much smaller stop will have to be used with it so that, in its altered condition, it will be a slow lens instead of a rapid one.

BROMIDES FOR PLATINOTYPES.—T. MORLEY.—If the prints, when immersed in a solution of bichloride of mercury, fade, there is no question that they are silver prints, and not platinotypes. Your friends can, if they choose, proceed against the parties under the False Trades Description Law; but probably, when the fraud is charged against them, they will gladly refund the money, rather than stand the exposure.

WM. HUME.—It is difficult to assign a satisfactory explanation for the reversal. The most feasible seems to be that, as a similar result, viz., a positive from a positive, may be produced by considerable over-exposure, the latter cause is really at the bottom of the matter. We ourselves have produced analogous results on plates previously exposed to light, also by subjecting the exposed plate for a considerable time to the influence of the dark-room light. Such experiences as yours are very common. Sorry we can give no decided information on the point.

LENS BOUGHT AT SALE.—C. A. S. In selling a lens at auction, the auctioneer cannot be held responsible for its quality, and you have no redress whatever. The lens, you say, bears no name, and is very inferior but that has nothing to do with the auctioneer. It was sent to him to sell to the highest bidder, and of course, as at all auctions, the buyer must use his discretion. Read the conditions of sale, which are printed on the catalogue. Even at an auction sale, you must not expect to get an instrument for a pound equal to one that a first-class maker catalogues for more than six times that sum.

C. H. PRICE.—Sorry we are unable to help you. We have inserted query in The Inquirer column.

COLOURS FOR SPOTTING NEGATIVES.—S. PALMER says: "I, as an amateur, have great difficulty in stopping out pinholes, &c. in my negatives. Almost all who have said anything on the subject recommend a different colour from the others. Some say Indian ink, some Venetian red, some sepia, others indigo or Prussian blue, &c. Which is best?"—It really matters little which colour is used, so long as its printing value, as applied, thickly or thinly, equals that of the portion on which it is used. A novice will generally get on best with a colour that most nearly approximates that of the negative. Any tint may, of course, be obtained by an admixture of colours to match that.

THE X RAYS.—X RAYS says: "Would any one give me a rough outline of the X rays, to be a guide, as I want to go through the operation for fun at a party? Of course, no photographs will be taken."—In reply: We presume our correspondent simply wishes to produce the phenomena of the phosphorescent Crookes' tubes, and desires to know how to proceed. Articles giving the necessary information appeared in the JOURNAL of February 28 and in many subsequent issues. Under our Editorial Table we have also noticed several books dealing with the phenomena. But, while our correspondent is about it, he might add to the "fun" of himself and his friends by actually taking a radiograph, as the additional expense thereby incurred is slight.

VARNISHING NEGATIVES.—T. BIDGOOD writes: "How are negatives varnished? I have obtained two or three different makers' varnish, and they all seem pretty much alike, and the directions for application are the same with all: Warm the plate, pour on the varnish, flow over the plate, then drain off and dry the plate before the fire. Now, how is any one to do this? I have tried many times, with the result that more varnish is spoilt than used, and as much, almost, gets on the back of the glass as remains on the front. Are these directions given by the makers to cause amateurs to waste the varnish and so increase the sale? How do professional photographers varnish their negatives?"—Professionals varnish their negatives in the way quoted by our correspondent. With a little practice there will be no difficulty in flowing the varnish evenly over the plate and draining it off without spilling or letting it get on the back.

BOOKS ON LENSES AND ENLARGING.—AMBITIOUS says: "1. I have always been at a loss to thoroughly understand how to obtain the focus of any lens, and what that really means. I know that different lenses have different focus, and are suitable for certain subjects; and, as a first-class assistant operator, &c., who aspires to fill a good position as a first-class photographer in time, I keenly feel the lack of that knowledge. Therefore, if you could advise me upon any course I could take—I presume it would be books—I should be very grateful. I have seen books giving different focus of lenses, but they seem so complicated; I want something that starts at the beginning. 2. Also, I wanted to know of a book that deals with enlarging thoroughly, describing its different parts and uses, and how to work it."—1. Possibly the best book devoted to the subject is that by the late J. Traill Taylor on *Photographic Optics*. It is published by Messrs. Whittaker & Co., White Hart-street, Paternoster-square, price *3s. 6d.* A few weeks spent in a careful study of that book will impart to you much knowledge likely to be useful to you as a photographer. 2. Mr. Fallowfield, 126, Charing Cross-road, W.C., publishes a book on bromide enlarging, price 1s., which will give you an insight into the principles of enlarging. A book which deals exhaustively with the details of every enlarging process has probably yet to appear.

RECOVERY OF GOLD.—BLACKBURN writes: "I am engaged in a business where about eight quires of paper per week are printed. Certain reasons make it imperative that the toning of the same be done rapidly. To effect this, I use a freshly-made, strong, hot borax bath. The prints are toned in from three to five minutes, fresh gold being added whenever the least sign of slowness appears. I feel sure that a large quantity of gold is wasted, that is, in the sense of not being deposited on the prints, so latterly I have been trying to recover the same by adding a small quantity of sulphate of iron in solution to a Winchester of the toning solution, in which nearly a quarter of a pound of borax and three tubes of gold had been used. This caused a precipitate of a very fine nature to fall in two or three days, and, when filtered, the supernatant liquid was as black as ink, so I then added a much larger quantity of iron solution, and found that the precipitate was thrown down in a very short time. Kindly inform me if I am doing right by adding so large a quantity of iron, or if it will interfere with the subsequent recovery of the gold. On that point can you tell me how I should proceed to do the same myself, instead of sending it to the refiners?"—The proceeding is quite right. The sulphate of iron should be added so long as anything can be precipitated. The precipitate contains silver as well as gold. It is well to acidify the iron solution strongly with sulphuric acid before adding it to the old toning solution. If our correspondent is not familiar with chemical manipulations, he will find it best to send the residue to the refiner. However, the gold may be recovered in this way: First, well wash the residue with water, then put into a glass flask, and boil in dilute sulphuric acid to remove all traces of the iron, well wash again, and drain closely. Next add nitro-hydrochloric acid and boil again. This will dissolve the gold. Drain off on to a filter and repeat the operation to ensure the solution of all the gold. Wash the precipitate, which is chloride of silver, in two or three changes of distilled water, which are also put through the filter. The filtrate is now an acid solution of chloride of gold. If, now, a filtered solution of protosulphate of iron be added, it will throw down the gold in a pure state. It can then be converted into chloride of gold by dissolving in nitro-hydrochloric acid and crystallising.

EX CATHEDRÂ.

Photographers and others who use acetylene will be interested to know that there is a probability of the insurance companies taking cognisance of it as a more or less dangerous explosive, and therefore likely to influence the granting of policies. We some months ago stated that an American Fire Underwriters' Association had recommended to its members the refusal of permission for its use in buildings covered by their policies, and we have been recently shown a letter from an English office to a photographer insuring his premises in which a preliminary inquiry is made as to whether acetylene is used. We presume the English Offices have taken up the cautious attitude of the American insurance associations; but it is interesting to note that the American offices object to the use of *compressed* acetylene in cylinders, and not to the gas directly generated from the carbide, surrounding which, as they properly remark, no special hazard attaches. We hope, therefore, that the English offices have not been misled in the matter.

* * *

The Eastman Photographic Materials Company have recently opened a new branch at 91, Markgrafen-strasse, Berlin. In addition, the Paris premises of the Company at 4, Place Vendôme have undergone enlargement, a step that is in contemplation as regards the London establishment at 115–117, Oxford-street, which have been found inadequate for the growing business of the Company. We also gather from Mr. Dickman, the Managing Director, that branches in other Continental capitals besides those named will ere long probably be opened. The Company are to be congratulated on these unmistakable signs of well-deserved prosperity.

* * *

A new delight to those whose works secure the advantage of being hung at photographic exhibitions has been revealed to us by a well-known provincial photographer, some of whose photographs are now on view in Piccadilly and Pall Mall. He was asked by a journal to forward particulars of his exhibits, and, having done so, received the following communication: "I beg to acknowledge receipt of particulars with which you have favoured me, and find therein materials for an excellent article. No doubt, it would be very useful to you for us to give such an article, as it would probably lead to a large increase in your business, such increase being of a permanent character. I shall be happy to give directions for the article to be prepared forthwith, and should be glad to know whether you have any blocks for the purpose of illustrating the same, and also if, by way of *quid pro quo*, you will take, say, 100 copies of the journal containing the article. On receipt of your reply, I will forward proof of article. Your business with our readers ought certainly to be considerable."

* * *

The system of advertising here outlined is comparatively old, and in some respects possibly has much to commend it. To photographers generally, however, its advantages are not clear, as, with few exceptions, they depend almost exclusively upon local patronage, which is perhaps not likely to be influenced by notices in a journal which appeals to persons at a distance connected with railways, steamships, mines, &c. However, unlike the diary scheme for inducing photographers to take portraits for nothing, so often mentioned by us of late, a *quid pro quo* does enter into the latest idea of utilising professional photographers to commercial advantage.

* * *

From the Polytechnic Institution, 309, Regent-street, we have received the winter programme of craft instruction in

photography and photo-engraving. Lectures and practical courses are given in most photographic subjects, and special attention appears to be devoted to the process department, in which three-colour negative-making, screen-negative making, half-tone block-making, photogravure, photo-lithography, and collotype are prominently mentioned.

* * *

In the Journal recently we gave particulars of a process for embossing photographs, that is, the imparting of low relief to portrait studies and similar subjects. We have since had the opportunity of examining some specimens produced by the process. Printed in platinum, bromide, or carbon, it can readily be imagined that a portrait bust in relief would, if suitably framed, be possessed of a highly effective and artistic appearance. Such, indeed, were the characteristics of the specimens that were shown to us. These bas-relief photographs are just now very popular in America, and we are of opinion that there is a field open for them in this country.

* * *

According to a transatlantic contemporary, the position of colour photography in America by the McDonough and Joly processes is hardly yet in a satisfactory condition. The company recently organized in Virginia to make photographs in colour has, it is said, acquired the right to work the process of McDonough, of Chicago, and it is expected that the necessary plant will be ready for actual work in a short time. On the other hand, however, in conversation with the two gentlemen who had charge of Joly's colour process in America, it was learned by our contemporary that McDonough's patents are of no value, being antedated by those secured by the Joly combination. Those directly connected with both the processes mentioned are very secretive as to their plans, but it seems certain that there will be fighting in the courts before either process is worked commercially.

SINGLE TRANSPARENCIES IN NATURAL COLOURS.

One of the features of the process of photography in natural colours which Mr. Bennetto, of Newquay, Cornwall, is alleged to have discovered, consists in the fact, as vouched for by those who have seen the results projected on to a screen by means of the optical lantern, that, to all appearances, one transparency only, on which is impressed the colours of the original subject, is employed. This seems to them to dispose of the idea that the three-colour process, as practised so successfully by Mr. F. E. Ives and others, is the method chosen by Mr. Bennetto for the production of his results.

It is suggested to us by a correspondent this week that the process of producing natural colours in a single transparency, such as Mr. Bennetto's method is said to be, is a distinct departure, the more especially as it is claimed that no colour, dye, or pigment, is employed in the attainment of the colours; and we are asked if we had previously heard mention of such a process. It may be of interest, therefore, if we outline a method of colour photography, which, if it does not exactly coincide with that attributed to Mr. Bennetto, at least allows of absolute comparison with it, in that it admits of the preparation of what *appears* to be a single transparency in the colours of nature.

To Mr. F. E. Ives it is that we are indebted for the few details of the process that we append. Quite recently Mr. Ives was kind enough to show us some lantern slides made by the process, and they struck us as being so beautiful and faithful to the colours of the originals that, were they projected on to a screen, at Newquay or elsewhere, they could not fail to excite the highest admiration.

Here is the process, which, we may remark, has been published before by Mr. Ives, both in this country and America. The system is applicable either to glass or paper prints.

The three negatives are taken in the photo-chromoscopic camera in the ordinary way. To prepare the positive the procedure is as follows: A thin sheet of clear celluloid coated with bichromated gelatine is exposed under the triple negative. The resulting print, which shows the three images in a delicate brown colour, is placed in hot water, which dissolves away all the gelatine that is not rendered insoluble by the action of light, and leaves the image in very low relief in transparent gelatine, the shadows of the picture being represented by various thicknesses of gelatine, and the extreme high lights by clear celluloid.

The positives are next coloured by the following method. The three images are cut apart, and each one is coloured up by soaking in a solution of a dye the colour of which is nearly complementary to the fundamental sensation which that image represents. The dye is taken up by the gelatine in proportion to its thickness. The coloured prints are superposed so as to bring the three images into register and make them appear as one, and, if, says Mr. Ives, the deepest shadows are then a neutral black, the colours should be right throughout all the shades of the picture, and will be, if the correct printing colours are used and the known theoretical conditions of success adhered to. The three celluloid positives are finally cemented up between cover glasses with Canada balsam, and fastened by a paper binding at the edges.

It will be observed from the foregoing that the production of the colours depends on a dyeing action of the gelatine. The colours, however, may be produced without the *direct* use of dyes, but to this process we shall not on the present occasion allude. We may, nevertheless, state that to those who have given this subject close attention it is probably an obvious system of working.

Natural colour transparencies by the above method are not, Mr. Ives assures us, over-easy to produce; but, when properly made, we can testify to the beauty of the results. We trust we have said sufficient to satisfy our correspondent and others that the production of what is apparently a single transparency in colours is not the novelty it is supposed to be.

Geological Photographs.—The Photographic Committee of the British Association state in their report that they have received about two hundred new geological photographs during the year, but that still many portions of the British isles are wofully ill-represented in the collection, which, although now lodged at Jermyn-street, still hopes to receive marked increases during the next few years. We are sure that there must be many of our readers who would willingly devote time and trouble to furthering the objects of the Committee, if they possessed full details as to what was wanted, and in what form.

A New Mode of Dehydrating Alcohol or Ether.—According to a German scientific journal, aluminium amalgam is very serviceable for this purpose, as it reacts with the water to the production of hydrogen gas, which escapes, and the insoluble hydroxide of aluminium, which can be removed by filtration or

decantation. To prepare the amalgam, aluminium turnings, freed from oil, are treated with soda lye until a strong escape of hydrogen occurs. The surface is then rinsed with water, and treated for two minutes with a half per cent. solution of bichloride of mercury. These operations are repeated after a short time. The preparation is then quickly washed with water, alcohol, and ether, and the product kept under petroleum ether.

Miniature Painting.—On Friday last the Princess of Wales, with the Prince and Princess Charles of Denmark and the Princess Victoria of Wales, paid a visit to the Exhibition of the Society of Miniature Painters, in New Bond-street. We understand that this Exhibition, as regards visitors, is a success. If the attempt now being made to resuscitate miniature painting proves successful, it should also create a demand for good coloured photographic miniatures, such as used to be done five-and-twenty or thirty years back. In the Daguerreotype days, the well-to-do public were pleased to pay half a guinea to a guinea, or more, extra to have their portraits coloured. A good trade was also done in coloured glass positives, from one shilling to ten being charged extra for the colouring. The colouring of small photographic portraits, however, seems almost to have died out of late years.

Dark-room Ventilation.—In a general way the need for ventilating the dark room has been so often dwelt upon that it has gone beyond the realms of discussion; but, to strengthen the hands of those who demand its universal application, it will be well to draw attention to a particular phase of it which is, to some extent, novel. In coal gas there is always a certain amount of carbonic oxide, and also, when gas is imperfectly burnt, some of this gas is sent into the atmosphere among the products of combustion. This and leaky joints might lead to the constant presence of a small amount in the air breathed in the usually small apartment. At the recent British Association meeting, Dr. Haldane explained that the continued inhalation of small portions of this gas is much more dangerous than the momentary reception of a large quantity of it in the lungs. The best antidote is the inhalation of oxygen. It has been found that, when more than thirty per cent. of the blood has been saturated with the gas, violent motion will bring about collapse.

Broken Plates.—The judgment given in the Sheffield County Court, reported in our last issue, seems a little anomalous. The plaintiff sued for the value of plates supplied. The defence was that the plates were delivered by the railway company smashed to atoms, owing to insufficient packing and labelling. The railway company refused responsibility in the matter, as the package was not labelled glass. In the result the Judge gave his decision in favour of the plaintiff for the amount claimed, and gave the defendant leave to commence an action for damages against the plaintiff, or the railway company, for the breakage, as he may be advised, he having received nothing of any value for his money. It is possible that, had the case been tried by another Judge, the ruling might have been different. However, in a case of this kind in the future, we should advise the plaintiff, and any of our readers, to refuse to receive a parcel when broken glass can be heard within. Then the sender will have to fight the matter out with the railway company.

Chloride Papers.—A writer in a contemporary, in giving his observations on the state of photography at the Antipodes, says very few were using chloride papers; most were content with their old and tried friend albumen. On reading this, one is naturally led to ask if albumen is not a chloride paper, and quite as much so as a collodio-chloride or gelatino-chloride one? With albumen the image is formed on chloride of silver, just the same as in the other two papers named, the only difference is in the vehicle holding it, and that with collodion and gelatine the chloride of silver is held in suspension as an emulsion when applied to the paper. In the case of albumen, the vehicle is salted with a chloride, and the chloride of silver is formed by double decomposition when the paper is sensitised on the silver bath. We allude to this matter because some novices in photography—and not a few—seem to imagine that albumen paper is simply paper coated with plain white of egg and sensitised on a silver bath. Of course, this remark only applies to those, and there are many, who have never taken the trouble to read even the most elementary work on the theory of the art they practise.

On the Nature of Röntgen Rays.—Professor A. Róiti continues to publish accounts of his investigations on what he term cryptochroism, which is equivalent to colour in Röntgen rays. Experimenting on the transparency of metals, he found two sheets of brass of a certain thickness were equivalent to eight of aluminium; but other combinations of the three metals did not follow proportionately, thus proving that rays which have traversed a metal plate are, in some way, different from the rays that come direct from the Crookes' tube in respect of their penetrating power upon other metals, or even the same metal.

The Most Recent Application of Röntgen Rays.—A correspondent of *La Nature* is responsible for this latest sensation. He writes to that journal that an American, having secretly purchased some fragments of an Egyptian mummy, his friends began to cast doubts on its genuineness. One of them even went so far as to say that the mummy's hand, or so-called hand, was merely a well-shaped imitation in resin, covered with pieces of stuff borrowed from mummy rubbish, upon which the finger nails had been cleverly arranged. To verify the real state of affairs, and without destroying the hand and foot, for which he had, no doubt, paid dear, he had them radiographed. The experiment succeeded, to the joy of the antiquary and the confusion of the sceptics. The presence of the bones was revealed with the utmost sharpness, and the authenticity of these thirty or forty century-old human documents satisfactorily established, thanks to Röntgen's discovery.

Reversed Röntgen Photographs.—In reference to the experiments of Mr. Espin, described in our last, the following reply appears in the Journal from which we extracted (the *English Mechanic*) the description by Mr. Espin himself, who has done some interesting and valuable work in the byways of X-ray work.

THE following experiments are, I believe, upon the lines suggested by Mr. Espin in his letter.

"(1) Upon the left-hand half of a film, washers, discs, &c., were placed, the other half of the film was secured by a sheet of platinum; an exposure of one minute was given, and then the metal objects were rapidly shifted to the half of the film which had been screened from the rays, and left there for a minute. Upon development, a sharp negative was got on the left hand of film (as was to be expected), the other half was blank.

"(2) The above arrangement was again made; but, after moving the objects to the right hand of the film, the left was screened to prevent fogging, and another exposure of one minute given. Result: two sharp negatives.

"(3) Placing objects *under* film, and on metal sheets under film: no result.

"(4) Making exposure of two minutes, then moving object to right-hand (unexposed) half of film, and leaving them for twenty minutes. Result: negative only on left side."

Has Mr. Espin found it possible to get a negative and a positive each time an exposure is made, when film, objects, and tube are arranged in a manner identical with their disposal when he first obtained these curious results?

While upon the subject, a tube I have in which the vacuum is very high, owing to use, can be excited with powerful currents and slight heating. The screen is then brilliantly illuminated, and, if the hand is placed behind, there is scarcely any diminution of fluorescence, the hand and bones being scarcely visible, the rays apparently passing *easily* through the bones. By further heating the tube the bones are seen more plainly, but with nothing like the distinctness with which they stand out when one of my other tubes is used.

While experimenting, I have so frequently been impressed with the difference of results obtained from different tubes, that I should be interested to hear whether Mr. Espin has noticed any difference in screen work while using the tube he worked with when he got the results he describes. These results may be due to some alteration in the rays.

F. J. R.

An Interesting Case.—A case of interest, in more ways than one, to photographers was tried in the Westminster County Court by his Honour, Judge Lumley Smith, on Wednesday week. Mr. Mendelssohn was the plaintiff, and a Mr. Aspinall the defendant. The claim was for nineteen guineas, being fifteen guineas for the right to reproduce a copyright photograph of Madame Patti in an advertisement of a specific for beautifying the complexion, and four guineas for a block. The smaller sum was paid into court, but the larger one was disputed on the ground that for the fifteen guineas the defendant expected to get the negative as well as the exclusive right to the photograph, as Madame Patti had referred him to Mr. Mendelssohn. In the end the judgment was for the amount claimed and costs, his Honour remarking, that the defendant paid for the right to use the photograph, and no one had interfered with his right.

During the examination, and cross-examination, some interesting facts were elicited. First, it is evident that Madame Patti has no objection to her portrait being used in connexion with toilet requisites. Next, that it cost the plaintiff 10*l.* to go to Madame Patti's residence in Wales, and back, to take the photographs, and that he gave her three dozen portraits free of charge. In cross-examination the plaintiff said that Madame Patti paid him 45*l.* for copies of the photographs she ordered, and photographs of M. Nicolini, views of Craig-y-nos, and the district. He also said that this is not a large sum for photographs. Of course, no photographer would consider any sum too large for photographs, but we do happen to know a good many who would like to have such a business line just now, and who would not object to its being repeated, if only occasionally.

Fatal Explosion of Acetylene Gas.—On Saturday last, according to a Reuter telegram, two men lost their lives, and a third was injured, at the Picket Works in the Montmartre district of Paris by the bursting of an acetylene gas cylinder. One of the unfortunate men was cut in two, and one of his arms was torn off and found lying a dozen feet from the rest of the remains. The body of the other victim was also torn to pieces. The walls of the building were blown down, and neighbouring buildings were much damaged. The report of the catastrophe is meagre, but it is stated that it occurred in the gasometer room, which is a special and spacious building separated from the main portion of the factory. It is said that the men were engaged in checking a number of holders that had recently been returned, and were supposed to be empty. The report says that the remains of the two victims were covered with fine carbon dust, and the effects of the explosion were similar to those of dynamite.

It is unfortunate for the immediate future of acetylene that its advent should be accompanied by this disaster, and one of a somewhat similar nature, if we remember rightly, in America a few months back. It is well understood that acetylene gas, like coal gas, hydrogen, vapour of ether, benzoline, &c., forms an explosive compound when mixed with a certain proportion of air. Only a few weeks ago a lady was killed, and another injured, at Hull, through some boys, in playing, applying a lighted match to an empty benzole drum. Until fuller details are given it is, of course, impossible to hazard an opinion as to what led to the explosion in Paris, but its unfortunate occurrence, whatever the cause, will certainly not tend to inspire confidence in its safety, in the compressed form, for the lantern. There is, however, a vast difference in employing the gas for cylinders, and using it from the portable apparatus now in the market in which the gas is consumed as fast as it is generated.

JOTTINGS.

The "usual thing" of the photographic autumn has, of course, happened. I allude to the annual squabble, the Linked Ring and the Salon *versus* the Royal Photographic Society and its Exhibition. I am sorry to say that the Salon young men's way of trying to persuade people that the Piccadilly Exhibition was started in the interests of pictorial photography, and not to rival and damage the Royal Exhibition, lacks both dignity and generosity. Sneers at the Society's charter, at its name "Royal," and at its Fellowship—concerning which there appears to be an odd delusion that it is to be had as easily as, let us say, membership of the Linked Ring—make light and amusing reading, it is true, but in what way they help the Salon or pictorial photography I fail to perceive. Again, the mild mendacity of the statement that the Royal Photographic Society's Exhibition is entirely a "scientific" one—the Linked Ringers appear to have hit upon this choice morsel of affectation and impertinence as a kind of battle cry this year—forms a fitting companion for the pitiful fiction, now being circulated, that it is an "honour" for an exhibitor to have his photographs hung at the Dudley Gallery. The sooner this kind of thing is stopped the sooner the Photographic Salon, which, as an exhibition, is at least good enough to be judged and to win success on its merits, will earn the sympathy and respect of many who at present are sickened by the attitudinisations, the log rollings, the mutual admiration, and the childish carping at the Royal Photographic Society, in which some Links permit themselves to indulge.

For several years, at the Society's Exhibition in Pall Mall, the proportion of "commercial" work shown has been on the decrease; and this year, as every one knows, it has dwindled down to nothing. It would appear that the time when professional photographers made, sustained, and enhanced their reputations at Pall Mall has departed, and that exhibits of a "commercial" nature no longer stand much chance of being accepted and hung there. In this one respect the Society has, perhaps, moved too fast. To comply with the requirements of pictorial portraiture, as it is understood by modern selecting committees, is possibly not in the power of the photographers who were once pillars of strength to the Exhibition; and so they have to stand out. "Pictorial" portraiture is all very well in an exhibition; but is there one sitter out of a hundred that would tolerate it, much less pay for it? It is fortunate that the smaller London exhibitions, and those in the provinces, do not debar "commercial" work, otherwise it would be a bad look out for professionals anxious to get the chance of having their work publicly shown, adjudicated upon, and criticised.

Of course, the sympathy I here express for "commercial" photography and photographers will not be shared by the superior young gentlemen above alluded to, who are so uncommercial as to send their photographs to an exhibition where medals are not awarded, but which, nevertheless, gives them an opportunity of selling those photographs several times over, and charging one, two, three, or four guineas a copy. This is not commercialism, I suppose? Nevertheless, I know that many thoughtful men deplore with me the tendency there is to lose sight of the fact that photographic exhibitions are intimately bound up with the bread-and-butter side of photography.

A visit to the Exhibition in Pall Mall was once looked upon as an annual duty by numerous professional photographers, who went to see what their rivals and competitors were doing, and profited accordingly. I should not be surprised if the highly "artistic" character of the present display did not finally alienate many professionals from this traditional habit. I have certainly heard many express themselves both puzzled and disappointed at the great swing the pendulum has made. "Where are the photographs?" has been the mournful question often asked. Well, well, "the old order changeth, giving place to new," even in photography. So there's an end of it.

The awards at Pall Mall appear to have given satisfaction—indeed, not for many years has there been so little grumbling or surprise at the Judges' decisions. In the technical section, however, one exhibit was passed over which I certainly think should have marked itself out for judicial recognition. I allude to the Stigmatic lens. This is a lens which is claimed, at an aperture of *f*-4, to embrace an angle of 60°, over which it is said to define perfectly, while the field is flat, and both spherical aberration and astigmatism are eliminated. Compared with the Petzval portrait lens—the nearest approach to

the Stigmatic as regards angular aperture—Mr. Aldis's lens, if it possesses the optical properties that are claimed for it (and there is no reason to suppose that it does not), constitutes a really remarkable advance in lens construction. It would, therefore, be interesting to know why the Judges passed it over; the more particularly as the same Judges last year awarded the medal to a lens for which—admirable instrument though it may be—far less important optical claims were made than are made for the Stigmatic.

Mr. Bennetto, of Newquay, Cornwall, still declines to dance to the music of this JOURNAL, and state how he produces his so-called photographs in natural colours. I should think Mr. Bennetto is rather sorry he made a confidant of the local journalist who announced in his best local journales that, "after seven years of experiment," &c., "our well-known fellow-townsman" had found out how to take photographs in natural colours. It cannot be pleasant to Mr. Bennetto to know that his claims are doubted and received with scepticism: but for this he has only himself and his precipitate journalistic friend to thank. A still tongue makes a wise patentee. Personally, I hope Mr. Bennetto has made a genuinely original discovery, out of which he will profit. I also hope he has familiarised himself with what has already been done and achieved in the way of colour photography. It would be most mortifying to him, I'm sure, to discover that, after all, he was not the first in the field with the particular method he was working; and, reading between the lines of what has appeared on the subject in these pages, I should not be surprised if this did not prove to be the case. COSMOS.

THE THEORY OF DEVELOPMENT.

[London and Provincial Photographic Association.]

IT is not my intention to advocate any particular form of development. I wish to speak entirely theoretically of what takes place during the development of the image. It is a curious state of things that this, one of the most important operations in the practice of photography, has received far less attention, from the chemical point of view, than anything else.

When I started photography, we had one developer, gallic acid, which was used in the calotype and waxed-paper processes, and there was then some excuse for no theory being advanced as to its action on the sensitive film; but, as time went on, we got pyro and sulphate of iron for physical development, and lately the number of developing agents at our command has been greatly increased by the advent of amidol, metol, &c. Pyro, being that in most general use, will be the one I shall speak of, but the same theory applies to all.

A little light was recently thrown upon one action of pyro by Mr. Haddon, who pointed out that pyro itself exercised no tanning action on gelatine. I will go further, however, and say that there is no tanning action even with oxidised pyro, and might also say that pyro is not a developer. It is a fact in chemistry that any partially oxidised substance is always greedy for further combination with oxygen, and if we notice the construction of pyrogallic acid, which is $C_6H_3(OH)_3$, it will be seen that already three of its atoms are oxidised, and it is, therefore, very suitable for use as a developing agent on this account.

If we take pyrogallic acid, and apply it to an exposed plate, what takes place? First, the bromine is liberated wherever light has acted, and it is this liberated bromine, and not the pyro, which tans the gelatine. If pyro were a tanning agent, then such a process as Warnerke's, where the plate is developed with pyro, and then placed in hot water when that part upon which light has not acted, and where there has been no development of an image, is dissolved, would be impossible. I hold the theory that it is the nascent bromine that tans the gelatine.

If a plain gelatine plate is soaked in a solution of pyro and ammonia for several hours, and then put in hot water, it will melt readily, proving that, although subjected to the action of oxidised pyro, no tanning action has taken place. I know that old notions are hard to get rid of, as is the so-called rising and setting of the sun, which is only illusive. Things are not what they seem, and this tanning action, though appearing to be produced by pyrogallic action, is not due to it.

Now, as to the development of the image, what is the constitution of the image in the plate? It has been said that the undeveloped image in the plate consists of silver sub-bromide; but silver sub-bromide has never yet been proved to be present, and there is no evidence that silver sub-bromide has been made except once by the German chemist, Guntz. It has been assumed that it exists, but no proof can be given. The change to silver sub-bromide I consider ought to be visible if existent, and I hold that the phenomenon of development can be accounted for without the supposed change to sub-bromide. In the development of a plate the operations, which are well known, consist in pouring the pyro solution into the dish or vessel containing the plate, when the image gradually appears till sufficient intensity is obtained, when it is stopped by various means, such as plunging in water &c. What is the action which takes place, and what part of the pyro does the work? Pyro contains three oxidised atoms of hydrogen and three atoms of hydrogen unoxidised and waiting to be oxidised. It is generally thought that the hydrogen of the pyro develops the picture, but it is not so. The plate contains bromide of silver, consisting of bromine and silver in equal proportions, and the atoms of each are arranged in a definite order upon the plate. We are taught that all atoms are free to move, so the atoms of bromine and silver are free to move, and the action of light is to move these out of their position, and they are, as it were, polarised. There is no evidence that the bromine is given off, but the position of the atom is changed. I consider the action of light simply causes a rearrangement of the atoms.

In the Daguerreotype process we have a copper plate which is coated with silver by electrical deposition, which receives a high polish. This surface is exposed to the vapour of iodine and bromine, which produces a sensitive film. After exposure, this is developed by subjecting the surface to the vapour of mercury, when the mercury combines with the silver of the exposed portions, forming an amalgam. But there is no evidence that a sub-iodide or sub-bromide of silver is formed. In the modern plate the case is somewhat similar, but the results of the application of the various developers are different. Every one present has, no doubt, experimented with the simple form of galvanic battery, made of simple elements of zinc and copper, which, when properly coupled, give a current of electricity, and has noticed that the action only lasts a short time. This is due to the plates becoming polarised, or, in other words, the hydrogen of the decomposed water adheres to the negative element and prevents further action. In Daniel's battery, which gives a constant current, the negative element is immersed in a solution of sulphate of copper, and the evolved hydrogen is used in reducing the copper from its combination with sulphuric acid, and thus removed.

In development there is a similar process going on. You have the atoms of silver bromide which have been acted upon by light on the one side, and the hydrogen atoms of the pyro on the other. A weak electric current is established, the water becoming polarised and presenting its hydrogen atoms to the negative element, silver bromide, and its oxygen atom to the positive hydrogen of the pyro. The immediate result is the decomposition of a molecule of water, the hydrogen of the water, not of the pyro, combining with the bromine of the silver bromide, thus reducing the silver to the metallic state, hydrobromic acid being formed. The oxygen of the water combines with the hydrogen of the pyro.

A plain solution of pyrogallic acid will exert some developing action on a plate, but this action is very slight. Here we have hydrobromic acid formed immediately reduction takes place, and nothing to combine with it and remove it. When an alkali is also present in the solution, the alkali combines with the hydrobromic acid as soon as it is formed, and the development is continuous.

Some years ago I experimented with the view of developing by water alone, and after many failures succeeded. I prepared a copper plate, coated with collodio-bromide emulsion, and exposed it in the camera in the usual way. I then placed the copper plate in water, and also a zinc plate, and caused them to touch at the edges, when I got a faint image. For example, in a landscape subject, the sky would perhaps appear, but with very little detail. In a further experiment an ordinary gelatine emulsion plate was used. After exposure the film was stripped from the glass, and transferred to a plate of silvered copper. This was immersed in distilled water, with a slight trace of alkali-ammonia. A zinc plate was also immersed, and caused to touch the copper plate, and the picture which I pass round was produced.

Temperature has an influence. If the water be intensely cold, scarcely any development is possible, while, as the temperature is raised, so the action increases.

There is nothing written as far as I know as to what is the result of developing on the developers themselves. It seems a very obscure point. The probability is that the first stage of oxidation of the pyro is the formation of a brown purpurogallin, any further oxidation causing the carbon molecule to fall to pieces, thus liberating carbon in the film in the form of the well-known pyro stain. EDWIN BANKS.

OPTICAL DIAGRAM OF A DOUBLET LENS.

THE diagram of an ordinary doublet lens which we illustrate this week is the natural sequel to Mr. Hett's diagram of tele-photographic lenses published in our issue of March 27 last.

Mr. Hett says:—

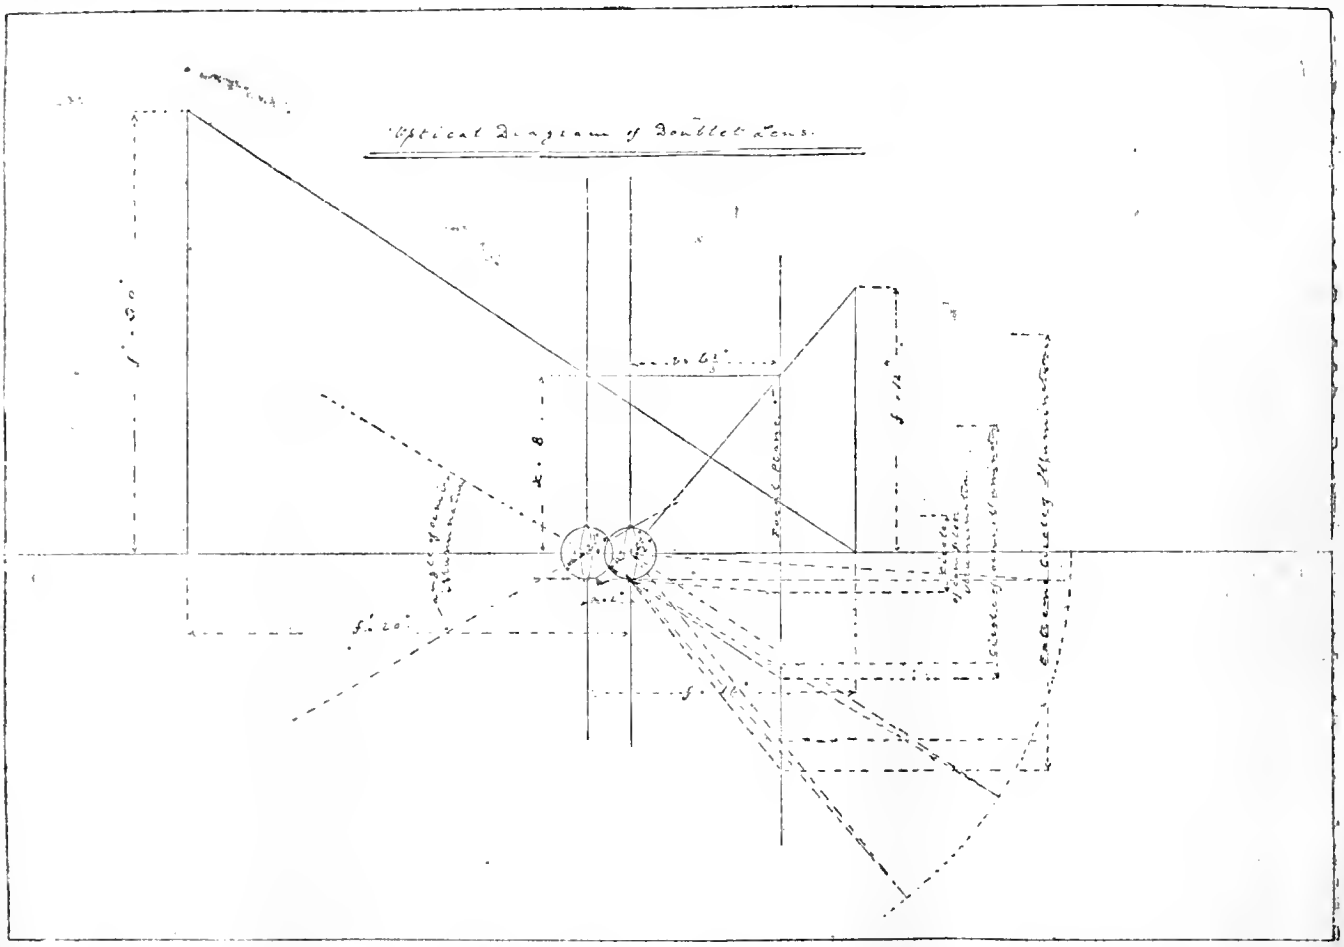
"In this figure the various data are as follows:

Focus of front lens	= 12	and is represented by		f
Aperture of "	= $2\frac{1}{2}$	"	"	a
Focus of back lens	= 20	"	"	f'
Aperture of "	= $2\frac{1}{2}$	"	"	a''
Distances of lenses apart	= 2	"	"	d

"Found by construing,

Equivalent focus	= 8"	"	"	x
Back focus	= $6\frac{2}{3}$"	"	"	c

"The circles of complete and semi extreme illumination shown, as well as the angle of semi-illumination, are modified by the use of stops. Perhaps it may be well to explain how these circles are arrived at. As an example, I take the circle of semi-illumination (this is not shown accurately), and take a pencil of light passing through the centre of the front lens and the extreme edge of the aperture of the back lenses, and finally cut an area of a circle struck with the radius $f' = 20''$ from the centre of the anterior



lens. The point in the arc where the junction is taken is covered to the centre of the anterior lens by a straight line, parallel to which the pencil of light will emerge from the back lens. This is drawn in, and the point where it cuts the focal plane is in the circumference of the circle of semi-illumination.

"The other portion of the construction is, I find, self-explanatory."

CARBON PRINTING WITHOUT TRANSFER.

At the present time, when considerable attention is being directed to this paper, it may be of interest to give a *précis* of the chapter upon this subject which appears in the new work (*Das Pigmentverfahren*) by Dr. J. M. Eder.

It is curious to note that the earliest of all carbon processes, patented by Poitevin in 1855, contained the germ of this process, and that it was also used by Pouncey in 1858.

In 1885 Mariot had introduced into the K. u. K. Militargeographischen Institute in Vienna a somewhat similar process for line work, really for the reproduction of maps and charts, but it was not till 1889 that Artigue, an amateur photographer of Bordeaux, showed some prints at the Paris Photographic Exhibition, which were remarkable on account of the delicacy of the half-tones, the great depth of the shadows, and for the fact that they were prepared without transfer.

It was not until 1894 that Artigue placed his paper on the market, and considerable difficulty was experienced in obtaining it.

Artigue paper is essentially a gelatinised or well-sized paper, coated with a thin film of gum arabic, containing a lot of some pigment—usually lamp-black—which is, when dry, sensitised from the back. After exposure, it is developed with a somewhat thick paste of sawdust and warm water, the development being partly due to mechanical attrition of the unexposed and still soluble gum, and partly to solution of the same in the water.

Mariot's process, which is specially suitable for line work, is as follows: Good raw paper is first gelatinised by being drawn through a 1:60 solution of gelatine, and then dried and coated with a mixture of—

Gelatine	60 grains.
Gum arabic	60 „
White sugar	120 „
Distilled water	1 ounce.

The gelatine should be soaked in half the water for an hour, and the gum arabic in the other half, and the latter be well stirred till dissolved, the two solutions mixed, the sugar added, and the whole heated till perfect solution is effected, and then the solution filtered through linen.

The previously gelatinised paper should be first soaked in water till the gelatine has swollen, then the paper laid film down on a sheet of glass, and excess of water removed with a squeegee, and then turned film up and the above solution spread over it with a leather roller. It has been found that an ordinary indiarubber squeegee may be used instead of the leather roller. The paper should now be laid over a wide shelf or semicircular piece of wood till just the surface moisture goes and the film is still tacky. It should be then placed in a dusting box, such as is used for photogravure, the powder being a mixture of—

French lamp-black or vine-black	5 parts.
White sugar	100 „

The paper must be left in the dusting box for from eight to twelve minutes, or till it is uniformly covered with an even coating of powder, and shows quite black and opaque. The paper is then dried, and can be kept for a long time in this condition.

To sensitise it, the sheet is lightly dusted with a cloth or soft brush, and then immersed in the following:—

Potassium bichromate	50 grains.
Ammonium	50 „
Distilled water	14 ounces.

When dissolved, add

Strong solution of ammonia	*Quant. suff.*

That is until the colour turns a bright yellow, and then add:—

Chromic acid	20 grains.
Alcohol	3½ ounces.

After sensitising, which takes two or three minutes, the paper is dried, exposed, and developed in warm water, and finally sprayed with cold water.

Another process of Mariot's for the same purpose is the following: Paper must be gelatinised as described above, and then coated with the following mixture:—

English red	26 grains.
Indigo	10 „
Vine-black	5 „
Gum arabic	20 „
White sugar	24 „
Potassium bichromate	18 „
Distilled water	1 ounce.
Caustic ammonia	20 minims.
Chromic acid	5 grains.
Glacial acetic acid	30 minims.

The indigo should be rubbed up with alcohol and burnt, and then mixed with the other colours and sugar in a mortar with a little water, and the water allowed to evaporate. The gum arabic, which should be in powder, should be rubbed down with one or two drops of alcohol, and the potassium bichromate, previously dissolved in the water, added gradually with constant rubbing in the mortar, and this gradually added to the colours, and then the caustic ammonia, the chromic and glacial acetic acid added, and the whole pressed through linen, and the previously gelatinised paper coated with this in the dark, dried, exposed, and developed in water at from 35° to 70° C., then well washed with cold water, preferably with a rose, and dried.

Although no formulæ for the preparation of Artigue's paper have been published by Artigue himself, several others have suggested working formulæ. Duchochois suggested the following:—

Glucose	20 minims.
Sugar	10 grains.
Honey	5 „
Gelatine	10 „
Water	1 ounce.

Dissolve by the aid of heat, and add 180 grains of lamp-black previously rubbed down very fine with alcohol. The paper is coated with this, dried, and then sensitised by brushing with a two and a half per cent. solution of potassium bichromate.

Another process suggested by Duchochois is to use a fluid starch paste and incorporate the colour, and then spread thinly on paper, and, when dry, sensitise from the back.

Dr. Mallman suggested coating damp Rives paper with a one or two per cent. solution of gelatine, allowing 0·32 c. c. to every ten square centimetres of surface; then, when this was set, dusting with ivory-black and sensitising by immersion in solution of potassium bichromate.

Watzek, of Vienna, recommends the use of a not too rough drawing-paper, which should be previously sized with starch. The sensitive mixture is composed of the volume of the pigment (lamp-black, burnt sienna, Indian red, English red, Paris blue) and one and a half volumes of a forty per cent. gum arabic solution, to which sufficient of a ten per cent. solution of potassium bichromate is added. With moist-tube colours, Watzek uses equal parts of colour, gum solution, and bichromate solution.

Rouillé-Ladevèze, in his little work, *Sepia-photo et Sanguine-photo*, (Gauthier-Villars, Paris, 1894), recommends the following solutions:

1. Pure gum arabic	192 grains.
Water	1 ounce.
2. Potassium bichromate	48 grains.
Water	1 ounce.

Mix in equal parts, allow to stand for twenty-four hours, and then filter through linen, and add the pigment in the form of a paste, allowing twenty-four grains of colour to every ounce of the above mixture.

Whilst the preparation of the bichromated gum presents no particular difficulty, I have found that it is by no means easy to ensure absolute evenness of coating if the colour be incorporated; and, whilst I have a heliogravure dusting box, there was considerable unwillingness on my part to clear out the asphalt and utilise it for pigmentary colours for this process, and I therefore looked about for some means of dusting on the powder, which should be simple and not costly.

Dredging the colour on from a box is simple, and almost costless, for a round card box, such as used for collars, was obtained, the lid removed and knocked out of the rim; in the box the colour was placed, and over the top was tightly stretched some of the finest muslin, and the rim of the lid jammed on to keep the muslin taut. Now, by tapping and shaking the brush, the colour was easily powdered all over the surface of the paper; but, as fine muslin was used, it took some considerable time, with the result that one end of the paper became less tacky, and therefore showed less vigour or development. The substitution of coarser muslin produced a somewhat lumpy or coarse granular deposit, and therefore some other method was looked for.

The first thing which suggested itself was one of the small powder bellows, such as are used for insecticide powders, but this was found to give a coarse, lumpy deposit, and was given up. An ordinary scent diffuser was tried, but this was found useless, as the pressure of the ball was not sufficient to force the powder from the bottle. It then occurred to me that an insufflator, such as is used for blowing powders into the throat or the nostrils, might be used, and this has given excellent results.

The insufflator I used consists of two indiarubber balls, one a pump, the other an air reservoir connected with an ebonite pipe, into which, by means of a sliding piece, the powder is placed, whence it is carried by the pressure of the air. These can be obtained with various nozzles or nipples, to give either a narrow stream or a diffused spray, and the latter is to be preferred.

Whilst many operators have commended the total immersion of the paper, it is not, in my opinion, so favourable as painting the back of the paper, nor do I commend the combination of the bichromate with the pigmented gum, for, as is well known, in this state the paper will not keep. To sensitise the paper, it is advisable to support it on a sheet of glass slightly smaller than the sheet of paper, in order to prevent the sensitising from creeping on to the surface, which must be next the glass.

The concentration of the sensitiser may vary from one to five per cent.; the more concentrated it is, the harder the prints. Von Schöller, whose picture at the Pall Mall Exhibition has been medalled, recommends soaking the exposed print in cold water first, taking care to avoid air bubbles, and then placing in water at from 25° to 27° C., till the outlines appear, then laying on a sheet of glass and developing with the usual sawdust and water at 20° C. The hotter the water the greater the contrast in the prints, and, by careful manipulation with a soft brush and water at various temperatures, very great command is to be exercised over the results.

A. D. Pretzl.

PHOTOGRAPHY AND THE BICYCLE.

[Journal of the Photographic Society of India.]

With the rapid spread of bicycle riding among all classes throughout the world, there must be many photographers who desire to take advantage of the peculiar facilities for rapid and independent locomotion afforded by the bicycle to secure pictorial mementoes of their rambles in strange places.

The tricycle has long since been adapted to the carriage of the photographer and his kit, and apparatus of a fairly large size can easily be taken without any inconvenience beyond the extra weight to be propelled. The bicycle does not, however, offer the same facilities as a luggage carrier, and the amount of kit to be carried is much more limited, both in size and weight, besides which the question of *balance* and comfort in riding long distances have to be considered. Still, with the improved small hand cameras now available, much may be done.

The year-books, to which one naturally looked for information on this subject, scarcely deal with it; but, in a little French book entitled *Le Photo-cycliste*, published by the author, M. Georges Lanquest, at 1, Rue Gay-Lussac, Paris, we find a full discussion of the question of apparatus, dress, &c., together with a lot of hints and dodges and useful information, both for the cyclist and the photographer, male and female, or, as our author calls them, the "photocycleman and "cyclswoman." We can here only indicate the general principles advocated by the author, leaving those interested to refer to the book for further information.

The first question to be considered is the apparatus, which must

necessarily be limited in weight and bulk, and should ordinarily not exceed quarter-plate size, though with films a larger size may be taken for a short run or for any special purpose. A small, light, magazine hand camera of simple construction is the most suitable, and should be fitted with a first-class lens, so that the pictures may stand considerable enlargement. It should be strongly made, well put together, and packed in a strong light outer case or waterproof cover, so as to avoid injury in case of a fall and be protected from rain, dust, and heat. A light folding stand may be carried strapped to the frame, but can well be dispensed with if the bicycle itself is used as a stand, the camera being attached by a clamp screw to the handle bar.

As regards sensitive plates, celluloid films, either cut to size or in a roller slide, are undoubtedly the lightest and most convenient; but, if glass plates are preferred, the number that can be carried on the machine must depend upon the size of the apparatus. Some dozens of plates one and a half to two inches square could be carried without inconvenience, while more than a dozen or two of quarter-plates would be difficult to carry without inconvenience and a considerable addition to weight and bulk.

It is obviously not desirable to encumber one's self with extra plates and the requirements for developing or printing *en route*. These, if necessary, should be carried with one's luggage, to be forwarded by train, parcel post, or other local conveyance. If absolutely required, a few small graduated bottles of concentrated developer and fixing solution may be taken, together with a couple of celluloid trays distinctively marked, one for developing and the other for fixing. Developing and fixing cartridges or tabloids would also be found convenient. The bicycle lamp can readily be made to serve as a dark-room lamp by screening it with a piece of suitable non-actinic paper or cloth. Our author tells how to do this, and also how to improvise a bicycle lamp on occasion. He also goes fully into the details of developing, fixing, and printing negatives, but this we need not refer to further.

Our author also deals pretty fully with the question of clothing, and gives a lot of hints for drying one's things after getting wet and avoiding colds and chills. When taking an extended tour, a change of clothing should be carried on the machine. It should be limited to the necessary requirements, and the garments should, as far as possible, be of woollen material, to avoid chills. A spare pair of shoes or boots should be included. This clothing, together with toilet requisites and spare photographic kit, should be well packed in a waterproof valise or square of mackintosh for protection against wet and dust, and may be carried attached to the handle bar of the machine and above the camera. On the top is the waterproof cape, which should never be omitted. On an extended tour in out-of-the-way places, a few simple medicines may also be taken (for these tabloids will be most convenient, though not mentioned by our author); but it will also be desirable, in any case, to carry a small graduated bottle of alcoholic solution of corrosive sublimate, about 1 to 100. One part of this in ten of water, or better spirit, say whisky or brandy, forms a useful antiseptic application for cuts and wounds received in falling on dirty roads. The wound should be well washed with this, and then protected with sticking-plaster or cotton-wool—or a little vaseline may be rubbed on. A five per cent. solution of boracic acid in water is also recommended, and has not the poisonous properties of the mercurial salt. The author says that a solution of permanganate of potash diluted or Condy's Fluid may also be used.

The Machine.—Before starting on a tour the machine should be carefully and thoroughly inspected and all nuts tightened up—the gearing of the chain seen to and the bearings oiled. The tires should be inflated sufficiently but not too much in hot weather, otherwise the expansion of the contained air may cause strain or bursting.

At the end of the day's journey carefully clean the machine, if possible, doing it one's self. First wash off the mud with a soft sponge and water, taking care not to scratch the enamel. Dry with a soft leather. Then lay the bicycle down on its side, placing paper or cloth below to prevent injury from rubbing or dirt. Then wash out the bearings of the wheels with a little kerosine oil, turning the wheel all the while till the bearings are quite free from gravel and mud and the oil runs out quite clear. Keep turning the wheels till the petroleum is all out, and then wipe the machine and dry it with a soft leather. Do not let the oil get on to the tires or enamelled parts of the machine. The chain can be greased with vaseline. On starting again, a few drops of oil should be supplied to the bearings. The author also describes how to use a pneumatic tire, and gives a good many hints for the repair and preservation of the machine. The booklet also contains the rules current in France for the running of cycles on the public roads as well as for photographing, and tables of the multiplication and development of machines—according to the size of the wheels and gearing.

In THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1895, M. Albert Levy gives his experience of a bicycle tour from Dieppe to Havre with a camera. His camera, specially made for films 7×5, weighed eight pounds, and he found the best place for it was between the legs, inside the frame, on an aluminium carrier weighing one pound. The tripod he carried across the handle bar, and the six holders in a box behind the seat; a little baggage-carrier in aluminium, to hold necessary changes of linen, shoes, &c., was placed in front of the bicycle. Altogether, his baggage weighed over twenty pounds. The first day he did thirty miles without any trouble, taking a few views; the second day was not so satisfactory, as he had rain; but the third day, running against a high wind, wet through even his waterproof, he managed with difficulty to get to Etretat, where he changed clothes and finished his journey to Havre in a carriage. He concludes by saying: "Photography while riding a bicycle is not always fun, and I understand parties having given it up as not practical. The bicycle is a very good and almost perfect machine for pleasure and exercise, but it is as yet in a very crude state if one wants it for any practical use, to carry some tools along, of any weight, say, from four to five pounds up, and that is small enough; but, as the machine is now constructed, put it where you may, it changes the balance altogether too much."

The subject is one of some interest, and, if any of our readers have practical experience of bicycle photography, we should be glad if they will communicate it for the benefit of their brethren. The important points are the amount of weight that can be carried without discomfort, and the best distribution of it. We are inclined to agree with Mr. Levy that the best position for luggage is inside the framing. The available space is not more than four inches wide, if so much, but a light case made of Willesden cardboard, or aluminium, three inches deep, made to fit the frame, would easily hold a small camera and the necessary clothes, &c. One of the new binocular or other so-called pocket cameras could easily be carried hung over the shoulders. Some of the home makers advertise camera carriers to be fixed on the handle bars.

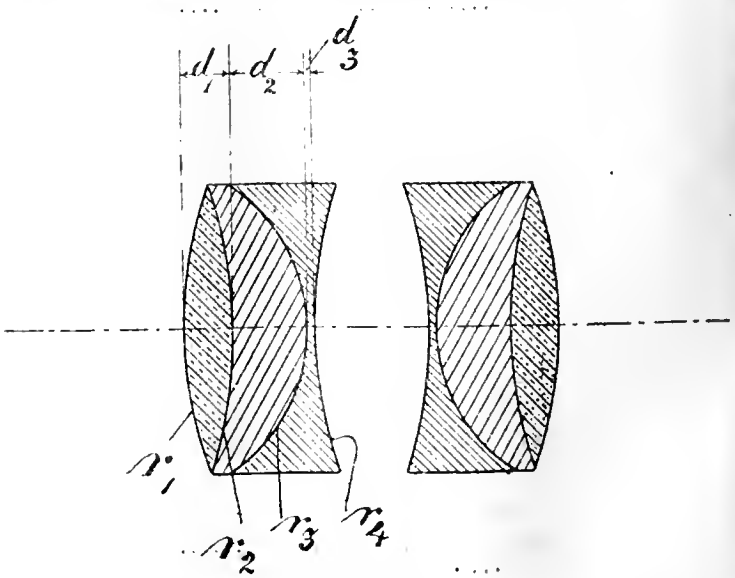
COLONEL J. WATERHOUSE.

VOIGTLÄNDER'S IMPROVEMENTS IN LENSES.

THE patentee, Herr Friedrich Ritter von Voigtländer remarks:—

Since the invention of the unsymmetrical anastigmato-photographic objectives with higher correction of the astigmatic error, it has been the desire of the opticians to construct symmetrical anastigmatical objectives of the same perfection. Such a symmetrical anastigmat, which has been called collinear, and for which letters patent were granted in 1894 under No. 21,458, consists of two equal systems of three bases cemented together in that way, that one positive meniscus of least refractive power lies between one biconvex lens of highest, and one biconcave lens of least refraction. This combination has met with a great success. But, however useful it might be, yet the highest illuminating power of this construction, *i.e.* the highest ratio of clear aperture and length of focus, could never be brought above 1 : 6·3, and so it has been the case with all the other constructions of symmetrical anastigmats.

Recent mathematical researches and practical investigations made it likely that only slight alterations of the optical properties of the medium lens in the so-called "collinear" would afford the possibility of attaining a higher illuminating power. Practical experiments and with the finest precision in the performance of the optical surfaces assisted the mathematical researches, so that I finally succeeded in designing and constructing a symmetrical anastigmatic collinear of the relative aperture 1 : 4·5, twice as luminous as the most luminous symmetrical anastigmat hitherto



known. Only a slight difference of the optical properties of the medium lens made this success possible, whereas any greater alterations lead to impossible curvatures and impossible forms of lenses. This new construction is therefore a most sensitive one, because it is not possible to

neglect the least differences in the optical properties, the curvatures, and the thicknesses of the lenses. This sensitiveness undoubtedly is the reason of all the ill-successes of the constructing opticians in that direction.

In the accompanying drawing, the new spherically chromatically and an astigmatically corrected double-objective of the ratio of aperture 1 : 4·5, is shown in a diagrammatic representation. The precise data of the construction are as follows:—

Species of glasses $L_1 : n_D = 1{\cdot}6065$
$L_2 : n_D = 1{\cdot}5150$
$L_3 : n_D = 1{\cdot}53645$

Radii $r_1 = 54{\cdot}58$ mm. Thicknesses : $d_1 = 6{\cdot}4$ mm.
$r_2 = 59{\cdot}273$ mm.
$r_3 = 22{\cdot}5$ mm. $d_2 = 10$ mm.
$r_4 = 59{\cdot}273$ mm. $d_3 = 1$ mm.

Working aperture : 33·6 mm., Length of focus 151 mm.
Relative aperture 1 : 4·5.

The claims are for (1) a spherically, chromatically, and astigmatically corrected double-objective of the relative aperture 1 : 4·5, consisting of equal systems of the same correction, of which each is composed of a positive meniscus of least refractive power cemented between a biconvex and a biconcave lens of higher refractive power. (2), The employment of a single system of the kind referred to in the first claim as an independent photographic objective.

LAMBERT'S IMPROVEMENTS IN PHOTOGRAPHIC DISHES.

M. Lambert's invention relates to improvements in invertible photographic dishes or baths permitting of the development or other treatment of photographic plates without the possibility of any of the liquid escaping from the dish or bath even if the latter be turned on end or on its side for watching the appearance of the image upon the plate, or even upside down, and also permitting development without fear of soiling the hands by the developing liquid, and without having to touch the plate until after the developing operation is completed.

In the drawing, fig. 1 represents a vertical section on the line 1–2 of fig. 2, of a photographic dish, bath, or basin, constructed in conformity with my invention.

Fig. 2 is a plan view thereof.

Fig. 3 is a vertical section of the edges of the dish, bath, or basin, forming a cover.

Fig. 4 is a vertical section of the base or bottom frame of the basin.

Fig. 5 is a vertical section taken on the line 3–4 of fig. 2, showing the arrangement serving to withdraw the glass plate from the basin.

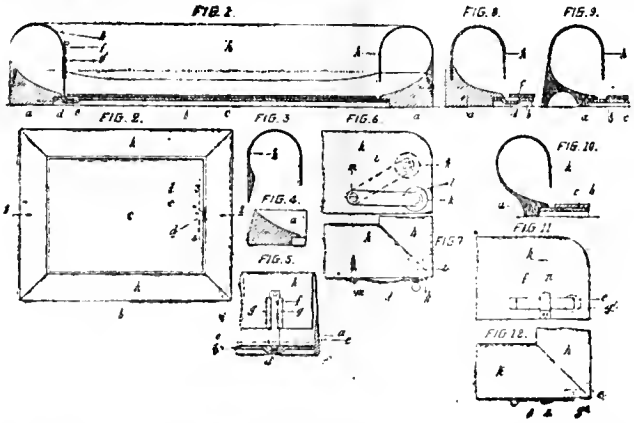
Fig. 6 shows in elevation the device for closing the orifice of the channel for discharging the liquid contained in the bath.

Fig. 7 is a plan view thereof, corresponding to fig. 6.

Figs. 8, 9, and 10 show in vertical sections some modifications of the edges forming the cover of the basin.

Figs. 11 and 12 illustrate in elevation and plan view respectively a modification of the device serving to release the glass plate or the photographic plate from the dish, bath, or basin.

In these different figures similar reference letters refer to similar parts.



The patentee says: "My improved bath or dish comprises principally a frame or base, *a*, of wood or any other suitable material, provided at its bottom with a rebate serving to receive a glass plate, *b*, forming the transparent bottom of the dish or bath; this glass plate, upon which the photographic plate, *c*, rests, is provided with a recess, *d*, in which is located a hook, *e*, on the end of a rod, *f*, mounted in guides, *g*, fixed upon the interior wall of the turned-over edges, *h*, forming the cover of the bath or dish; these turned-over edges, *h*, of aluminium, enamelled sheet metal, celluloid, gutta percha, or any other suitable material, may be of various shapes, for example, such as represented in fig. 3, or that represented in fig. 8, and may be fixed upon the base, *a*, of the bath in any suitable manner so as to ensure a water tight joint in the bath. The said base may sometimes be made integral with the curved edges of the dish or bath as shown in figs. 9 and 10, and the glass plate, *b*, may be without a recess, *d*; in this case, when not in use, the aforesaid hook, *e*, is located in a hollow, g^1, provided in one of the walls of the dish, and the rod, *f*, carrying the hook, is held in place by a small claw, *n*, fixed in any suitable manner on the dish or bath as shown in figs. 11 and 12. When required for use, the rod, *f*, is of course removed, and is employed in a similar manner to the device shown in figs. 1, 2, and 6.

"The base, *a*, is provided with a channel, *i*, for emptying the liquid, the exterior orifice of which channel is closed by a stopper, or washer of indiarubber, *k*, held in place by the action of a spring, *l*, pivoted upon the dish or bath by means of a screw, *m*.

"Fig. 6 shows in full lines the position of the stopper, closing the discharge opening for the liquid contained in the bath, and in dotted lines, this same stopper during the discharge of the liquid. The channel for emptying the liquid may, of course, be arranged at any suitable place, for example at the upper part of the edges of the basin, and may be closed by a screw stopper.

"From the preceding it is evident that the liquid contained in the dish cannot be spilled outside the same whatever position of the dish may be, as the liquid will always flow into the chamber, or recess, formed by the turned-over edges of the dish, *h*, even when the dish is turned upside down.

"The photographic plate, *c*, resting upon the glass base, *b*, of the dish will be maintained in contact with the same by suction, and therefore the dish may be placed vertically in order to watch, by transmitted light, the development of the image without having to withdraw the photographic plate from the dish, and without fear of spilling the developing liquid.

"After the developing operation is finished, the photographic plate is removed from the basin, for example, by means of the hooked rod, *f*, aforesaid by drawing the same upwards, so that its hook, *e*, will lift the plate, or by any other suitable mechanism, for example, such as represented in figs. 11 and 12, without the fingers having to come into contact with the liquid during the whole operation."

The claim is for the improved invertible dish or bath for photographic purposes, the essential characteristic feature of which consists in providing curved edges to the dish, basin, or bath, so as to form a reservoir enabling the said dish, basin, or bath, to be inclined or turned in any direction, without the contained liquid being enabled to escape or to be spilled.

THE APOTHECARY AS A PHOTO-STOCK DEALER.

[American Journal of Photography.]

A pamphlet has lately been issued and distributed broadcast among druggists, apothecaries, and cross-road storekeepers, setting forth in glowing terms how fortunes are to be accumulated by the sale of photographic supplies. The pamphlet seems to be the effort of one who signs him or herself with the high-sounding title of "Secretary of the American League of Amateur Photographers," an organization which, so far as our own investigations are concerned, we must confess appears to be a somewhat mythical one.

Nor have we been able to locate the headquarters of this great corporation. In fact, the reference smacks greatly of the well-known story of the "Tailors of Tooley Street." However, we will let that pass. No notice should have been taken of the subject, which by the way is marked copyrighted, were it not for the misleading tenour of the contents of the pamphlet, which is really a conglomeration of stale matter, and bears evidence of having been published in the interests of some chemical laboratory for the express purpose of booming their specialties.

Now, this whole matter concerns the inexperienced amateur and the unsophisticated apothecary. It has nothing whatever to do with the professional photographer, photo-scientist, or advanced and intelligent amateur, all of whom are well aware that their success depends fully as much upon the freshness and purity of the chemicals employed as upon the plates and optical appliances, and none of the above need advice from any official of an Amateur League as to what to use or who to purchase from.

It is well known to every professional and intelligent amateur that the regular photo-stock dealer, who is educated to the wants of the profession, has their individual interests at heart, and permits neither plate nor chemicals to leave his place unless he is morally sure that they are fresh and first-class. Further, he has no occasion to deceive his customer, his success in business depends upon them. If either chemicals or lot of plates do not come up to the full standard, they are at once returned to the manufacturer, who in turn replaces them, as the dealer is a large and valued customer.

How different the case with an apothecary who lays in a few dozen plates or a few ounces of chemicals of a kind to retail out by grain or scruple, which, by the way, are apt to deteriorate by becoming stale upon the shelves of such dealers as have but a limited demand for goods of this character. He has no recourse; his only remedy is to sell the chemicals at prescription rates.

A few illustrations which came directly under the writer's notice will suffice. A photographic friend, a few months ago, having use for four

ounces of distilled water and thirty grains of citric acid, sent the order with a bottle to a neighbouring apothecary. The order was filled at a charge of thirty-five cents. It is true the bottle was neatly wrapped in a piece of white paper and tied with a baby-blue string, but that did not make the solution any better.

In another instance, in a different part of the town, three ounces of hypo were called for. The salt was carefully weighed upon a well-balanced scale, not a grain over-weight; this was done up in a double white paper and tied with a pink string and a gilt label. Price 45 cents, or 15 cents per ounce. Upon the purchaser objecting to the exorbitant charge, he was blandly informed that "we only keep pure chemicals." This was supplemented with the information that photo-stock dealers handle refuse chemicals only.

When this case came to our notice a little investigation was started as to prices charged by apothecaries who made a speciality of photographic requisites for amateurs. The result was that hypo brought from five to fifteen cents per ounce. One druggist sold it, put up in packages of one-quarter pound, under his own name as his special brand, expressly for amateur use, for twenty-five cents per package. Three apothecaries had no sulphite of soda, another kindly furnished half a pound of sodium carb. crystals for twenty-five cents.

Even the honourable secretary of the Amateur League of American Photographers quotes an instance where he was let off with twenty cents for a pound of hypo.

He further goes on to state that the druggist is not "in it" so far as concerns present trade relations with the photo-amateur. The writer agrees with him there, and will add that the intelligent apothecary who is wise unto his generation will stay out. He will not be deceived by any suave arguments from agents of concerns who fail to impress the professional bread-winner with the wonderful superiority of their wares, and now seek to unload them upon the village druggist.

The great bulk of photographic supplies will always be used by the professional and commercial branches of the photographic art, who will, as heretofore, look to the reputable stock houses for their supplies.

In comparison with the professional branch, the amateur guild is a comparatively small one; but, even of the latter, the intelligent and painstaking ones will hardly be tempted to enter upon untried or risky paths so far as their supplies are concerned, and cannot be induced to go to an apothecary for chemicals or supplies unless he is caught away from home, or at unawares, in which case he expects to pay prescription prices. Such cases, however, are few and far between, and would hardly justify any retail druggist or apothecary to open a special department of photographic supplies.

J. Focus Snappschotte.

The Inquirer.

*** *In this column we from time to time print questions that may be addressed to individual contributors to our pages, or such as are sent to us with the view of eliciting information from a variety of sources. We invite the co-operation of our readers in rendering this feature of the* Journal *useful and instructive.*

Hydriodate of Potash.—Novice writes: "I have an old work on photography in which I find a formula containing hydriodate of potash, but I cannot meet with this in any of the dealers' lists. Can you tell me what it is?"—Iodide of potassium.

The Action of Alum on Gelatine.—J. C. asks: "What is the difference between the action of ordinary alum and chrome alum upon gelatine? For some purposes the ordinary alum is recommended, for others chrome alum. Why? Have they different reactions, or may they be used indiscriminately?"

Tectorium.—H. P. writes: "In the Journal of October 16, in an article on *Glass Substitutes in Germany*, you mention tectorium, which, I take it, is wire-wove roofing. You say this is an English invention. I have, for some considerable time, tried for the address where this can be obtained. If you can furnish me with this, you will greatly oblige."—We rely on our readers for the information desired.

Classes in Photography.—W. D. says: "In reply to your correspondent, 'Snark,' in Friday week's Journal, asking for classes in photography in connexion with the Science and Art Department, as far as I can find out, the Science and Art Department do not hold examinations in photography, so that there are not likely to be any classes in connexion with it. There are, however, classes in photography at the Birkbeck Institute and the South-West London Polytechnic, as well as those at the Regent-street Polytechnic."

Cleaning Glass.—Young Amateur asks: "Which is the best way of cleaning glass plates previous to squeegeeing prints on to them for 'opalines?' I am told that the perfect adhesion of the prints depends, in a great measure, upon the glass being absolutely clean. I have several formulæ for cleaning pastes and solutions, but I want to know which is best, the purely chemical cleaning with nitric acid and soda, or similar substances, or such mixtures as tripoli, china clay, or whiting, with ammonia and alcohol. Each has its bad points, but does either plan offer any material advantage over the other?"

Carbon Printing Query.—J. E. Behrend says: "I recently came across an old formula for photo-lithography, in which iodide of silver is combined with the bichromatised gelatine, but for what purpose is not very evident, as no developing process is carried out that would affect the iodide. It struck me, however, that it might be possible, by using a tissue containing silver bromide as well as pigment, to combine the sensitiveness of the Warnerke process with the colour of ordinary carbon tissue. Is this possible?"—In reply, we believe that, when Mr. Warnerke first introduced his process, he made some experiments in this direction, but whether they turned out practically successful we do not know.

Pyro and Amidol.—Yorkshireman writes: "I am an ardent admirer of 'good old pyro,' and, although I use a formula of this developer, which suits my requirements exactly, I object to stained hands. My skin is very rough, and the stains, even of freshly made developer, are difficult of removal, even with solution of chloride of lime. I may mention that I always use my pyro dry, and other chemicals in ten per cent. solutions. I have tried amidol several times, but cannot get the results I wish. Could any reader give me the equivalents in grains of amidol to pyro; sulphite of soda to carbonate of soda; and the action of bromide of potash in solution with amidol, as I understood its action was not the same as in solutions of pyro. Having tried all the developers, one naturally, after ten years' experience, returns to pyro, knowing there is nothing to beat it; but business compels one to have clean hands."

Stained Gelatine Negatives.—Phœnix writes: "I have three unvarnished gelatine negatives that have got wet in the printing frames while in contact with gelatino-chloride paper, how can I prevent their ultimate staining? I have had this accident on previous occasions, and have taken precautions, as soon as the mishap was discovered, to prevent the stains, but, I am sorry to say, not successfully. My method consists in, first of all, thoroughly soaking the negative in clean water, then in solution of salt, and after that in clean fresh hypo, followed by copious washing. One would think that this treatment, applied before any stain has appeared, would prevent it; but not so, the invisible silver compound formed with the gelatine remains, and, on exposure to light in the printing frame, comes out as an appreciable discolouration, though not so bad as would be the case without the preventive measures. Can you suggest any further treatment before exposure to light?"

Our Editorial Table.

Catalogue Received.

A. E. Hoyles & Co., 70A, Shakespeare-street, Nottingham.

Messrs. Hoyles' catalogue is styled a "guide to studio furnishing," which suggests its principal feature, viz., that it is devoted to illustrated particulars of painted backgrounds, studio accessories, rustic furniture, and sundries. It thus appeals to our professional readers, who should find it useful for reference when they are desirous of making additions to their studio furniture.

"Photograms" of 1896.

London: Dawbarn & Ward, 6, Farringdon-avenue, E.C.

The difficulties in producing a work of this character before the widespread interest excited by the Exhibitions of the Photographic Salon and the Royal Photographic Society has abated enhance the credit that is due to the editors and staff of our contemporary for the rapidity with which they have completed their task. The volume opens with a brief record of technical progress in 1896, and includes reproductions, not only of many of the principal photographs now hanging in Pall Mall and Piccadilly, but also of several non-exhibited works, including contributions from Canada, Australia, and America. Pictorially speaking, the reproductions are almost fully representative of the best English work, and, it goes without saying, that the get-up of the volume and the quality and printing of the blocks are exceedingly good.

Mr. Gleeson White's critical remarks are eminently appreciative and discriminative, although here and there we encounter unavoidable commonplaces of the phraseology of criticism, which we specially commend to the notice of Mr. George Davison, the Rev. F. C. Lambert, and others of their kind who are so fond of carping at the shortcomings of those whose constant duty it is to write about exhibitions in the photographic papers. Mr. Snowden Ward makes an apology for the "criticism against time" that he prints, but we are sorry that he did not enter a protest against the toleration of press-view pests and bores, whose mission it appears to be to make it as difficult as possible for editors of photographic papers to get through their by no means enviable labours on these occasions.

We cordially endorse a manly and outspoken protest against the photography of the merely naked that is uttered in the volume. Our American photographic friends are especial sinners in this respect, and we hope that they will seize the advice here given, to go through a thorough course of study with competent advisers when undertaking such work, and to exhibit a considerable diffidence in showing their results. We can all the more appropriately subscribe to this wise counsel from the fact that before us, as we write, are two American photographic publications having nude studies that are simply crude and vulgar records of physical facts.

We see mention of a Bristol Exhibition this year, and the statement that a good deal of the work shown there is to be found in the pages of *Photograms* of 1896. The Exhibition does not open for nearly two months yet. A trifling slip like this, however, may well be pardoned in face of the great skill and care that are expended on the volume as a whole.

"Primus" Novelties.

W. Butcher & Son, Blackheath.

"Primus" Diagram Lantern Plates.—These are glass plates, coated with a dark pigment on one side, upon which, by the aid of a fine point, diagrams, drawings, or writings may be scratched. When placed in the lantern, the projected image gives the inscription or drawing as white lines on a black ground. Many uses will suggest themselves for these prepared glasses.

"Primus" Lantern-slide Masks.—This, the "Drinkwater Butt" series, gives a selection of no less than sixteen different shapes, in rectangular, oval, circular, and cushion form. The masks are spotted with white spaces for writing upon. Lanternists should appreciate the series.

"Primus" Notice Lantern Plates.—These plates are coated on one side with a transparent preparation which takes writing ink, so that inscriptions may be rapidly written thereon for projecting on to the lantern screen.

"Primus" Photogravette. — This is a simple arrangement permitting of contact negatives being made from pictures in books, &c.

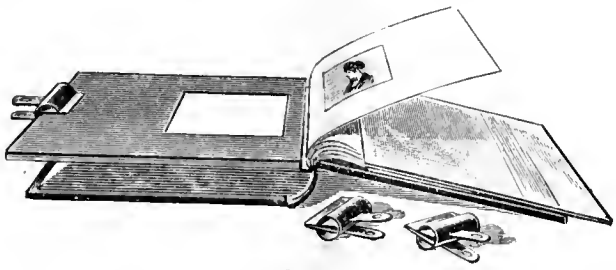


Fig. 1.

Fig. 1 represents the baseboard and carrier, with the plate placed in position in the book, film side upwards.

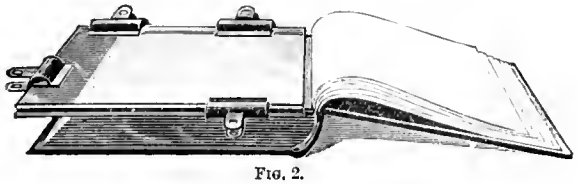

Fig. 2.

Fig. 2 represents the picture to be copied folded over on to the plate with the back of same uppermost; a glass plate is also placed over this, and the whole clamped together by means of the four clips.

The apparatus consists of a stiff baseboard, a carrier for the sensitive plate; a thick cover glass, and four strong clips. Contact between the sensitive plate and the print to be copied having been made (of course in the dark room) exposure is made to artificial light, and development is pursued in the usual way.

This method of copying by contact will, no doubt, be found useful by many in emergency.

Cloud Negatives.

The Brighton Photographic Company, Clarence-square, Brighton.

Some capital specimens of cloud negatives, made by the Brighton Photographic Company, are before us. They are printed by means of the carbon process, and are mounted on transparent celluloid. The era of white skies in photographs has quite passed, and if the photographer is unable to get clouds in his negatives, and has not the opportunity of making his own cloud negatives, all further excuse is taken from him by reason of the ready accessibility of such pleasing and satisfactory specimens as those submitted to us by the Brighton Photographic Company.

News and Notes.

Messrs. Henry & Co., of St. Martin's-lane, announce for publication two illustrated annuals, *The Pageant* and *The Parade*, both under the editorship of Mr. Gleeson White.

Royal Photographic Society.—Technical Meeting, Tuesday, October 27, at the Gallery, 5A, Pall Mall East, at 8 p.m. Demonstration of acetylene apparatus for portraiture and the optical lantern, by Mr. C. Hoddle.

The Austin-Edwards Monthly Film Negative Competition. — The prize camera for current month has been awarded to Mr. J. A. C. Branfill, 25, Rosendale-road, West Dulwich, for his negative, *St. Paul's from Newton's Wharf*.

The Hackney Photographic Society's Exhibition will be held in the Morley Hall, Hackney, on November 17, 18, 19, and 20. Entry forms are now ready, and may be had on application. The Society is prepared to collect pictures entered for the Exhibition from the Pall Mall and Salon at a charge of 3*d*. per picture, minimum 6*d*. Communications should be addressed to the Secretary, Mr. W. F. Fenton-Jones, 12, King Edward-road, Hackney, N.E.

Photographic Club.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock precisely, on Wednesday evening, the 28th inst. Travellers' Night. Mr. T. Charters White will give a lecture entitled *Switzerland*, which will be illustrated with lantern slides. Members are requested to note that the meetings of the Club will be commenced punctually each week at eight o'clock during the ensuing winter session.

The Walworth Junior Postal Camera Club.—The Hon. Secretary and Treasurer (Mr. P. C. Cornford), of 11, Grosvenor-street, Camberwell, London, S.E., writes: "Will you allow me space in the columns of your valuable paper to state that there are three vacancies in the above Club, caused by recent resignations, through pressure of other matters, and that I shall be pleased to send all particulars as to membership to any amateur who would care to join us, on receipt of one penny stamp."

Radiography in an Attempted Murder Case.—Henry Goodwin was again brought up last week at the Salford Police-court, and charged before Mr. R. Hankinson and Mr. Alderman Jenkins with burglary and attempting to murder Mr. Israel Rosenblum, merchant, Northumberland-street, Higher Broughton. Prisoner was remanded for another week on the application of Chief Detective Inspector Lyogue, who said there was now a likelihood of Mr. Rosenblum's recovery, but he would not be in a fit state to attend court for two or three weeks. In the course of an interview, Dr. Walmsley, the medical attendant of Mr. Rosenblum, stated that his patient had been radiographed by Mr. Chadwick, of St. Mary's-street, and, as the result of the process, the bullet was discovered in the chest. An operation with a view to its extraction will be made in the course of a few days.

M. Paul Desjardins has been instrumental in starting a society in Paris, known as the Union pour l'Action Morale, the object of which is to check the demoralising influence—growing every day—of certain posters, illustrated journals, and theatrical photographs displayed on the street walls and in the shop windows and kiosks. The subject is one which, of course, offers an easy excuse for ridicule in a sceptical city like Paris; but one can afford to ignore all cheap sarcasm, for the matter is a serious one and deserves to be considered as such. All cant and prudery apart, one may well be shocked at the shameless display of more or less naked figures which modern advertising thrusts in the faces of all and sundry. I am aware of the strong-minded argument, that corruption exists, and will exist, whether such pictures be displayed or not, and that they do nothing to increase it; that men's lower instincts are very much the same as they were in the earliest times, as gross and as animal; that progress is a snare and a delusion, and so on. Be it so, for the sake of argument; but the admission by no means implies that we are therefore to tolerate these scandalous exhibitions, which stand out in all their effrontery from the walls, and by their gaudy colouring must needs attract the attention of all who pass them by, not only men, but women and girls, and young children. It must be admitted that it is no easy task to bring about an improvement in these matters, but every one with a healthy mind, every self-respecting man who values the dignity of humanity, will wish all success to M. Paul Desjardins and his efforts.—*The Studio*.

THORIUM.—The rare metal thorium, discovered early in the present century by Berzelius, has lately sprung into importance in a curious manner. When burned, the metal emits a light more brilliant than that of magnesium, but, until the invention of incandescent gas burners, in which the flame is incased in a metallic mantle, no use was discovered for it. Upon experimenting upon various substances, it was found that the oxide of thorium, called thoria, makes the best mantle for such burners, and, a demand being thus created for it, the value of thoria sprang from about 2*d.* to 5*l.* a pound. At the present time a search is being made for new sources from which thoria can be obtained, and this search is being conducted in many countries. Originally the new metal was found only in certain rare minerals in Norway. Recently it has been discovered that the mineral monazite contains a liberal quantity of thoria, and monazite is found in North Carolina, Canada, and Brazil.

Patent News.

THE following applications for Patents were made between October 7 and 14, 1896:—

MAGIC LANTERN.—No. 22,456. "Improvements in the Optical or Magic Lantern." H. STOCKWELL.

FOCUSSING.—No. 22,538. "Improvements in the Method of and in Means for Focussing Photographic Cameras." A. BAMVENS.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

October.	Name of Society.	Subject.
26	Bradford	*Platinotype for Beginners.* Walter Booth.
26	Camera Club	*What the Artist has to say about Colour.* G. A. Storey, A.R.A.
26	North Middlesex	*Artigue System of Carbon Printing without Transfer.* J. A. Sinclair, F.R.P.S.
26	Richmond	*Systematic Development.* Alfred Watkins.
26-31	Southport	Annual Exhibition.
26	Stafford Y.M.C.A.	*Enlarging.* H. Cliff.
27	Birmingham Photo. Society	*Practical Pictorial Photography.* A. Horsley Hinton.

30	Croydon Microscopical	Conversational Meeting.

ROYAL PHOTOGRAPHIC SOCIETY.

OCTOBER 20,—Photo-mechanical Meeting,—Mr. Horace Wilmer in the chair.

HALF-TONE DIRECT FROM NATURE.

Mr. WILLIAM GAMBLE read a paper upon this subject. In his early experience with the half-tone process, he said he had been told that it was impossible to make a half-tone negative direct from a landscape, a sitter, or even from still-life objects, and this because the screen could only deal with a plain surface; and, further, because, even if this difficulty could be overcome, the exposure would be prolonged to such an extent that the range of subjects which could be dealt with would be very limited. The first objection he characterised as absurd, while the second could only hold good in the days when screens were less clear than at present, when wet-collodion platea were believed to be indispensable, and when the method of adjusting the screen and diaphragm to produce varied effects was not known. Amongst other things which the use of dry plates had made practicable was the problem of direct half-tone from nature. By their means exposure was reduced and apparatus made more compact, and the screen could be set much closer, or even in contact with the plates, rendering it possible to use shorter-focus lenses and smaller cameras. It was quite possible to take direct half-tone negatives by the existing methods for copying from prints, but the length of exposure made this course impracticable except for still-life subjects, and the question to be solved was how to reduce the exposure. With this object, the size of the diaphragm might be increased if the distance of the screen could be sufficiently reduced to compensate for it; but this would mean that the aperture would be increased at the expense of the shadows of the picture, and a preliminary exposure with a small stop appeared to be essential to avoid this disadvantage. The use of screens with thinner lines would be a reversion to an obsolete practice, and such screens rendered the shadows imperfectly. A third way of reducing exposure would be to use more rapid plates, and the lecturer doubted the necessity of a slow-process plate. He had made half-tone negatives on ordinary plates, and produced very good prints from them, it was simply a matter of adapting the printing to suit the negative. With the assistance of Mr. Brantill, he had prepared a series of tables, showing maximum screen distance for a stop of a certain size. He had designed a dark slide containing mechanism for adjusting the screen as close as one sixty-fourth of an inch, and it was consequently possible to use a large stop, and therefore to materially reduce the exposure, and also to employ lenses of shorter focus. The rule that short-focus lenses were unsuitable for half-tone needed qualification. It was rather a matter of angle than focal length, a narrow angle being requisite in order to project sharp dots on the plate at the usual screen distances. With a camera fitted with a cross-line screen it was quite easy to make a direct half-tone negative, just as though the object in front of the camera was a paper print, the only difference being that the negative would be more vigorous than one made from a print. One of the chief troubles to be overcome arose from the fact that the high lights would be over-exposed before the dots in the shadows had had time to form. This could be met by making either a preliminary or final exposure on a sheet of white cardboard with a small stop in the lens, producing a grain of dots all over the plate not larger than they should ultimately be in the shadows. This dodge, however, although very effective in the process studio, could hardly be applied out of doors or in a portrait studio. The same object could be attained by preparing plates beforehand, but then they would have to be used at once without removal from the slide, for, if removed, they could not be replaced so that the dots came again just under the openings of the screen. Another method of graining the plates was to place a very small stop in the lens, in front of the lens a small condenser, and behind the condenser, and at a suitable distance, a strong source of light, very fine black dots being produced on development after final exposure upon the subject. The idea of a vignetted screen seemed in theory the most perfect for the process, but in practice the dots would probably be "woolly" or unsharp, and it was questionable whether the shadow dots would stand reduction so as to produce sharpness. Apart from the idea of making a grained negative direct, it had been suggested that it would be more practicable to take the negative in the ordinary way, and make a grained transparency from it, or to make an ordinary positive and from that a grained negative, and the paper concluded by enumerating some methods upon these lines.

Mr. Gamble showed the camera and dark slide with which his experiments had been made, together with a set of diaphragms of various shapes and lantern slides illustrating the character of the dots obtained.

The Rev. F. C. LAMBERT remarked that the paper was one which would amply repay consideration, but which it was scarcely possible to discuss on the present occasion, and, this being the general opinion, no discussion took place.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

OCTOBER 15,—Mr. H. Snowden Ward in the chair.

Mr. A. E. Allen was elected a member of the Association.

The HON. SECRETARY reminded the members of the print competition, arranged for November 5. Photographs are to be taken solely within the London postal district, and he hoped to see a lot of entries on that date.

SPOTS, PINHOLES, &C.

Mr. Mackie showed an albumen paper print, covered with spots, which had been fixed in two hypo baths so as to ensure proper fixation, the cause of which he could not explain.

It was thought to be due to splashes of something or other, but nothing definite was suggested.

Mr. HODD inquired the reason why negatives, after intensification, frequently show pinholes not before visible. He had met with many examples lately. They had been blackened with ammonia.

Mr. WALL had never met with it with any blackening agent but ammonia. The only reason he could suggest was that the silver was dissolved by the ammonia. A cure for it was not to use ammonia, but that did not explain it.

Mr. EVERITT said air bubbles might have been formed during the bleaching of the plate with the mercury, and so form a contrast between those places and the intensified parts surrounding them.

Mr. HODD could not accept this as the reason, because, where the pinholes were, there was absolutely clear glass.

Mr. MACKIE said it was a common experience, and he thought it due more to the gelatine than anything else.

Mr. BANKS stated that it was a very common thing with the wet-collodion process, but the explanation which applied to collodion negatives would not do so with gelatine plates. The explanation as to collodion was that there was a piling up of the image on the surface of the collodion, which was unable to carry it, and so gave way.

Mr. MACKIE said he had ventured a statement at a previous meeting that a negative with a long exposure generally required long development. He referred to some negatives taken in the British Museum, which took from ten to twelve minutes to develop, as against three minutes with studio work with relatively the same exposure. It had been said that they must have been under-exposed, but he did not think so, and showed a specimen to support his statement.

Mr. EVERITT denied saying they must be under-exposed, but considered that, under the conditions given by Mr. Mackie, the studio negative received relatively more exposure than the Museum negative.

Mr. WALL could only infer that that meant that the Museum negatives were under-exposed. He had seen some of them, and did not hold that opinion, however.

Mr. EVERITT replied that the studio negative might be over-exposed.

The CHAIRMAN read the following from the question-box: "What is the action of caustic potash in the silver bath?"

This was supplemented by Mr. RAPSON saying that light action was required, after the addition of the caustic potash, to finish the precipitation of the deposit that is formed.

Mr. MACKIE replied that it first neutralises the acid, and then reacts with the silver, forming oxide of silver. Light or heat was required to reduce the organic matter.

A lecture was given by Mr. EDWIN BANKS on

THE THEORY OF DEVELOPMENT [see page 677].

Mr. HADDON expressed the interest with which he had heard the lecture. With reference to his own paper, which had been mentioned, he still maintained that the insolubility of the gelatine was due to the combination of the oxidised pyro with the gelatine. In his experiment he had bubbled air for some hours through a solution of pyro and an alkaline carbonate, and at the end of that time Nelson's gelatine was soaked in the solution and then thoroughly washed. Previously it went into solution at 35° C.; but, after being heated with the oxidised pyro, it would not go into solution at the boiling point of water. Here was a case in which no bromine came into contact with the gelatine. The only means which would lower its melting point was the addition of hydrochloric acid. The colour was due to the oxidised pyro. He did not agree that it was the liberated bromine that rendered the gelatine insoluble. That there was something more than a mere alteration in the vibration of the molecules of bromide of silver under the action of light was proved by the fact that the medium which supported the bromide of silver had more influence on the speed of the plate. A good deal depended upon the power of the medium itself to take up bromine.

Mr. WALL thought it a pity that the lecture had not been written. He felt in doubt as to some of the points raised by Mr. Banks. The electrical theory carried a good deal of weight with it, and there was a strong argument in favour of the image being formed entirely by some sort of rearrangement of the molecules. He did not agree as to the composition of the stain in the silver image, and did not think it was deposited carbon from the pyro.

Mr. EVERITT said, so far as he could judge, it was worthy of very close consideration. Mr. Banks started his theory with a great deal of evidence in its favour, and it was one which he hoped would be carried beyond the theoretical stage, and endeavours made to substantiate it by experiment. He asked how the theory would fit in with the phenomenon of reversal of the image? If it could be done, it would be more than had been previously done. With reference to the difference between Mr. Banks and Mr. Haddon on the question of the tanning action of pyro, he thought it possible that both might be right. It may be that the tanning action produced in development may be due to the bromine, while, under Mr. Haddon's conditions, his contention may be correct that the oxidised pyro was the tanning agent.

Mr. BANKS, in reply to Mr. Haddon's statement that gelatine became insoluble in the experiment mentioned, stated that Watts says that an alkaline carbonate oxidises pyro into di-gallic acid or tannin, but he still failed to see the proof that pyro was a tanning agent on the gelatine in the development of the plate. In answer to Mr. Wall, he inquired what was the pyro stain in the image if not carbon? The theory that it was carbon was borne out. For instance, take an exposed plate and soak it in a strong solution of pyro for five or six minutes until thoroughly saturated. The pyro penetrates the film, and is imprisoned with the silver bromide, and, if the plate is flooded with ammonia, it may be rocked as much as you please, but nothing will disturb the pyro. The result is that the image will be as hard and intense as possible, and the pyro is decomposed within the film. If the silver of such an image is removed by any means, there still remains a negative in pyro stain. He did not claim that it was absolutely pure carbon, but no means had been found to dissolve it. He did not see why his theory should not agree with reversal as asked by Mr. Everitt.

The CHAIRMAN had listened with great interest to Mr. Banks' new theory, and said that it appeared that Dr. Burton Cox's well-known experiments had, after all, a good deal of truth in them, and he hoped to see very shortly the perpetrator of the hoax step forward to claim the reward which had been offered for his discovery.

PHOTOGRAPHIC CLUB.

OCTOBER 14,—Mr. Naegali in the chair.

The HON. SECRETARY made a statement in reference to the punctual commencement of the meetings during the winter sessions. In the summer time he said we are apt perhaps to be a little slack and informal, but it is proposed, especially in view of the fact that some of the members leave at an early period of the evening, that in future the meetings shall begin sharp at eight.

Mr. HODDLE gave a demonstration of acetylene gas and of his Incanto gas generator. He stated that the gas was made by the addition of calcium carbide to water; the process, therefore, of gas manufacture is simplicity itself. His apparatus consists of two galvanised cylinders constructed to slide one within the other on the well-known principle of a gas-holder. Within the inner cylinder is a device for holding the calcium carbide in such a way that, when the outside container is partially filled with water, the weight of the inside cylinder presses down the receptacle which contains the carbide into the body of water contained in the outside case. In this way the action of the gas-holder (which is at the same time the gas-generator) becomes automatic through the rising and falling of the inner cylinder. The apparatus has a suitable device for cooling and condensing the moisture in the newly prepared gas. One pound of carbide gives off five feet of acetylene gas, and this quantity will burn for two hours with two burners suitable for the gas. The carbide costs, including packing, about 6*d.* per pound. The demonstrator stated that he had been experimenting and using the gas in his generators for years, and had suffered no ill effects from the smell of the gas. In reply to questions, he said that the gas itself, as well as the calcium carbide, had a strong, and some people thought a disagreeable, smell. Its luminosity was about fifteen times that of coal gas. He had not experienced any explosion. The demonstration was illustrated by the use of the Incanto apparatus. The use of the gas was also demonstrated in the lantern, and slides were projected by its means upon the screen.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE following is the annual report of the Society for the session 1895-96:—

In submitting the Society's forty-first annual report, your Council have much pleasure in stating that, on reviewing the past twelve months' work, it is gratifying to feel that the interest in every way has been thoroughly maintained amongst the members.

If you remember, at the last annual meeting your attention was directed towards the providing of subjects at the general meetings by members outside the Council who, although taking an interest, were lax in coming forward. Without dwelling further on this matter, your Council further urges you to bring forward any suggestions or papers which would be of interest to the welfare of the Society.

There have been nine general meetings held in the Society's rooms and three outdoor meetings. In November, 1895, Mr. H. Wade gave an interesting demonstration on the process of carbon printing, exhibiting examples of the various modes of varying results. The December meeting was devoted to a paper given by Mr. S. L. Coulthurst on *Hand-camera Work*, reviewing the position of the camera, and also by describing the lens, shutter, changing plates, developer, &c. In January, 1896, the subjects of the meeting were varied: Mr. H. Smith on *Colouring Gelatine Photographs;* Mr. F. Edwards on *Modes of Intensifying Dry Plates*, with a demonstration; Mr. A. S. Casson on *Collodio-chloride Paper*, also with a demonstration. The March meeting was occupied by Mr. A. Brothers on photographing the corona without an eclipse. In April the Society were fortunate in having the services of Mr. N. Luboshez, of the Eastman's Photographic Materials Company, who delivered a most interesting lecture on *Successful Portraiture, and Platinum-bromide Printing.* For the May meeting, Mr. Harry Wade gave a paper and demonstration on the *Home Preparation and Manipulation of the Plain Salted Silver Paper.* The last meeting was of a technical character, when Mr. H. M. Whitefield opened a discussion on *Washing and Finishing Prints.*

Your Society held a most successful Exhibition in the month of February, which, in number and quality of exhibits, almost surpassed those of previous years. The Exhibition was opened for two evenings, the first of which was partly occupied by a display of the competing lantern slides, also by a descriptive lecture by Mr. H. Wade, entitled *Glimpses and Glances*, and the following evening by Mr. S. L. Coulthurst, exhibiting a series of slides illustrating *Street Life in Manchester.* In the competitive classes the awards were close, and the thanks of the Society are due to Messrs. W. Artingstall, J. W. Wade, and George Wheeler, who acted as Judges.

Owing to the rooms of 36, George-street, not being available for indoor meetings during the summer months of June, July, and August, it was decided the meetings should partake of a social character, and be held at some suitable place convenient to Manchester on the Saturday following the date of the monthly meeting. The first arranged was:—Delamere and Mouldsworth, on June 13; Chelford for Astle Park, on July 11; Bramhall for Bramhall Hall, August 8. The interest, as shown by the attendances at each meeting, was highly gratifying, and the new feature in having these summer meetings proved an exceptional success.

Referring to the lantern section of your Society, the members have not come forward with their usual enthusiasm, and the meetings were not well attended; doubtless, due, in a great measure, to the room being uncomfortable during the winter months; but, in the new premises, a much larger gathering is expected.

At the first meeting of this section, Mr. J. Hyde gave a lecture on *Switzerland and its Glaciers*, employing slides by M. Fevrier, of Paris. January meeting, Mr. A. S. Casson contributed a paper on *Stereoscopy on the Screens.*

The thanks of the Society are due to Mr. J. W. Wade, of the Manchester Amateur Society, who, for the February meeting, gave his method of producing various colours in lantern slides, accompanied by a set of slides showing results obtained. At the same meeting Mr. Hill Whitefield demonstrated his method of printing clouds in lantern slides. The March meeting was devoted to members' slides.

The thanks of the Society are also due to Mr. Harry Wade for reporting the various meetings, also to the publishers of photographic periodicals for gratis copies sent during the year, including the firms who have contributed exhibits of apparatus and specimens, which have increased the interest of meetings.

The roll of the Society contains the names of ninety-five members, of which ten have resigned. During the year twelve new members have been elected, thus showing an increase of two.

In conclusion, the Council, in retiring from office, beg to draw your attention of having been able to secure more commodious and comfortable rooms at 44, Moseley-street, known as the Chamber of Commerce Rooms, than those which have been hitherto occupied by the Society. Trusting that such a change will be beneficial, and also that the welfare of the Society will be fully sustained in the future, with confidence leaves the election of its successor to the members who are gathered here this evening.

The following were elected the Council for 1897:—*President:* Mr. S. Chilton.—*Vice-Presidents:* Messrs. A. E. Casson, F. Edwards, W. Tomlinson, H. M. Whitefield, and J. Wood.—*Council:* Messrs. T. M. Brooke, J. Hyde, J. Peddie, J. C. Wolfenden, C. H. Coote, H. V. Lawes, A. Heywood, F. W. Masters, H. Wade, J. Whittaker, and H. Woolley.—*Lantern Committee:* Messrs. W. Tomlinson, J. C. Wolfenden, H. Wade, and J. Whittaker.—*Hon. Curator:* Mr. J. Whittaker.—*Hon. Librarian:* Mr. C. H. Coote.—*Hon. Reporter:* Mr. Harry Wade.—*Hon. Treasurer:* Mr. G. W. Coote.—*Hon. Secretary (pro tem.):* Mr. A. E. Casson.

Hackney Photographic Society.—October 13, Mr. R Beckett presiding.—In a discussion on halation, Mr. GOSLING said that he had found a difficulty in getting complete optical contact with gummed backing papers. Mr. FARMER had found a certain tissue to be effective. Dr. ROLAND SMITH had used with success commercial burnt sugar mixed with methylated spirit. A paper by the Rev. F. C. Lambert was read, in the absence of the author, by Mr. E. PUTTOCK. It was on

THE TREATMENT OF THE FIGURE,

and contained much useful advice as to posing, lighting, composition, &c. A series of slides were shown on the screen to illustrate the subject. In a discussion as to the advisability or otherwise of ruling a focussing screen with

lines to assist composition, Mr. RAWLINGS deprecated the practice, as being liable to lead to a cramped style and too much uniformity. The CHAIRMAN said that the system of composition could never be carried out on fixed lines. Each must depend on its own requirements. The composition of a picture often depended on masses and tones as well as lines.

North Middlesex Photographic Society.—October 12, Mr. Mummery (the President) presiding.—The ordinary business of the evening was suspended, as this was a meeting to which ladies were invited, being a lantern lecture, by Mr. FENTON-JONES, of the Hackney Photographic Society, entitled

VENICE AND LUCERNE.

The lecture proved very interesting, and was enlivened by humorous quotations from Mark Twain descriptive of some of the scenery. The audience showed their approval by the hearty manner in which they respouded to the vote of thanks, proposed by Mr. PITHER and seconded by Mr. LISETT. Mr. Fenton-Jones, in replying, said that he hoped that the tie which already existed between the Hackney and North Middlesex Societies would continue and gain in strength.

Richmond Camera Club.—The winter session was opened on the 5th inst. by a

LANTERN SHOW OF PHOTO-MICROGRAPHS

by Mr. J. CHARTERS WHITE. Over a hundred most interesting slides were projected on the screen, and explained by Mr. Charters White in his characteristic humorous manner.

On Monday, the 12th inst., the PRESIDENT (Mr. J. P. Cembrano, jun.) read a paper on

EXHIBITIONS AND HINTS TO EXHIBITORS.

After contrasting the present system of Exhibitions with that of a few years ago in respect to classes and awards, Mr. Cembrano proceeded to touch on "the two greatest and best organized photographic Exhibitions of the present day," namely, the Pall Mall Exhibition and the Salon. He advocated raising the standard of exhibits still higher, and of doing away with awards entirely. Moreover, he suggested that the Royal Photographic Society should hold two Exhibitions yearly, one dedicated entirely to the pictorial side of photography, and the other to the scientific and industrial aspect. Mr. Cembrano gave high praise to the "Salon" promoters, in that they have made it possible to hold in this country a series of successful annual Exhibitions without charging for wall space or awarding medals. He concluded a most interesting paper with some excellent hints to exhibitors, one of which is a sort of "negative," namely, If an exhibitor wants to ensure not being hung, and not getting an award, he will frame his exhibit in a gaudy plush and gold frame, with all sorts of enrichments.

South London Photographic Society.—At the last meeting of the Society, held at Hanover Hall, Hanover Park, Peckham, the President (Mr. F. W. Edwards, F.R.P.S.) in the chair, Mr. ROBERT ROBERTS (Prosser Roberts Drug Company) gave before a crowded meeting a demonstration of *Photography with the Röntgen Rays*. The demonstration gave clear and concise directions of what to do and what to avoid in order to attain success. A negative of a hand, showing a malformation, was taken and developed. The pose of the fluorescent screen was shown. Samples of Mr. Norman Vine's retouching powders were distributed.

Woodford Photographic Society.—October 15, Annual Meeting.—After the usual routine business had been gone through, the SECRETARY submitted his report upon the state of the Society, its work and finances for the past year. He said the membership had increased, but the attendance could hardly be considered satisfactory. Demonstrations upon *Platinotype*, by Mr. W. H. Bennett, and *Lantern-slide Making*, by Mr. Marriage; *A Holiday in Derbyshire*, illustrated by a set of nearly fifty lantern slides, by Mr. Ember; and the Leeds slides, circulating among the affiliated societies, formed part of the year's work. The excellence of the work shown at the Exhibition last November was touched upon, and congratulations offered to those members whose pictures were shown at Pall Mall. The balance-sheet showed that last year's deficit had been wiped off, a balance in hand of 1*l.* 15*s.* remaining. An appeal was made to the members to endeavour to increase the membership, and, if possible, to draw within the Society the many photographers in and about Woodford who do not belong to any other society, a course which would benefit them and generally conduce to an improvement in photographic work done in the neighbourhood. Mr. WILMER, at the conclusion of the report, in proposing a vote of thanks to the retiring officers, warmly praised the Secretary for his interest and exertions on the Society's behalf during the past year. The officers elected for the present year are:—*President:* Mr. E. Marriage.—*Council:* Messrs. Caird, Goodwin, and Malby.—*Lanternist:* Mr. E. Noble.—*Hon Secretary and Treasurer:* Mr. F. E. Ember. The programme for the present year is a capital one.

Ashton-under-Lyne Photographic Society.—This Society had a very successful opening night for the winter on Tuesday evening, October 13. The lecturer was Mr. W. Lamond Howie, and his lantern views were simply superb. We are inclined to think they are the best that have ever been exhibited in Ashton; but lantern views generally have attained to such perfection that one is almost inclined to say the same thing after every fresh lecture. Of course, everything depends upon the photographer's eye for the picturesque, and this Mr. Lamond Howie possesses in a high degree. Bleak stretches of snow and rock are, one would think, very difficult to make interesting, and yet Mr. Howie sets himself to this almost impossible task and succeeds to admiration. He always puts into his slides a sufficient number of striking features to make every fresh one arrest the attention and impress upon the mind that one is viewing some of the most marvellous features on the varied surface of the globe. It makes a wonderful difference when one views objects at an angle of something like eighty degrees. If Stamford-street, for instance, could be upended from Cockbrook to St. Peter's at such a degree, with all its houses sticking out on either side, the appearance would be most astonishing. Standing at the Park gates, St. Peter's Church would be brought apparently quite close to the eye, but it would still be at the same absolute distance. One's ideas are for a while quite upset. Distances cannot be gauged by a stranger to mountains with any approach to accuracy, and great mistakes are made in guessing what they really are. The same difficulty must necessarily be experienced in estimating the height of mountains shown on the screen. The lecturer has frequently to impress upon his audience that things are not just what they seem, but a considerable deal different. It is not altogether the atmosphere, although that, of course, is clear; but the changed angle of vision accounts for much more. For those who did not appreciate the mountains so much as they ought to have done, Mr. Howie had some views of the Milan Cathedral and of the old Roman architecture of Aosta, which could not fail to prove very striking.

Darwen Photographic Association.—October 15.—M. J. Lees, of the Manchester Amateur Photographic Society, delivered a lecture entitled *A Tour in Spain*, illustrated by lantern slides from photographs taken by the lecturer himself whilst on a holiday there. The Rev. Henry Irving (President of the Association) occupied the chair, and there was a large attendance of members. The lecture was keenly enjoyed by all present, as it was both interesting and instructive. In the concluding portion of the lecture Mr. Lees gave a vivid description of a Spanish bull-fight as witnessed by himself during his tour. The lecturer was accorded a hearty vote of thanks.

Wolverhampton Photographic Society.—This Society commenced its session for 1896–7 on Friday, October 16, at the Blind Institute, Victoria-street, where the society's room are situated. Mr. H. E. Perry (President) occupied the chair.—Mr. E. C. Middleton, of the Birmingham Photographic Society, gave an interesting demonstration of

THE CARBON PROCESS.

After a brief review of the chief points in the history of the process, the lecturer called attention to its three great advantages, viz., permanence, wide range of colour, and simplicity. The permanence of carbon prints arises from the fact that the finished picture consists simply of any suitable artist's pigment locked up in gelatine which has been converted into a kind of parchment; and, as the makers of the materials are careful to use only stable pigments and paper of the highest quality, the permanence of the result is as perfect as in the case of ordinary engravings. As any permanent artist's pigment may be chosen, there is a wide range of colour for the prints. The simplicity of the process, particularly in the case of single transfer, is due to the fact that the gelatine tissue, which consists of ordinary gelatine mixed with pigment, supported upon a backing of paper, is supplied by the makers in a variety of colours ready-sensitised, and it is only necessary to expose a piece of the tissue to the light behind a negative, measuring the time by a simple actinometer. The exposed tissue is then soaked in cold water, and pressed down on to paper, glass, or any desired material which can be made waterproof. A short immersion in warm water, which now follows, dissolves away the bulk of the pigment, leaving the picture on its paper or other support. The only other steps necessary are a slight washing and dryiog. The prints by this single-transfer process are reversed as regards rights and lefts unless a reversed negative is used. By the double-transfer process, which involves another simple operation, this can be obviated. The lecturer practically demonstrated the single-transfer process, developing the pictures upon various kinds of drawing-paper, opal glass, and also upon plain glass for transparencies. The operations of the double-transfer variation were next shown. The whole of the demonstrations were performed with Mr. Middleton's accustomed dexterity and neatness, and gave much pleasure to those who were fortunate enough to witness them. Those who had not previously seen the carbon picture developing out clearly and beautifully from the seemingly hopeless mess of pigment were quite fascinated, and, no doubt, many members will forsake silver printing, with its doubtful permanency, now that they have seen the ease and beauty of the carbon process.

Photographic Society of Ireland.—The winter session, 1896–97, of the Photographic Society of Ireland was opened at their rooms, 35, Dawson-street, on Friday, October 9, when the PRESIDENT of the Society (Mr. Alfred Werner), who occupied the chair, delivered an address on the history and development of the art. There was a good attendance. The President, who was well received, said he would deal with the question of photography principally from a scientific point of view; but, as he desired to keep himself in touch with all the members, he hoped, during the session, to also address himself to those whose studies were not so far advanced, and to those who looked at the question from a practical or technical point of view. The lecturer then referred to the discoveries of Daguerre in, 1839, in relation to the transference of images to plates. Daguerre had worked fifteen years before he had made these discoveries. The speaker next detailed the various experiments by which it was found possible to transfer images to plates, and the means by which photography, one of the foremost and most beautiful discoveries of the nineteenth century, had arrived at its present state of perfection. With photography time had worked many changes. Several new processes had been discovered since 1839 for the transference of images to plates, some to only sink into the sea of oblivion, and others to remain until ousted by more improved methods still. Continuing, the lecturer pointed out the methods by which the art is now worked, and concluded amid applause. The remainder of the programme consisted of magic-lantern views and musical selections, followed by refreshments. Miss Ruthven opened the musical part of the proceedings with a pianoforte solo, given with much acceptance. Miss Ferguson and Mr. W. J. Erskine gave a duet, "O that we two were Maying," very creditably. Miss Brien was successful with her song, "For the sake of the past," and was accompanied on the piano by Miss Ruthven, Miss Mabel Brien playing a violin obbligato with taste and finish. A number of comic songs were contributed by Mr Arthur James, and, needless to say, drew forth flattering tokens of approval. The magic-lantern views from handsome slides by Messrs. Victor Smith (Secretary of the Society), J. H. Gane, A. C. Ruthven, A. W. Geddis, and J. Keogh, proved a pleasant item on the programme, and unmistakably showed the perfection to which the photographic art has been brought. Tea, &c., brought an enjoyable evening to a close. Professor Scott and Mr. Geddis managed the lantern.

1896.	FORTHCOMING EXHIBITIONS
Oct. 23-Nov. 7	Photographic Salon, Dudley Gallery, Piccadilly. Alfred Maskell, Dudley Gallery, Piccadilly.
,, 23-Nov. 12	Royal Photographic Society. R. Child Bayley, 12, Hanover-square.
,, 26-31	Southport Social Photographic Club.
November 12	Dulwich Photographic Society.
,, 17-20.....	Hackney Photographic Society. W. F. Fenton-Jones, 12, King Edward Road, Hackney.
December 3, 4.....	Aintree Photographic Society. E. P. Heron, 2 Tilney-street, Orrell Park, Aintree, Liverpool.
,, 28-31.....	Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.
Dec. 1896-Jan. 1897	Bristol International. Hon. Secretary, 20, Berkeley-square, Clifton, Bristol.

Correspondence.

PRINTING UNDER GREEN GLASS.

To the EDITORS.

GENTLEMEN,—Seeing in your issue of last week a letter about the colour of albumen prints made under green glass, I beg leave to enclose two prints from a negative of a monkey, the grey one printed under green glass, the brown one in the ordinary way. The grey print became grey during printing, and did not change colour at all during toning. The paper used for both prints was from the same sheet of Edwards's double albumenised paper, and toned in the same bath.—I am, yours, &c., S. A. A.

October 15, 1896.

[The grey print, compared with that having the brown tone, is flat and lacking in detail.—EDS.]

RE "NOTES ON RADIOGRAPHY."

To the EDITORS.

GENTLEMEN,—I read with much interest Mr. Hall-Edwards's experience with the X rays, and observe that he would like experimenters to communicate their own experience in this direction. Your readers may be interested in knowing what effect a shock from a ten-inch spark may produce when accidentally taken through the hands. Whilst engaged on Röntgen X rays at Earl's Court Exhibition a month or two back, I was unfortunate enough to get a severe shock through the hand whilst engaged in putting on a tube, an official standing at the coil attending the switch. The shock at the time showed no ill effects, but about a week afterwards my fingers on left hand, where I felt it most, began to swell and look very purple. My doctor told me to run cold water freely over the hand, but I found this only caused a further apparent inflammation.

Of my own accord, I began to poultice with hot linseed, and got relief. I should have said that, during this swelling and inflammation, a burning pain was constantly present, and, of course, stiffness of the hand and fingers. The poulticing soon gave ease, however, and on the back of the fingers there came large blisters, which filled with a watery fluid, so that each finger was double its normal size, or, rather, thickness. The blisters gradually gave out, and had a tendency to dry up. By degrees I peeled off the blister skin, and found a new, pink-coloured skin had formed underneath. All this time—some three weeks or so—I had to keep my hand tied, as it was not only unsightly, but tender, and somewhat painful. I don't know if any similar experiences have been met with, but this is the effect it had on myself.

Another curious thing that happened was that five or six tubes—which had all done a fair share of work—one day refused to give us any effects. I did not know of the method of reversing the current for some time through the tube, but put it down to air having worked in, as the tubes gave out a violet ray when the current was turned on; probably the effect may have been due to atmospheric change, or non-uniformity of the electric discharge. Mr. Hall-Edwards mentions barometrical influences, and, if he will take the suggestion, I fancy dampness directly a great source of trouble, as the sparks would often fly round the outside of the tube instead of passing through; but this, I suppose, he has noticed.

Plates would often be over-exposed in dry weather, and underdone on damp or rainy days. I will conclude by saying that there were many curious things I could mention, but am afraid space cannot be afforded, so must thank our Editors in anticipation, and hope that what I have said may not be altogether unprofitable.—I am, yours, &c.,

101A, *Fulham Palace-road, Hammersmith, W.* F. G. WILLATT.

AMATEURISM AND PROFESSIONALISM.

To the EDITORS.

GENTLEMEN,—I wrote "Dogberry," and he was good enough to say in your JOURNAL "it was a very reasonable letter." I wrote again, and this time he says he has got another "rather rambling letter" from me, and he has found that I do cabinets too cheap, but he does not notice that it is on account of the *false amateur* taking away my work. I think that even the quarter of a loaf is better than no bread, and, if any of my brother professionals are not pleased with my way, I have only to say, Perhaps my method of conducting business is as good as their own. But "Dogberry" complains of some other professional charging too high a price for his pictures. Who set "Dogberry" up as judge? Was it this thing he calls common sense? But, if you, Mr. Editor, would give me fair play, you would put my letter in full in the JOURNAL. I dare say "Dogberry" will give it to you.—I am, yours, &c.,

ARCHIBALD ROBERTSON.

88, *Glassford-street, Glasgow, October* 16, 1896.

[We shall be happy to print the letter referred to.—EDS.]

"THE POOR CHEMIST."

To the EDITORS.

GENTLEMEN,—"Dogberry" does me too much honour. I have no wish to pose in any degree as a champion of the Pharmaceutical Society; far from it. I wrote, firstly, to point out certain inaccuracies and absurdities; secondly, because I was sorry to see signs of ill feeling between two bodies so closely allied (looking at it broadly) as chemists and photographers. I have, in common with a good many other people, a great dislike to half truths and one-sided statements, also to persons like "Medico" foisting, as new and original, old jokes and legends which have been known in the trade for many years. I heard that "ill-Evans" story at least ten years ago; but life isn't long enough, or the days are too short, for this kind of work. I can only wish some of your readers and contributors could have a few weeks behind a busy drug (?) counter.

The Society was in the right over those Edinburgh cases; but, while prosecuting Mr. Hume, they pass over another firm of photo *chemists*, equally eminent, who have had no qualified assistant for years! What is sauce for one, &c.

I must confess I do not appreciate, as perhaps I might do, the principles which are supposed to actuate the Pharmaceutical Society. I believe their chief aim is to improve the status of the pharmacist. The results of the last examination read as follows:—Candidates examined, 164; *failed*, 114; passed, 50! This shows that the meshes of the pharmaceutical net are pretty fine. The list of "restricted" drugs and chemicals remains practically at the same point as in '68. The bulk of the "dispensing" is done by the doctors, some of whom are not above private clubs of their own, something after the style of the club portrait business you know. Life assurance schemes, burial funds, and an occasional bean feast, form, so I am told, part of the general scheme. All very high class and professional, as you will perceive! Then, again, practically all pharmacy—that is to say, the preparation of drugs, tinctures, extracts, and so on—is done ready to hand by the wholesale firms. So that in a great many instances a "penny in the slot" machine might very well take the place of the average *chemist!* the quasi-scientific, semi-professional, up-to-date product of the Pharmaceutical Society.

All this accounts, naturally, for the fact of so many chemists being chemists only in name.

I ask your sympathy once more on behalf of the poor chemist.—I am, yours, &c., J. PIKE, *Chemist and Dental Surgeon.*

Nottingham.

To the EDITORS.

GENTLEMEN,—What a pity it is that some of your correspondents will write such erroneous statements about the Poisons Act!

I notice that Mr. H. Bennett, in his letter to you, says: "It is not educational attainments at all, but membership of the Pharmaceutical Society, that qualifies the man to sell poisons" May I be allowed to inform him, firstly, that educational attainments are necessary, legally; and, secondly, that membership of the Pharmaceutical Society is quite unnecessary. Also, let me add that five-sixths of the whole body of chemists are *not* members of the Pharmaceutical Society, and that a large majority have not the slightest connexion whatever with the Pharmaceutical Society, beyond, of course, the fact, that the Society has at some time or other examined them, and keeps a register of their existence. I observe that "Nemo," in his last letter to you, still continues to wander along the devious paths of romance instead of keeping to the beaten track of fact; but, at all events, I am glad to notice that the exceedingly offensive tone which marked his former letter has not been employed. I am sorry that he has to complain of his being called a liar; but, if he stigmatises a whole body of men as rogues, what can he expect?

With regard to his statement in your last issue, why does he use the expressions, "Is that correct or not?" "I understand that," "apparently," "I should very much like to hear some one else's opinion?"

Why, on earth, does he not take the trouble to find out all about these little things before writing about them? Every sentence that he has written plainly shows that his letter has been composed by one who knows scarcely the outlines (let alone the details) of the subject which he discusses with so much fervour.—I am, yours, &c.

October 16, 1896. A PHARMACEUTICAL CHEMIST.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2, *York-street. Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

J. W. Gavin, 85, St. Giles, Norwich, Norfolk.—*Photograph of Rev. Canon Arthur Charles Copeman.*

H. C. Parlow, 25, Chapel-street, Hythe, Kent.—*Photograph of Sketch entitled,* "*A Vision of a Night at Hythe.*"

RECEIVED.—VICTOR THOMAS; CHLORO-PLATINATE; AN ANXIOUS INQUIRER; C. FRYATT; G. PRESTON, and others. In our next.

STUDIO.—R. A. L. P. H. So far as one can judge from the plan, there would be no good in putting a window where suggested; indeed, it would be harmful, as introducing more front light, and there is too much of that already. Let well alone.

PAPER FOR COLLODIO-CHLORIDE.—S. WILSON. We do not know any one in this country who supplies a suitable baryta for this work in small quantities. It may, we know, be obtained in retail quantities from either Romain Talbot, Berlin, or Liesegang, Düsseldorf.

RELIEFS.—MOULD writes: "Can moulds be cast in fusible metal from 'swelled gelatine' reliefs?"—No, not direct, as the heat of the metal, low as it would be, is sufficient to melt the gelatine. Plaster of Paris casts may be taken, and from them moulds in the fusible metal.

CARBON PRINTING ON ROUGH PAPER.—B. A. CAMBS asks: "How are carbon prints on the very rough paper one sees at the Exhibition produced? How is it possible to transfer the image from either flexible support or from glass on to that kind of paper?"—The prints are all, we believe, produced by the single transfer method. Double transfer is not suited for very rough paper.

ILLEGAL EXHIBITION OF PORTRAITS.—W. W. Certainly the father of the child can prevent you from exhibiting the portrait in the window, and, in doing so, will put you to unpleasant law costs. The best thing you can do is to remove the picture at once, and tender an apology. Your having gone to the expense of having the portrait enlarged and coloured is no affair of the parents.

LENS FOR LANTERN.—T. FORDEN. The No. 1 B lens will be the best amongst your stock for the lantern, though it is of a little longer focus than lanterns are generally fitted with. If you use the lantern, as you propose to do, for enlarging purposes, as well as for projecting, then the lens in question will be better than the regular lantern lenses, because its optical and chemical foci are coincident.

PHOTO-LITHOGRAPHY; PHOTO-ZINCOGRAPHY.—J. C. says: "I will feel grateful for the information, through your columns, whether there is any book published giving a full practical treatise upon photo-lithography. I would also like to know of anything on photo-zincography."—In reply: *Photo-lithography*, by G. Fritz (translated by Mr. E. J. Wall), published by Dawbarn & Ward, Farringdon-avenue, price 3*s*. We believe, the book also treats of zinco work.

WOODBURYTYPE.—T. says: "Can you refer me to any book on Woodburytype printing, or, failing this, to any account of it from which an idea could be obtained as to the cost of plant, &c., required to work it in its most modern form, and also working instructions?"—In reply: Messrs. Marion & Co., Soho-square, publish a *Practical Guide to Photo-mechanical Printing Processes*, by W. K. Burton (price 4*s*.), which possibly gives the information you want.

MOUNTS.—EDGAR SCAMMELL inquires: "Do you consider mounts fit for photographic use which, upon the application of moist blue litmus paper to their surface, turn same red in a course of a few minutes?"—We do not, if the redness is due to acid in the mounts; but, if it be due to colouring matter with which the mount is tinted, the case may be different. Colouring matter that may stain a wet print need not necessarily have otherwise an injurious action upon it.

DEFECT IN LENS.—R. SMELLEY. 1. There is not much the matter, it is only the glasses of the combination coming uncemented. Any photographic lens maker will set the matter right by simply recementing the glasses. Although this is a very simple matter, we should not recommend you to attempt the work yourself. 2. With regard to the chips on the other combination, they will do no practical harm, though it will be well to just touch them over with black varnish to avoid reflections.

FOGGY NEGATIVER.—ROGO says: "Is there any remedy for the fogginess of negative from which I enclose rough print? It was developed partly with pyro and ammonia, washed, and finished with pyro soda. I blame this change of developers to the fog, and, if you could say if anything can be done with it, I should feel grateful."—In reply: By carefully reducing with ferridcyanide of potassium and hypo, you may get rid of some of the veil. You would then, of course, have to intensify the deposit.

SAVING RESIDUES, &C.—DEVONSHIRE says: "A scientific gentleman gave me to understand that the print-out papers did not contain more than one half grain of silver to the sheet. Kindly give me your opinion in the matter in your next issue, as, if such is the case, the clippings are not worth saving, I at the present having not less than fifty pounds' weight of clippings."—In reply: We cannot at the moment lay our hands on precise information, but we think your scientific friend was wrongly informed. However, we should recommend you to keep both clippings and the wash waters before toning.

DYES FOR ORTHOCHROMATIC PHOTOGRAPHY.—HELIOS. Brilliant yellow can be obtained of Messrs. A. Leonhardt & Co., of Mulheim, near Frankfort-on-Maine. As to the other dyes, no doubt, if you address Mr. F. E. Ives at 119, Shaftesbury-avenue, London, W.C., he will give you the information you require. Sorry we cannot lay our hands upon it.

FERROTYPE.—C. CLIFFORD asks: "1. Can you give me a formula for a collodion emulsion that will give positive pictures (ferrotype dry plates, same as used in the simplex machines), or would the ordinary collodion bromide emulsion answer this purpose. 2. Where can I obtain gun-cotton?"—1. We do not know the formula by which the plates named are prepared, as it is not published. Probably one or other of the formulæ in the ALMANAC for the current year will answer with a little modification. 2. A suitable pyroxyline for collodion emulsion may be obtained from Messrs. Rouch, 161, Strand.

NATURALISTIC FOCUSSING.—GWYNFA says: "Last week I had the sight of some photographs, studies of draped figures with wood scenes for backgrounds, taken out doors. The great thing about them was, that they were all out of focus except the face. At a distance they seemed sharp, but, on examining same from the face, it crept away into a mist, thus giving a most striking effect. Can you explain how this effect is obtained?"—In reply: Probably the pictures were "naturalistically" focussed—that is to say, focally speaking, everything else was subordinated to the principal object. Possibly, also, a Dallmeyer-Bergheim lens was used.

ENAMELLING PRINTS.—J. G. MARTIN writes: "I have lately tried to enamel prints by squeegeeing on to plate glass, but somehow I cannot succeed because of dull spots over the print, which, I think, are caused by parts of it not adhering to the glass, and which I do not know how to remedy. Perhaps you would kindly let me know how to successfully treat them."—Our correspondent does not say what kind of prints he desires to enamel. However, perfect contact is easily secured if the print and glass are brought into contact under water. In the case of albumen prints, the glass should be coated with collodion after it has been French-chalked, and the print immersed in a weak solution of gelatine before it is squeegeed on to the plate.

CONSUMPTION OF GOLD IN TONING.—PRINTER writes: "My employer complains of the quantity of gold I use. He says his brother's printer only uses two-thirds of the gold I do for a given quantity of paper. I don't know how he manages it, because I know he cannot be more careful in working than I am. There is this difference in our prints (and that is the reason of my writing), although the same paper is used, and the same formula for toning bath, their prints are only toned to a warm brown, my governor will have purple blacks. Will that account for the greater consumption of gold?"—Yes. The deeper the prints are toned the greater must be the gold deposited upon them. Hence the larger consumption. Point this out to your employer the next time he complains.

DIAPHRAGM APERTURES.—FOCUS says: "I should be pleased if you could, through your valuable columns, explain to me the *f* method of photographic lenses. How is the relative value of stops calculated for lenses of various focal lengths, &c.? All my lenses were made before the *f* method was popularised, and, though I know exactly what each stop in each lens will accomplish, yet I am thoroughly at sea when my amateur friends with exposure meters, &c., mention, say, *f*-32, *f*-16, &c."—In reply: The matter is very simple: *f*-32 or *f*-16, as the case may be, simply means that the diameter of the diaphragm opening is one-thirty-second or one-sixteenth the focal length of the lens. According to the Royal Photographic Society's standards, *f*-4 is taken as unit; the next smaller is *f*-5·6, then *f*-8, and so on to *f*-11·3, *f*-16, *f*-22·6, *f*-32, *f*-45.2, and *f*-64. In practice, the exposure required with *f*-5·6 would be double that of *f*-4; with *f*-8, double that of *f*-5 6, and so on. If you require further information, write again.

LENS, SHUTTER, &C.—W. K. S. says: "I shall be greatly obliged if you can inform me if I can purchase a doublet lens for about 3*l*. or 3*l*. 10*s*. for my quarter-plate hand camera, and what would be the largest figure (portrait) I could get fully defined in shadow at ten, fifteen, or twenty feet, and who would be the best maker to go to? I should also be glad to know if I can use my present shutter, that works in front of my lens, and is detached from the lens, provided I altered the aperture to the size of the doublet worked at, or should I have to make the aperture still larger, allowing it worked, say, within a quarter or three-eighths of an inch of the lens?"—In reply: 1. For the price named, a good five-inch doublet may be obtained; but, as we never make recommendations of particular makes of apparatus, we are obliged to leave you to make your own selection. 2. Three inches, two inches, and one and a half inches approximately, assuming the figure to be five feet eight inches high. 3. A little larger.

ALUM AND HYPO; THE ARTIGUE PROCESS.—ALUM HYPO says: "1. About a year or more ago you published an article (an editorial, I think) giving the reactions which take place in an alum-hypo bath, that is, the products which are formed when alum is added to the hypo solution. Will you kindly give me the action again, as I am unable to locate the article? 2. Regarding the Artigue carbon process, is it patented in America? and, if so, can you give me the address of the patentee, or forward my letter to him? We, no doubt, could make it profitable for him if the process is all that is claimed for it. If it is not patented, can you say how it is made? 3. What is your opinion of it? I see very many contradictory reports of it."—In reply: 1. Can you refer to the JOURNAL of April 19, 1895, in which a very exhaustive article on the subject appears? 2. We do not know if the process is patented in America. Details of the preparation of the paper have not been published. We will ascertain M. Artigue's address for you by next week, so that you may communicate with him direct. 3. We have seen results on Artigue paper comparable to the finest platinum prints.

Contents.

EX CATHEDRÂ.

We are informed that an Exhibition of Photographic Portraiture will be opened at the Camera Club on Tuesday, November 2, and will be continued until Tuesday, December 8, inclusive. The collection will consist almost exclusively of pure portraiture, and will include some of the best portraits shown at past Exhibitions as well as newer pictures. Such an Exhibition should prove attractive, inasmuch as counterfeit presentments of famous men and beautiful women never fail to draw interested attention and comment, either from pictorial treatment of the subject or from the fame and personality of the originals. Contributions have already been promised by many well-known workers including Messrs. Cameron, H. P. & R. W. Robinson, W. E. Debenham, Craig Annan, Craigie, Walery, Lambert, Watmough Webster, Lyonel Clark, J. Stuart, W. Crooke, R. Faulkner, A. Ellis, E. Calland, T. Manly, F. Hollyer, and Mrs. Brian Hodgson.

* * *

The members of the Linked Ring gave, at the Dudley Gallery, on Friday evening, October 23, a smoking *conversazione*, inviting a large number of guests to partake of their hospitality. A short but entertaining musical programme was gone through. Mr. Malan and Mr. F. Nathan performed on the banjo, Mr. H. Clifford Bennett sang, Mr. Harting recited, and Mr. David Devant gave a shadowgraphic display. Mr. Maskell and the other members of the Ring present were assiduous in their attentions to the guests, among whom were Messrs. Francis Cobb, E. R. Ashton, Rev. F. C. Lambert, Messrs. Rowland Briant, Thomas Manly, Lyddell Sawyer, W. Crooke, Fred Hollyer, J. B. B. Wellington, R. W. Robinson, H. E. Davis, Valentine Blanchard, Lionel C. Bennett, W. L. Colls, G. H. James, R. P. Drage, Assheton Smith, H. Snowden Ward, Fleetwood Pritchard, R. B. Lodge, Major Lysaght, Arthur Allingham, C. E. Pearce, James Cadett, J. Bulbeck, T. Bedding, J. J. Acworth, A. J. Golding, W. Thomas, R. Child Bayley, F. Carruthers Gould, O. Huskisson, General Burlton, E. J. Wall, Chas. F. Robinson, Rev. J. R. C. Gale, Messrs. C. R. Rowe, G. Davison, Harvey Löhr, J. Fuerst, Horsley Hinton, Rev. R. Fowler, Messrs. E. Calland, A. Mackie, H. Hay Cameron, Wilson Noble, &c.

* * *

Photography in the Technology of Explosives is the title of a paper recently read before the Federated Institution of Mining Engineers by Mr. Alfred Sierch. The aim of the author was to utilise photography as a means of measuring the nature and intensity of explosive flashes, so as to confirm the generally accepted opinion that the safety of an explosive increases in proportion as the flash decreases. Mr. Sierch finds that photography affords a better means of determining the nature and manner of the decomposition of the explosive than either analysis or ignition tests, excluding, moreover, when carefully employed, all risk of error. Photography shows undoubtedly that each variety of explosive is characterised by its distinctive flash, this being especially manifested by photographic pictures obtained in the case of two different explosives suspended one above the other and ignited simultaneously. This fact by itself, he adds, indicates a certain regularity of decomposition and invites one to a closer investigation. To the expert it foreshadows the possibility of obtaining a clearer insight into the value of an explosive material, it being important to him to ascertain in the quickest manner the action of the individual constituents, the correctness of the method of preparation, and the influence of the different mixtures. To the mining engineer it will afford a ready means for convincing himself in the simplest manner of the relative security of the explosives employed, as few collieries are provided with

an experimental gallery suitable for making experiments with explosives, and, moreover, such tests occupy much more time than is required for taking a photograph.

* * *

Mr. Sierch then goes on to detail the results of a number of experiments in photographing explosive compounds, thirty-three excellent collotype reproductions from his negatives being appended to the paper. A sketch of the photographic installation is given, from which it appears that Mr. Sierch's method of working was to place the camera on a studio stand behind a wooden partition, a small movable frame providing an opening for the lens. The camera was situated about seven feet from the suspended cartridge. The photographs were taken at night time, the cartridges being electrically exploded. We have no doubt that to mining engineers Mr. Sierch's singularly successful results will be instructive and valuable.

* * *

Messrs. W. Watson & Sons, of 313, High Holborn, inform us that they are about to put on the market a very much improved form of focus tube, in which the electrodes are widely separated, so that there is no chance of sparking between them outside the tube; also, by a simple device, the whole of the cathodic stream impinges upon the platinum anode, and a special metal is used by means of which hydrogen is stored, and when the tube gets high in vacuum it is only necessary for it to be warmed by a spirit lamp for it to be at once brought to the desired pitch of exhaustion. Messrs. Watson state these tubes are much more brilliant than any other form that they have yet seen.

* * *

Mr. C. P. Goerz, of Berlin, the maker of the well-known double anastigmat lenses, was recently the recipient at the hands of the German Emperor of a gold medal presented by the State for industrial progress.

ACETYLENE AND THE FIRE INSURANCE COMPANIES.

We deem it advisable, in the light of the result of certain inquiries we have been making, to expand the remarks we made on this subject last week, and to utter a word of caution to our readers. Those who are professionally engaged in photography know too well the heavy burden the insurance offices lay on their shoulders. Photography, which nowadays, in its processes, actually involves less risk of fire than keeping a draper's shop, is treated as a hazardous risk, and photographers' policies carry twice or thrice the premium paid by the average insurer. It is most difficult to understand why it should be so; but, when the officers of the companies are interrogated, they say, in effect, that the heads of the societies or companies meet periodically to compare notes, and the result has been to show that so many claims have been made by photographers that the high rate asked is necessary. One reason they give is that, when a fire does occur, the losses are always heavy on account of the easily damaged nature of the stock. We can scarcely believe this. A few rolls of silk, for example, might represent many score of pounds, and a jet of water or the action of heat might damage them easily. Possibly ill luck usually attends the photographer in this direction. We know of one professional photographer who was so unfortunate as to have six or seven fires in the town of his adoption, and whose ill luck was so persistent that he had other fires again when he commenced business afresh in another town. As he appears now to be permanently residing abroad, where he went with some haste after his last fire, he would not have to be reckoned with. Perhaps the insurance companies have experience of other equally unlucky men in the photographic ranks. Be that as it may, our readers may rest assured they will not be able to enjoy the conveniences promised from the use of acetylene gas without paying for them.

The following two paragraphs are *verbatim* extracts from one of the leading organs of the insurance interests, and nothing stronger could well be said:—

"The Latest Danger.

"We have warned our readers several times against the dangers of acetylene gas, and following close upon our prophecies comes the record of terrible explosions which have taken place both in Paris and in Lyons. By some accident, either by a blow or the breaking of a screw, the contents of a cylinder were resolved into their original constituents, hydrogen and carbon. Two men were instantly killed, and every window in the factory was smashed to atoms. This acetylene was used for lighting purposes. It is produced by lime and carbon, through the intermediary of the electric furnace, forming carbide of calcium. It is highly explosive and excessively dangerous, and fire insurance companies had better take instant steps to protect themselves against this new danger.

"The second accident was at a café at Lyons, where the place was entirely wrecked, and the proprietor and his wife sustained dreadful injuries. The explosion was due to the defective fittings of the café where it took place, acetylene being used for producing the light."

"The Latest Explosive.

"We observe that a large industry has been created in the manufacture of carbide of calcium, which is, so to speak, the reservoir of acetylene gas. We have had objections of a more or less pronounced character to gasolene, naphthaline, and the various forms in which the refined products of petroleum have been used in this and other countries, but, of all the dangerous chemical compounds which have ever been submitted to the ordinary householder or the commercial man, there is nothing that can even distantly approach acetylene gas. We consider this is, without exception, the most dangerous compound that has ever been introduced to the notice of the public in the character of an illuminant, and we think that its use should be absolutely debarred by fire insurance companies under any and all conditions, at least for the present. The adoption of acetylene gas for illuminating purposes should promptly render any risk uninsurable, no matter of what class. This is all we have to say on the subject at present, but what we say is written after due deliberation and with full knowledge of the subject."

As there is every probability of numerous attempts being made during the winter to utilise the enormous advantages possessed by the new illuminant, we put ourselves in communication with a few typical insurance offices in London and in the North; they were the Phœnix, the Sun, and the Manchester Fire Insurance Company, and we stated that their replies were for publication, in full or in abstract, in these pages. The letters are very unsatisfactory, and are appended below. We selected the three companies named as being offices of large and representative businesses. Of course, there were dozens of others that would have answered our purpose equally well. Our questions asked, What position the offices took with regard to the use and manufacture on a small scale of acetylene gas, &c., and

whether their existing policies would permit its employment, or the storage of small quantities of the calcium carbide?

The reply from the Phœnix reads:—

"In reply to your letters of the 19th and 21st inst., we beg to state that the offices generally do not like the use of acetylene gas."

From the Sun we have:—

"I regret that, as this subject is still under the consideration of the offices, I am not in a position to give a definite answer to your inquiry. For myself I may, however, say that, so far as I have gone, I incline to the opinion that, with certain safeguards relating to the place where the gas is made and to the storage of the carbide, the use of acetylene gas is not more hazardous than that of ordinary coal gas."

The Manchester Fire Insurance Company say:—

"Acetylene Gas.

"As a safe means of using this gas as an illuminant does not appear to have been yet discovered, our office are not at present prepared to allow its use on premises they insure."

No words of ours are needed to point the moral here. It is perfectly evident that, if any photographer use or make acetylene gas, he does it at his own risk. If its use should be attended by any untoward event in the shape of a fire, he would find it difficult, if not impossible, to obtain redress from the office he was insured in, and that, if he received any compensation at all, it would in all probability be in the nature of a compromise, and would not cover the amount of his losses.

In conclusion, therefore, the advice we would give to every photographer who contemplates experiments with acetylene would be that, before commencing any work at all, he should call in a representative of the office he is insured in, show him the apparatus to be used, and ask for official sanction to use it and to store a specified amount of carbide under whatever conditions of storage that may be required of him. This obtained, he should have his policy endorsed with the company's permission.

Beyond that, there is no room for us to say more, and we earnestly trust our remarks may not fall on deaf ears.

The Future President of the R.A.—The question that is now exercising the mind of the Art world is, Who is to be the new President of the Royal Academy? This question, if not actually decided, will, at least, be discussed at the general assembly of the Academy, which takes place next week. The general opinion seems to be that Mr. Val Prinsep is "first favourite," and Mr. W. B. Richmond second. Many artists, however, think the honour should go to Mr. Briton Rivière. It is said that it is the first-named gentleman's social position, rather than his artistic abilities, that has secured him the probable distinction. Whoever is elected as President, it is to be hoped that he will enjoy the honour longer than did his predecessor, the late Sir John Millais.

A New Fraud.—We have often had to expose impositions in connexion with photography—the coupon frauds and the free-portrait business, for instance. The latest thing is that of a man named Mayers, who was last week charged at the Reading Quarter Sessions on ten counts with obtaining money under false pretences. His dodge was to advertise to send a handsome enlarged portrait, and a free coupon, for a word-counting competition, to every one who would send him a small portrait and 7*s*. The first prize was to be 1000*l*, the second a villa worth 500*l*., and no end of prizes of less value. Some coupons were sent, but no handsome enlarged portraits. Mr. Mayers will have no opportunity of executing orders for some time to come, as the Court sentenced him to eight months' imprisonment. It is extraordinary how easily the British public is "gulled" in connexion with photography.

Another Application of the X Rays.—At an inquiry, last week, as to the cause of the death of a person who had been attended for cancer by an alleged specialist, the question was again raised as to the genuineness of a diploma that was produced. While questioning one of the witnesses as to some clear, and some "blurred," names upon it, the Coroner (Mr. Braxton Hicks) remarked to him, according to the reports in the daily papers: "I may tell you that we have had the Röntgen rays through it, and so we know all about it." The Coroner then produced a photograph of the certificate, which showed that there was, or had been, some old writing under the names. It is further stated that "the Röntgen rays showed that the parchment, where the names were written, was particularly thin, as if something had been rubbed out and other names filled in." It is a little difficult to conceive, from the reports of the case, what has been achieved by the Röntgen rays that could not be as well done by ordinary photography. The parchment was thinner where the erasure is said to have been made than in other parts, and that is precisely what photography would have revealed, as well as a difference in colour of the two inks. By the way, is not parchment, thick or thin, transparent to the Rontgen rays? We should like to know a little more about the application of the rays, in this instance, than is given in the reports that have appeared in the daily press.

The Pharmaceutical Society and its Prosecutions.—Judges who have to try the vexatious actions so often brought by the Pharmaceutical Society, or Trades Union, have frequently expressed regret that they have no option in the matter, but must impose the five-pound fine. They sometimes, however, emphasise their expressions by refusing to give costs, or reducing them to the lowest possible point. The Society recently proceeded, in the Sheffield County Court, against a firm of wholesale grocers for selling a bottle of Teasdale's chlorodine, because it contains a trace of morphine. When Judge Waddy gave judgment, which he said he was obliged to do in favour of the plaintiffs, he reserved the question of costs. Subsequently he found that costs must follow, and he cut them down to the lowest possible, remarking that he gave costs because he was compelled to do so; had he the power, he would not do it.

In all these prosecutions the penalties and costs go to the Pharmaceutical Society, who make a good thing out of them, and also the fines paid them to avoid proceedings. How different is the case with the medical profession! At the meeting of the Incorporated Medical Practitioners' Association, on Thursday, last week, Mr. Geo. Brown, in advocating the amendment of the Medical Acts, said that the Incorporated Society should have the power to prosecute every unqualified practitioner; and also that the fines should go to the Council, and not to the police, adding, that it was unfair that medical men should be called upon to pay all the expenses in connexion with the prosecution of those who were practising illegally. It is pretty certain that, if the Pharmaceutical Society was situated as the medical profession is, as regards the fines and costs, we should hear far less of their vexatious prosecutions, alleged to be instituted for the safety of the public?

The Druggists' Trades Union naturally feel aggrieved that the public are aware that proprietary medicines having the Government stamp are the same, whether purchased at the grocer's or the oil shop for ninepence or tenpence, as they get them from the registered pharmaceutical chemist for one shilling and three half-pence. Hence, if one of these medicines happen to contain ever so small a trace of one of the things named in their Act, they are at once down upon the seller. However, the larger proportion of the patent medicines do not contain any of the scheduled articles, and they can therefore be vended by any one, and the Pharmaceutical Trade Union are helpless in the matter, so far. But now the druggists are trying to bring pressure to bear on the manufacturers, to prevent their goods being

sold at the prices they now are at the oil shop and grocer's. If they do not do this, will they be boycotted?

At the Lambeth County Court a shopkeeper was recently mulct in a penalty and costs for selling a small quantity of oxalic acid, and also for using the words "consulting chemist" on his facia and on his labels. What say ye to this, ye F.C.S.'s? A man, whatever his qualifications, must not, according to this obnoxious Act, use the word "chemist," unless he is registered by the Pharmaceutical Society, even when it is prefixed by such terms as "photographic," "consulting," &c. Some of our correspondents have claimed that it is for the safety of the public that the Act was framed. But how often are registered chemists censured for the careless way they have vended poisons to suicides, and for not complying with the law; though who ever heard of the Pharmaceutical Society taking action in the matter against *them?*

FOREIGN NEWS AND NOTES.

Platinotype Printing.—Herr Joé points out, in a recent number of the *Photographisches Woehenblatt*, that, for the hot-bath process, fairly dense negatives are required, whilst for the cold bath much thinner may be used. For obtaining more brilliant pictures, he states that the hot-bath developer should be diluted with from two to six times the quantity of water, or else two to five per cent. of a one per cent. solution of potassium bichromate should be added. The cold bath is to be preferred, and, by warming the developer, much warmer tones are to be obtained. He ascribes the yellowing of the paper to the combination of the iron salts of the sensitising solution with the fibres of the paper, and states that old paper always gives yellow whites.

The Chemical Intensity of Light.—An important paper has just been presented to the Vienna Academy of Sciences by Professor Wiesner on the chemical intensity of light. The process adopted was very similar to the photographic method of Bunsen and Roscoe, and it seems from his report that the greatest chemical activity of the light is not always at noon, but sometimes even as early as eleven a.m., and, further, that at Cairo, even with a perfectly clear sky, there was a strong depression of chemical power. Taking the paper all round, it may be assumed that the generally accepted theory of the greater actinic power of the light is that it is in the morning, and, whilst at corresponding times in the evening the light is poorer, it agrees with the results obtained by Professor Wiesner.

A New Application of Photography.—Mr. Poulson, of Bay Ridge, New York, has built for himself a new house, which, should it be followed, would open up yet another new field for the application of photography. The new house is built entirely of metal, iron, with copper as the decorative material, and most of the decorations are produced by galvano-plastic methods. As this metal can be deposited upon reliefs produced by photography, it would be decidedly a big thing for photography to have our houses decorated by galvanoplastic plaques, tiles, &c., from photographs from Nature, or copies of well-known pictures, frescoes, and other decorative objects. Naturally, one wonders whether iron would stand the weather. Some years back, the lay journalist said aluminium houses were to be the next development in "Hausindustrie."

Photographic Bas Reliefs.—The examples of bas reliefs, shown recently by Mr. Taber at the Hotel Cecil, in the Strand, remind one of the old methods of photo-sculpture, and the more recent methods of making not only bas relievo, but also intaglio plaques, a process for making which was patented not long ago. But there is one method of making bas reliefs by photography which has received but little notice, and yet which might be exceedingly useful. Every visitor to the Natural History Museum at South Kensington must have noticed the casts of fishes, and other reptiles, many of which are not quite so perfect anatomically as they might be. Why not, then, adopt the suggestion, recently made on the Continent, of making radiographs of the internal structure of fishes, birds, and suchlike creatures, printing from the negatives thus obtained on a thick film of bichromated gelatine, and after treatment with water, to dissolve out the soluble gelatine, and cast into the mould thus obtained liquid plaster of Paris; or the mould might even be used for producing galvano-plastic deposits of copper?

Keeping Developers Indefinitely.—M. Hombló, a well-known amateur of Antwerp, has added yet another terror to photography. Some amateurs, not content with a developer which will keep for a week or two, have devised certain formulæ which will keep their developing power for months. Now, M. Hombló, recognising that oxygen is the enemy that has to be combated, suggests adding to every bottle of developer a small piece of calcium carbide, which would give off acetylene, which would naturally drive out the air and fill the bottle with C_2H_2, in which the developer will keep for ever and a day. Might one not ask what becomes of the calcium? would it not form calcium carbonate, supposing that an alkaline carbonate were present, and thus set free a caustic alkali, which is not always desirable? and, *de plus*, is not acetylene, *per se*, a reducer of every silver haloid? We think so.

A Simple Combined Bath.—For some time the tendency in toning baths for gelatino-chloride paper has been towards the simple sulphocyanide and gold bath, and many and virulent have been the attacks on the combined bath. Analysing these, one comes to the conclusion that practically the lead, alum, and acids are the chief enemies against whom these attacks have been levelled. Now comes Dr. John Nicol, of the *American Amateur Photographer*, to the front and couches his lanse in favour of the simple combined bath composed of A, hypo 400 grains, water 3 ounces; B, chloride of gold 1 grain, water 1 ounce; add B to A. In this the prints tone readily, and merely require a bath of salt and water and washing after to be permanent, but he spoils the whole thing by saying that the prints need not be washed first. It is generally understood that all gelatino and collodio-chloride papers contain free organic acid, such as citric or tartaric as preservative. Might one ask whether these would not decompose the hypo, giving rise to the formation of silver subsulphide, so called by Bothamley, which is generally called sulphur toning?

ON PHOTOGRAPHING OIL PAINTINGS, WITH SPECIAL REFERENCE TO STRAMONIUM AS COLOUR SENSITISER.

[American Journal of Photography.]

We think it may safely be said that nothing in the whole range of photographic practice presents more difficulties than copying of oil paintings if one has desire to correctly render the colour tone values of the originals.

We remember the expedients had recourse to in the days of wet-plate supremacy and the dissatisfaction at the results when compared with a fine engraving from the same subject.

We were compelled to acknowledge the victory of the graver over the sunbeam, pleading the limitations of our art in extenuation, and secretly sighing for some process which might translate more literally the delicacy and depth of relative tone.

We forget the exact date, but know it was early in the history of photography that Becquerel showed that chlorophyl made plates from one-fifth to one-tenth as sensitive to red of the spectrum as to the blue or violet.

Then Mr. Tres and Dr. Vogel followed with their important discoveries in orthochromatic photography.

We remember employing these colour sensitisers and also the yellow screen, but our results were of a rather flat, tame, and unprofitable (especially commercially) nature and abandoned, having to content ourselves and our patrons with smudges of dark for the brilliant red, yellows and greens of the painting, and pleading that all blues took light and without detail or gradations.

When gelatino-bromide plates attained supremacy we were rejoiced to see that the bromide of silver more correctly translated the adactinic rays than iodised collodion. Though far from the true relations, yet often when the exposures were prolonged and very sensitive plates used behind a yellow glass screen, excellent results followed in particular cases, even without staining the film, and we were presumptuous to maintain that the claim to orthochromatic effect was a scientific delusion. But further experience convinced us of our error. We found that the yellow screen and plenty of time did not always give us the wished-for results—merely a flattening of the blue and violet portion of the painting and a general tameness of the whole.

There is no truth in the assertion sometimes made by superficial observers that the yellow screen alone will produce as good results as the combined action of the screen and sensitiser.

Now, if it is at all necessary to preserve in the copy the correct values of the painting to give an idea of its artistic qualities, orthochromatic and orthochromatic plates only can be used till we find some other method.

We have been shown prints from negatives of oil paintings declared to have been made on ordinary brom-silver-gelatine plates, with no other expedient than the interposition of colour screens.

Possibly and probably they may deceive those for whom they are intended, who look only at the final results and care nothing for the means, but it does not require much photographic experience or even the

best of eyes to detect the work of the retoucher, an elaborate work which must have taken hours to do and have cost considerable money to effect upon the negative in approximating to the colour-tone values of the original. The fine stipple of the pencil could be detected with very slight magnification.

We have seen two to three dollars' worth of retouching made upon a four by five negative. We think photography can claim but little share in the successful result; at least the colour screen can demand small thanks for the contribution.

It is hardly just to seek to nullify the triumph obtained by patient investigation, by assertions of having no truth, and to seek to substantiate the declaration by falsifying results.

All honour to those who have laboured in orthochromatic photography, and all gratitude for the generous publication of the results.

Orthochromatic photography is an acknowledged fact, although not yet attained to perfection.

The majority of failures can be traced to careless or imperfect manipulation and from the employment of plates not freshly prepared.

To be successful orthochromatically, make your own plates just as you need them, handle them with the greatest care, in almost total darkness, and develop them under cover in the most subdued light, only occasionally looking at them to note the progress of development.

I have employed the orthochromatic plate especially for copying oil portraits, and for that purpose have found the following method most successful:—

Select a brand of plates of a high degree of sensitiveness and of a thickly coated emulsion. After thoroughly dusting the film, place it on a bath composed as follows:—

Strong ammonia	1 drachm.
Water	14 ounces.

Let it lie about a minute. The object of the immersion is both to soften the film, and also to render it more sensitive.

This operation must be done with the least ruby light possible.

After the plate has been uniformly moistened, remove it and drain the edges on bibulous paper. It is now ready for the colour sensitiser, which is made as follows:—

Alcoholic tincture of thorn apple	1 drachm.
Water	10 ounces.

Thorn apple is the ordinary Jamestown or Jimson weed which grows so plentifully on waste places, the Datura stramonium of the botanist.

I make use of the green burrs or seed vessels, macerating two in an ounce of strong alcohol over night, and employ 1 drachm to the 10 or 12 ounces of water. The plate is allowed to remain in this a minute or two, covered and rocked in two directions to ensure even absorption. The plate is then drained on blotting-paper and dried in absolute darkness.

I have found the stramonium solution superior to others in the rendering of the reds and yellows, and the blues, purples, and violets are rendered with much more detail.

Vermilion, Venetian red, cinnabar, Indian red, light red, carmine, rose pink, maroon, scarlet, cherry, garnet, crimson madder, pink and light blue are given with about the same intensity. Yellow, lemon, gamboge, cadmium, ochre, Naples yellow, orange, orange having about the same intensity as cobalt blue, violet and dark purple like light red. But the greens, both dark and light, are unaffected and no better than ordinary plates. Hence the process is of no value in copying landscapes where the green predominates, but for portraiture it is admirable, rendering the flesh tints excellently and the yellow and red or blue draperies.

I make use of a deep yellow screen placed behind the lens. The exposure is about ten to twenty times as long as for the normal plate.

Any of the ordinary developers can be used. I prefer the following alkaline pyro:—

A.

Sulphite soda	10 ounces.
Salsoda	5 ,,
Water	60 ,,

B.

Pyro	1 ounce.
Sulphite soda	1 drachm.
Sulphuric acid	15 drops.
Water	6 ounces.

For development, 1 drachm B to 1 ounce of A, and 4 to 6 ounces water.

The yellow screen is made by adding alcoholic solution of primrose yellow to plain collodion. The glass must be plate glass, to avoid distortion.

The process can be advantageously employed in copying old engravings which age has yellowed, and which present so much difficulty with ordinary plates.

I have not tried the stramonium sensitiser with the yellow light of petroleum without the screen. If the light of coal oil can be employed, the time of exposure can be greatly reduced.

Of course, there are devices for lighting the subject most advantageously, but the practical worker is well acquainted with them, as they are easily accessible to the amateur.

JOHN BARTLETT.

IS A YELLOW SCREEN NECESSARY IN USING ISOCHROMATIC PLATES FOR LANDSCAPE AND STUDIO WORK?

[Photographic Times.]

Of course, it is not *necessary*. The question, put more accurately, would be, "Is there any appreciable benefit in the use of isochromatic plates in landscape and studio work without a yellow screen?" The question is one that sounds as if a quite definite answer should be forthcoming at once, but it is not. Briefly stated, its present position is this: The makers of isochromatic plates all state that these have a distinct advantage over ordinary plates for landscapes (at any rate) without a yellow screen. A few of the users of them say the same, but I am not aware that these have made comparative tests with that accuracy that would be necessary to establish the claim. If asked how they know there is an advantage, the answer is generally something such as, "Oh, just look at that! I could have got nothing like that with an ordinary plate." But this is not enough.

As it seems to me undoubtedly the case that, *could it be fully established that isochromatic plates will show even a moderate advantage in landscape and portrait work without a screen, they would entirely supersede other plates*, it is worth trying to find what evidence there is one way or the other. It is only that bugbear, the yellow screen, that prevents photographers from taking to isochromatic plates for ordinary work as well as for special work.

In the first place, it must, of course, be at once admitted that, for sunset effects, or any kind of photography when the light is yellow, they show a decided advantage; but we are not considering these special cases, but rather the usual run of those in which the light is white.

A London maker of an excellent brand of orthochromatic plates has the temerity to send out as an advertisement two landscape prints—the same subject—one purporting to be printed from a negative on an ordinary plate, the other on an orthochromatic plate without yellow screen. I say temerity, because there is so *very* little difference between the two prints. If one did not look for it, he would not notice it at all. The distance *is* a trifle better rendered in the print from the isochromatic plate than in that from the other, but the difference is such as might arise from a slight difference in exposure or of treatment in development, or from a few minutes' interval of time between the making of one exposure and of the other.

I have myself *repeatedly* made comparative experiments between ordinary plates and orthochromatic plates without yellow screen, and have been able to find no advantage in the orthochromatic plates so far as the rendering of distances is concerned. Sometimes a slight superiority would be found in the rendering by the orthochromatic plate; but, on the other hand, the advantage would sometimes show with the ordinary plate. This has been the experience of all I have known who have made actual *comparative* experiments.

On the other hand, I have, at times, noticed a perceptible superiority in the rendering of foregrounds by orthochromatic plates without yellow screen, this particularly if the foreground includes many flowers.

It is difficult to see how it is to be expected that an orthochromatic plate without yellow screen can show any superiority over an ordinary plate in rendering distances. The plate is not reduced in sensitiveness to the blue—the blue rays are not cut off—and wherein is any advantage to be found in the increased sensitiveness to yellow? A plate is rendered many times more sensitive to yellow by orthochromatising; but, then, it is about many times nothing, and the sensitiveness to yellow is still but trifling.

So far as my experience goes, I can only say, with regret, that I believe that orthochromatic, or isochromatic, plates used without yellow screen have no advantage over ordinary in the rendering of distance of landscapes, and only a slight and occasional one in the rendering of foregrounds.

The same I believe to be the case in studio work, though my own experiments have been confined to portraits in the open air and in ordinary rooms.

Even with a yellow screen the results of landscapes on orthochromatic plates are often disappointing. Captain Abney has fully given the reason for this. On the other hand, there are many landscapes which are vastly better rendered by an orthochromatic plate with a yellow screen than on an ordinary plate without.

In portrait work, the improvement in results by the use of orthochromatic plates and yellow screens is so great that I am surprised professional photographers have not taken to the use of them generally. In the case of perfect moulding and a skin of the purest colour, without fleck or spot, they may show no particular advantage; but, with the ordinary run of sitters, the superiority of the results with an orthochromatic plate and yellow screen over those with an ordinary plate are greater than would be believed without trial. Not only is the necessary amount of retouching reduced—odd-looking lines and wrinkles come out less prominently, and shadows are less deep and harsh—but results superior to what could be got by any amount of retouching are to be had.

The increase of exposure, I suppose, is the cry against the system, and it is true that about three times the exposure is necessary with isochromatic plates with yellow screen than with ordinary plates without; yet see what portraits were made in the wet-plate days; and, even using an

isochromatic plate (rapid) and a yellow screen, the exposure will be at most one-tenth that with a wet plate.

When, I wonder, are we to have an orthochromatic plate *that includes its own yellow screen?* There is nothing impossible in this. I think it was Mr. W. B. Bolton who proposed that isochromatic plates should be sent out coated with yellow-stained collodion. This would, no doubt, be expensive, and better means might be devised, but landscape workers would certainly be willing to pay a high price for an orthochromatic plate including its own yellow screen. W. K. BURTON.

PAPER NEGATIVES.

"TURNING over the leaves of an old album the other day, I came unexpectedly across two souvenirs of the anxious days when, during the temporary absence of the Editor, I ran this *Journal*," says Il Pipistrello, in the *Journal of the Photographic Society of India*. "One of the relics was a whole-plate paper negative of the Burmese pagoda in the Eden Gardens, Calcutta; the other, a bromide print from it. Both were made by Mr. T. D. La Touche, and were sent me for criticism ten years ago. I do not quite remember what I said at the time, but I am certain that the negative and print could not have then inspired in me a tithe of the admiration they now evoke. Here they lie before me, after travelling round the world, as good as on the day they were made, exactly a decade ago. They take up no space, weigh nothing, and are practically imperishable. Can any one say as much for negatives on glass and albumenised paper prints? I confess I cannot. Of the hundreds of negatives made by me ten years back I have just two left, and my prints are represented by a yellowed album, which saddens me when I look at it, reminding me, as nothing else does, of the swift lapse of time and of the days that are no more. The negative bears the following data:—'Morgan and Kidd's Argentic bromide paper, Calcutta, July, 1886. Lens—Dallmeyer's Rapid Rectilinear. Exposure 2 secs. Light clear. 7 a.m. Developer, Pyro-ammonia." Held up against the light, the first thing that strikes me is the extreme fineness of the grain of the paper. The negative exactly resembles one on glass backed with matt varnish, and that it gives prints equal in *all* respects to those obtained from glass I have very satisfactory proof before me. Though the memorandum on the paper is yellow, the ink having lost colour, the print itself is indistinguishable from one made yesterday, and I defy any one to prove it is not from a negative on glass.

"I was thinking of turning my keepsakes into 'copy,' when the *Journal* for July came to hand, and hardened my half-formed designs into settled purpose. Mr. Newton is entitled to be heard with all respect, and I should not question his decision if he had given his reasons a little more clearly. He condemns paper negatives because, 'out of some hundreds taken there is scarcely one left in a printable condition.' He does not say why they are not in a printable condition. Very probably the paper is unevenly stained, but this defect arises from imperfect manipulation, and should not help to condemn a process. Then, also, Mr. Newton has been singularly unfortunate in his experience of the grain of the paper showing, of mould and of stains. Other workers know nothing of such troubles. The only valid objection brought forward relates to the difficulty of keeping the paper flat. Yes, this is a real difficulty when larger pictures than whole-plate are taken. But I think there is a good time coming for paper-negative workers, and that the home firm incidentally referred to in your editorial note has solved the problem. This stripping film has, I firmly believe, come to stay. At present the cut sizes of the negative paper do not go beyond whole-plate, but the makers would, on requisition, use stiff flat cardboard for larger sizes, the paper, of course, being removed after development, its only object being to keep the film perfectly flat during exposure. The film itself is composed entirely of photographic gelatine, and is practically structureless.

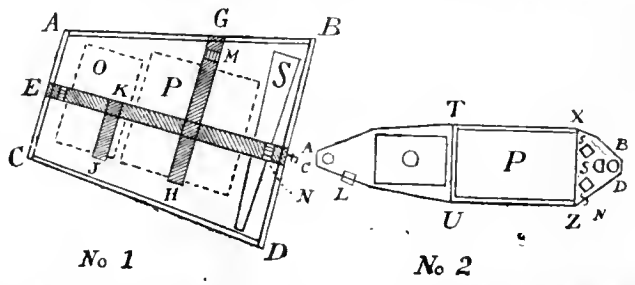
"Is it necessary to direct the attention of Indian workers to the claims of this film? In India you pay heavily for plates, because glass is so weighty—a packet of negative paper can be sent by post from England to India for a few pence. By getting it through the post you ensure the freshness of your film, and that is no light consideration in India. Then, not only is negative paper cheaper to start with than glass plates, but it is also not subject to breakage, is lighter than glass, stores in less space, admits retouching more readily, and is specially adapted to carbon printing. This last fact alone makes the film invaluable."

PHOTOGRAPHY AND THE BICYCLE.

IN answer to the article signed by Colonel J. Waterhouse, I would say, in regard to photography and the bicycle, that I have not given up altogether the idea of taking views while riding the bicycle and carrying my photo outfit with me. However, the weather is not exactly now what it should be. I have tried to improve on my former arrangements, and I have succeeded, at least, in regard to weight.

My principal aim was to reduce the weight, particularly on the front of the bicycle or handle bar. As you know that my aim is to take architectural subjects with perpendicular lines, I have to use a regular camera with rising front and a tripod; therefore an instantaneous hand camera is out of the question. I may add that I have been as yet unable to use the bicycle itself as a camera stand as being too unsteady and too low for general purposes. I have therefore made myself a camera for plates 7 × 5, which contains all requisites of lightness, with necessary adjuncts for taking architectural views, and cheapness (the whole outfit and twelve double dry-plate holders costing about 1*l.*). The whole outfit, less than four inches thick, including two double slides, fits easily inside the bicycle frame as well as the tripod, and weighs altogether, including two lenses, covers, and all, less than 9lb. I use glass plates, as much more reliable for good results, especially for enlargements, as films have an occasional bend, which is not conducive to sharpness when enlarged. You probably hear of some films which bend inwards, and some outwards, in the centre, while others have both effects at once, when these are not limited to a certain spot only.

I give you herewith a small design, which will give you an idea of my



new arrangement to carry my outfit inside the bicycle frame, and which is very light and solid at the same time. It is made of cotton strap about one inch wide.

A, B, C, D is the bicycle frame; E, F is a strap going all round front and rear tube, and closed by two buckles, L N, while at T U, and X Z, are two partitions, suitably placed to hold P, the camera in place and separate from S, the tripod, and O, another parcel (plates or extra holders). G H, with a buckle at M, holds the camera well suspended, and K J the parcel O. Where the straps cross each other they should be united. This whole outfit only weighs a few ounces, *and* may be used for any other parcels, the weight of which, being suspended from the top, always keeps it perpendicular.

You, of course, will understand that the design No. 1 shows the outfit from the side, and No. 2 from the top, omitting the cross bar and straps, which would interfere with clearness. I have made also a small package carrier to go on the handle bar, which weighs about ten ounces, but will leave this for another occasion. ALBERT LÉVY.

DRYING NEGATIVES BY HEAT.

THE patentee, Mr. Arthur Musker, states, "I apply heat, say, of a burner or lamp burning gas or oil, which acts upon a holder, base, or the like, containing or having upon it metallic plates, between which plates the negatives or photographs are adapted to be placed and held. In some cases, the heat is conveyed to such plates by having a hollow chamber or space between two metal plates, into which the gases for heating pass, or the heat may be conducted to such plates by the plate or part on which they are mounted, and to which heat is imparted by the lamp or burner.

"The action is that the plates between which the negatives or photographs are placed radiate the heat on to them to the required degree, and in a manner which renders the artificial drying by heat practicable, and without liability of in any way detrimentally affecting the quality of the negative or photograph.

"By this means negatives and photographs may be rapidly dried, and thereby the greater portion of the time they take to dry in, when dried in the ordinary way, saved."

Drawings and full description are also given, but the foregoing will enable the reader to grasp the method of carrying out the invention.

TAKING ANIMATED PHOTOGRAPHS: M. HENRI JOLY'S SYSTEM.

THE inventor, M. Henri Joly, after giving a detailed description of his invention, makes the following claims:—

1. A fold previously imparted to the film before its entering the dark chamber, the said fold remaining constant during the whole time of the displacement of the film, and thus enabling the abrupt movements, necessary for the operation of the apparatus, to merely act upon a non-extended portion of the film, and not upon the whole mass of the film.

2. In combination with the film hereinbefore claimed, two driving rollers for the film, actuated so as to receive a continuous rotary motion, and provided with two rows of points or teeth which enter into holes provided upon the edges of the film, so as to cause the latter to move along, one of the said driving rollers being placed near the magazine or

feed roller of the film, before the fold hereinbefore claimed is formed, and the other next to the dark chamber.

3. In combination with the fold imparted to the film and the two continuous driving rollers, as hereinbefore claimed, a frame actuated by a disc crank, imparting to it a to-and-fro movement, the said frame being placed beneath the dark chamber, and caused to act abruptly at equal intervals of time over the whole width of the film, so as to cause that part of the film which was previously located therein to rapidly leave the same, while forming, next to the dark chamber, a folded film to prevent the continuous driving roller from displacing that portion of the film which lies behind the dark chamber, while this latter is uncovered by the obturator (the said portion of the film being, at this moment, stationary).

4. In combination with the fold imparted to the film before its entering the dark chamber, the two continuous driving rollers, the frame with to-and-fro movement, an obturator opening the dark chamber during the stoppages of the film and closing the same during the displacements of the said film.

EXPERT TESTIMONY.

Within comparatively recent years there has arisen in our judicial system an apparent need for evidence bearing upon scientific questions requiring a knowledge not ordinarily possessed by the lay witness, and which is gradually being more and more supplied by the so-called "expert." He is paid to testify on behalf of one side or the other, and not infrequently is retained (says the *Electrical World*) to appear as often as cases arise in which his opinions are desired. That the most flagrant abuses in expert testimony have made themselves most prominent in criminal cases is perhaps to be attributed merely to the notoriety which these cases have attained. Whether it be the fault of our patent system or of our judicial system, the expert has become a prominent factor in all recent cases pertaining to patent litigation. It is not uncommon to find several experts on one side arrayed against perhaps as many more on the other, and, if each side has been able to retain men of practically equal prominence, that side having the greater number frequently produces no little effect on influencing the judicial decision. That men devoted to the interest of science should be willing to sell their opinions indiscriminately to either contending party, often being obliged to so modify their views as to make them harmonise with the unscientific but legal opinions of the counsel by whom they are employed, has become an evil which has justly brought forth criticism, must be acknowledged, and, unless modified or changed in some form, calls for future condemnation also.

In a contribution to the October number of the *Atlantic Monthly*, Professor John Trowbridge calls attention to the imperilled dignity of science and the law if the practice of indiscriminate scientific testifying is to continue. He points out the difficulty in which a Judge is placed when required to carefully weigh statements on scientific points; his attitude toward the scientific expert and the little regard he frequently holds for his opinions. He is therefore tempted to entirely ignore expert testimony, and rely upon his own common sense for framing his decision. The consequence has been that Judges may be classified under several headings, a classification based simply upon their legal decisions in the past, some being known as patent breakers and others the most strenuous advocates of broad patent claims. It is for this reason that suits are carried from court to court with the ultimate hope that a former decision will be reversed.

The result of this method has been well illustrated and can be vouched for by several of the larger manufacturing companies who have invested millions in this way during the past few years, with no immediate prospects of any material return on the investment. The chief benefit has been derived by patent lawyers and patent experts, while the stockholder has been forced to respond with the shekels. Professor Trowbridge does not, however, raise his criticisms without suggesting a remedy. It is to the effect that a Judge may call to his assistance any well-known professor of science not retained by the parties in dispute. The State should provide, and the Judge should appeal to the State for, such assistance, so that he might be aided in rendering a decision based upon scientific facts.

By this method both the standing of the bench and that of the professor would "gain in dignity, and the pursuit of truth will again be considered one of the chief characteristics of a scientific life." Whether the method suggested by Professor Trowbridge could be put in practice, and would be effective even if adopted, can only be determined by an actual trial. It is, however, well to call attention to these points, so that those who are tempted, merely from a pecuniary standpoint, to offer evidence on scientific questions, when such evidence would not be in entire accord with their best belief, may stop to consider the effective gain to be derived by so modifying their convictions as to make them harmonise with those of the contending counsel. It is not improbable that the day of the expert will soon be waning, and that the costly litigations of the past will not be duplicated in the future.

IMPROVEMENTS IN ALBUMEN PRINTING PAPER.

Herr Gustav Koppmann, the patentee of this process, says:—

"It is a well-known fact that the albumenised papers used for photographic positives lose their beautiful rose or bluish tint after a short time. Hitherto the proceeding consisted in mixing the corresponding colour solution with the albumen, covering the paper with this mixture. The colours used are the little light-proof aniline colours, mixing perfectly with the albumen.

"The above proceeding will be replaced by the following one of my invention, obviating the above-mentioned inconvenience by a more intimate combination of the dyeing material with the paper."

According to the proceeding of the applicant it is not any longer the solution of albumen which is coloured, the paper to be used being, on the contrary, evenly dyed with a layer of colour by an ordinary printing procedure. Hence the colour is brought into direct contact with the superficies of the paper, wherein precisely consists the innovation, and thus a possibility is given to employ a colour known as indifferent to light, thus, as, for instance, cobalt blue.

It is only after submitting the paper to this printing process that it is covered with albumen, and afterwards treated in the known manner, and then it is ready for being sensitised with the solution of nitrate of silver.

The above proceeding need not be limited to albumenised paper, but may be adopted wherever a constant ground colour is desirable for photographic positives.

The innovation of the proceeding consists consequently in the separation of the coloured solution, for the production of which a light-proof metallic colour, or any other as light-proof known suitable colour is made use of, from the albumen layer proper and its previous appliance.

The claim is for a coloured positive paper, wherein the coloured tint is produced by a light-proof coloured raw paper.

STEREOSCOPIC PHOTOGRAPHY.

[Abstract of paper read before the Sydney Working Men's College Photographic Club.]

Man has two eyes given him, and we may reasonably suppose, that however ornamental and beautiful they may be, and however wonderfully they act as windows for our inmost thoughts, and ofttimes speak more eloquently than lips or tongue, yet they were not made merely for ornament, but for use.

We need our eyes to see with. It matters not how lovely the landscape, how beautiful the form, how exquisite the colour; if we had no eyes, everything would be a sealed book to us, and, instead of being children of the light, we should have to spend our existence in endless night.

We need *two* eyes in order to see an object properly; hence, instead of being created with only one eye, placed, say, in our forehead, we are provided with two.

You will remember seeing on the screen the other night the eye of a fly. As he has so many things to look after and attend to, he has some thousands of eyes. We have, however, to be satisfied with two.

I have no doubt you have noticed the difference to be obtained by looking at a distant object through a telescope and an opera glass; in the one case only one eye is used, in the other two.

If we had only one eye, everything would present a flat appearance. We should not experience that effect of solidity we realise with two; and from an artistic point of view, at any rate, we know how very undesirable such a result would be. Hence it frequently happens that our photographs—when there is very little contrast of light and shade—when the light is not good, &c., have a very uninteresting, and, what is technically known as, a flat appearance.

Let any one try the experiment of walking up to a table with one eye closed, and snuffing a candle placed there. You will be rather surprised to find that, instead of performing that simple operation successfully, it will require one or two trials before you judge the right distance.

Or try to fill a tumbler placed on the same table under similar circumstances, and the chances are the water, instead of going into the tumbler, will flood the table.

Try the experiment of looking at an object first with one eye closed and then the other, without altering your position, especially some near object, and you will find that it presents quite a different appearance at one time to the other.

Hold up a photograph edgewise, look at it with one eye closed, and you are able to see the picture; close that eye, and open the other, you lose sight of the photograph, and see only the back of the card.

We really see objects from two different standpoints, in fact we get two impressions—a right-eye one and a left-eye one—in the stereoscopic camera with which each of us has been so wonderfully provided, and with which we are taking snap-shots every waking hour of our lives. The two pictures are then so combined by the mechanism of our eyes, nerves, and brain that they coalesce, and, instead of seeing double, the images are united; one picture is formed, standing out clear and solid in perfect relief.

This is just what the stereoscope does for photography. Instead of having a camera with one eye or lens, we have two lenses, really two

cameras combined, and so I say to my mind the stereoscopic camera is the most perfect of all.

The lenses are fixed about the same distance apart as the human eye, two and a half to three inches from centre to centre. The right lens takes an impression of the object from its standpoint, showing more of the right side than the left, and the left lens takes a view from its standpoint, showing more of the left side than the right, exactly in the same manner as our eyes. Thus two distinct pictures are obtained on one plate (two quarter-plates on one half-plate).

The stereoscope invented by Wheatstone, and perfected by Sir David Brewster, unites these pictures by means of two prisms arranged at a certain angle, and a stereoscopic view is the result. To a person who has never seen a stereoscopic picture, the first view is somewhat marvellous. Here you have two pictures apparently of no interest, seemingly perfectly unmeaning—a conglomeration of dark and light patches—and on looking at them you feel inclined to pity the crank who has produced a pair of such miserable-looking things; but place them behind the magic lenses of the stereoscope, and what a transformation!

In an instant the scene is replete with life. It is not a picture you are looking at. The reality is before you; the scene in all its details is there, everything stands out in perfect relief, everything is solid, everything real. You feel as though you had only to take one step to be in the midst of well-remembered spots, and linger long amid the beauties of hill and dale, mountain, plain, or river.

You can almost fancy you hear the breakers roar as you see them lashing in their fury the rocks at your feet; or hear the rippling rivulet dashing down the mountain glen, as it sheds its silvery spray on feathery fern and mossy boulders, murmuring its blithesome melody as it hurries to the sea; or listen to the music of the forest wild as you gaze on Nature's tangled wild-wood and peep into the lyre bird's nest in fairy dells; and scent the perfume of native musk and forest wild flowers as you see once more the mossy banks covered with delicate ferns, enamelled and bespangled in rich profusion with Nature's sweetest blooms; while, as you gaze on features well remembered, you feel it is not a portrait you are looking at, but the friend of long ago is there. You gaze into his eyes, and catch, as in days of yore, the merry twinkle lurking there, and hear once more the well-remembered music of lips long silent, which seems to float around you in notes of sweetest cadence, revibrating many a lost chord of fondest recollection, and thrilling with emotion the heart of each beholder.

We must leave our flights of fancy, however, and come to practical work.

There are three ways of practising stereoscopic photography.

1. To have a regular stereoscopic camera, and use it for that purpose only. There are many such in the market, and I need only refer you to a good catalogue, where you will find plenty from which to make a selection.

2. An ordinary half-plate camera, having a quarter or half-plate lens fitted into a sliding front. You first take a picture, say the right side, which fills one-half of your half-plate. Put on your cap, and slide the front two and a half or three inches; then take a view of the same object on the other half of the plate, having a partition down the middle of the camera.

3. An ordinary half-plate camera, having a separate front fitted with two quarter-plate lenses.

The plan I adopt is the third one. I have here a camera which I use for half-plate work of every kind. After taking my picture of a landscape, if I want a stereoscopic view of the same, all I have to do is to remove the front holding the single lens, and insert in its place the other front with two lenses. Then I place this diaphragm in, in a second, and I have virtually two cameras, my stereoscopic camera is complete. Thus, I really carry three cameras with me; and I can take half-plate, quarter-plate, or stereoscopic views. Very successful work *may* be done with one lens, provided the conditions of light, exposure, &c., be the same; but, to have perfect work, the two pictures must be taken at the same instant, thus necessitating the use of the stereoscopic camera proper.

Having your camera and dark slides ready, the manipulations of focussing, exposure, development, and printing are exactly the same as for ordinary photography.

In taking a stereoscopic picture you can leave your tomahawk at home, because what you would cut away to enable you to get a good view for an ordinary photograph will, in all probability, make a very interesting part of your stereoscopic view. A little more trouble is caused in mounting stereos than ordinary cards. It is necessary that the print taken by the right-eye lens is placed opposite the right eye, that by the left opposite the other one, when mounting them. I have a print here just out of the printing frame, and you see it is quite the reverse. This side was opposite the right lens, and this the left. It is necessary, therefore, to divide them, and mount on the card in such a way that the above conditions are fulfilled.

Before they are divided, it is best to mark them. I always put the letter R at the back of the half which was opposite the right lens, and then there can be no mistake, because, unless they are mounted in this manner, the stereoscopic effect will not be produced. If you were to mount two photographs taken by the right lens, or two taken by the left lens, no stereoscopic effect would be seen, nor would any such effect be had if two ordinary photographs be mounted on one card, and looked at through the *stereoscope*. You must have two distinct pictures, taken from two different positions, of the same object; and, however poor and tame they may appear, the stereoscope makes them instinct with life.

In mounting stereos, I use a piece of glass the exact width of the stereos—three and a quarter inches—and the length of the negative; in fact, I cut a negative to that width. I first place this on the print in such a position that I get a twig, or stone, or any object in both pictures in a straight line. I then trim the top and bottom to this width, thus ensuring that my pictures are in the same position. I next take two pieces of glass, three inches and a quarter by two inches and three-quarters, and place them on my prints in such a manner that they both cover the same object. It becomes then an easy matter to trim them to the exact size, when they can be mounted, making sure that the one marked R goes to the right.

The stereoscopic views can be printed on glass, in the same way as a lantern transparency. You can either have a single plate, five and a half inches by three and a quarter inches, or take two ordinary lantern plates, and bind them together after printing. I should like to say one or two words on the advantages of stereoscopic photography.

First, and chief, a more realistic picture is obtained, and greater pleasure afforded.

Second, the same picture can be used as an ordinary quarter-plate one.

Third, you have two negatives to print from for this purpose instead of one, which is an advantage if a number of copies be required.

Fourth, enlargements can be made from them very easily.

Fifth, the negatives are just the size for lantern transparencies.

T. C. Camm.

A NOVEL ETCHING PROCESS.

Travelling through Utah and on the way, I stopped at Salt Lake City, and during a conversation with a newspaper man, talking of engraving, he mentioned to me a new process just started in town by a party, of etching in onyx. This aroused my curiosity at once, says Mr. Chas. Chetham in *The Practical Process Worker*, and, wishing to see something of it, we hunted up the party and saw the affair. This onyx, to my view, seems to be only stalactites, and has not the many colours of Arizona onyx, and, being a lime formation, naturally has great affinity for acid. The onyx is produced in inexhaustible quantities from a mine near by, and easily cut and polished, which Arizona onyx is not. The slabs are cut type high and take a good polish, and can be produced at about ten cents per foot; the designs can be drawn on it or printed by the usual Bi Chr. Albumen solution only; for larger cuts the negative is coated with a heavier solution of stripping solution, for the reason that, instead of placing on glass reversed, it is squeegeed direct on to the sensitive coated slab, which is operated thus:—

The slab of onyx is laid on a level, and the solution is flowed over and excess drained off; it is dried by a gasoline lamp, like painters use, which throws out a long flame; this is flashed over the slab without touching with the flame and quickly dried; then it is rolled over with castor oil, and the negative gently rubbed down with the finger on a piece of woollen rag, absolute contact is secured, and no danger of breaking glass or the necessity of using printing frames. When exposed and ready for development, the film is lifted off and the oil removed with a rag saturated with turpentine; it is rolled up the usual way and developed, dried with a chamois skin powdered with dragon's blood, etched as usual, using nitric acid instead of muriatic, which is too violent in action. The etchings are effected by repeated rolling up and powdering. Of course, the four ways could not be used, owing to the nature of the material and difficulty of handling a thick slab, and poor conducting power, &c. The burning in is done with the same hand lamp and very quickly the etching proceeds till the requisite depth is secured. The close work is then stoppered out and the larger plans etched in strong acid. The router cannot be used, as the onyx is too hard and would quickly spoil the cutters, though the sand blast could be used to advantage if procurable. The slab can be cut by a saw to the requisite size and it is ready for the press. It can be stereotyped or electrotyped half-tone or finer work, if especially desirable for this process, and the people who control the affair are confident of a good thing, but the really practical photo-engraver need not fear any offensive competition, when in large establishments great quantities of work can be more easily done by the present methods.

The only real use it is adapted to is for ornamental purposes, such as tiling and decorative uses; ornamental designs are drawn on and etched, and can be filled in with gold or colours, or left in relief.

THE WELSBACH PATENTS IN THE GERMAN COURTS.

"On appeal, the Court has amended the Welsbach patents as follows:—Chief patent, 39,162. Claims 1 and 2 struck out, and Claim 3 limited as follows: The method set forth in the description, says the *Gas World*, of making incandescent bodies for incandescence burners out of the there described molecular mixtures of (*a*) lanthania, yttria, and magnesia; (*b*) lanthania and magnesia; (*c*) lanthania and yttria; (*d*) yttria and

magnesia; (*e*) zirconia, lanthania, and yttria; (*f*) zirconia and lanthania; or (*g*) zirconia and yttria; wherein the yttria may be replaced by a mixture of the so-called ytterite earths, the lanthania by a mixture of cerite earths free from didymium and containing little cerium, for white light; with addition of neodymzirconia to the mixtures for yellow light; with addition of erbia to one of the mixtures for green light or greenish light; through impregnation of tubular tissues, best prepared from vegetable fibre, eventually folded into shape, with the aid of the nitrates, sulphates, or equivalent soluble compounds.

"Patent 41,945. Claims 1, 2, and 4 replaced by the following:—In the method set forth in Claim 3 of the main patent, the addition of thoria to the mixtures there specified, as described in the previous patent. Claim 3 to stand. Claim 5 to read: In the method set forth in Claim 3 of the main patent and in 1 and 3 of this, for the production of a constant bright and yellow light, the addition of ceria to the mixtures as previously described. Claim 6, replacing zirconia and magnesia in patent 39,162 by thoria, so that the following mixtures may be used: (*a*) lanthania, yttria, and thoria; (*b*) lanthania and thoria; (*c*) yttria and thoria.

"Patent 74,745. Claim 1, add 'as described.' Claim 2, addition of thoria and uranium oxide to the mixtures specified in 39,162. Claim 3, the same addition to the mixtures specified in 41,945.

"The consequence of this judgment is that both parties claim substantial victory. The Welsbach Company rejoices that Claim 3 of the second patent, that is, the claim for the use of thoria, is to stand, instead of being cancelled; the opponents rejoice in the cancelling of the first two claims of the main patent, which they look upon as the basis of the Welsbach patent, the use, namely, of mantles made according to the method described; but, on the other hand, the phraseology of these claims has been carried almost bodily over into the amended form of Claim 3. The mixtures specified in 39,162 have now almost no practical value, for the practical material is mainly thoria."

THE CITY AND GUILDS OF LONDON INSTITUTE.

Report of the Examination Department.

By the courtesy of Sir Philip Magnus, we have received a copy of the report of the Examinations Department of the City and Guilds of London Institute. It deals with the examinations held in 1896. In the section devoted to photography there were 168 candidates. In the Honours grade seven passed, seventeen ranked "second," and thirty-two failed. In the ordinary, eighteen were marked "first"; fifty-four second, and forty failed. Thus there were ninety-six passes, and seventy-two failures.

With regard to the examination in photography, the report says:—

"The scheme of examination in photography has been very frequently modified in consequence of the rapidly changing condition of the trade, and a further alteration has been introduced into this year's programme, by which all candidates will be required to have passed a local practical examination before presenting themselves for the Institute's examination in the Ordinary Grade. This local examination may be held at any time between January 1 and March 12, and will be conducted by competent experts, to be locally appointed with the approval of the Institute. The object of this examination is to satisfy the Institute that the candidates have already acquired some practical knowledge of the subject before presenting themselves for the technical examination. It will be noted that the examiner in photography deprecates the system of teaching only some specific branch of the subject, and reports that 'there is no school in England where they teach photography generally.' The course of study recommended by the Institute is intended to afford an elementary knowledge of the general principles of photography, and a fuller and more detailed, and, at the same time, a practical acquaintance with some particular branch of the subject."

The following is an extract from the Examiner's report:—

"Section I. (Pure Photography).

"The answers in the Ordinary Grade have been particularly good, but in the Honours Section they are very poor. The candidates show a complete want of general photographic knowledge. This is, I am afraid, the result of the educational system. There is no school in England where they teach photography generally. The students learn only a few specific subjects, a knowledge of which they think they want. The result is very unsatisfactory, and will remain so until we have a school where students can learn photography as they learn other scientific subjects.

"Section II. (Photo-mechanical Processes).

"There has been a satisfactory increase in the number of candidates presenting themselves for examination in the Photo-mechanical Sections this year, partly due, no doubt, to a growing demand in this country for greater technical excellence in the quality of the work, and partly because of the increased facilities for practical instruction afforded by the Polytechnic and other technical institutions.

"The answers to the questions show an intelligent study of the subjects to which the student has directed his attention, but there is a strongly marked tendency on the part of nearly all the candidates to take up only one or two of the Photo-mechanical Sections. The two best papers indicate sound, practical knowledge of the subjects all round, but there are several of the papers, and practical work, which, though they do not stand high as to marks, are excellent so far as the single subjects taken up are concerned."

Those of our readers who are interested in the subject will find in the Journal of August 28 last the questions in the photographic examination that are to be set next May, as well as those that were set in the examination held in May of this year.

The Inquirer.

*** *In this column we from time to time print questions that may be addressed to individual contributors to our pages, or such as are sent to us with the view of eliciting information from a variety of sources. We invite the co-operation of our readers in rendering this feature of the* Journal *useful and instructive.*

Damaged Negative Surface.—In reply to "Alum," if he thoroughly soaks the negative, any markings that remain will be harmless, as they do not show on printing. Indeed, even when the crystals are still in and on the film, it is only in sunlight printing that they will show. Varnishes still further improve the appearance of the negative.—Syntax.

Bisulphite of Soda.—In reply to "Economy," Jerome writes: "If you substitute methyl orange for litmus as the 'indicator,' you will not experience any trouble in the matter of neutralising the bisulphite, especially if you employ sodium hydrate. Turmeric, I believe, is a good indicator for sulphurous acid, and would be perhaps better than the above, if carbonate of soda is used."

Sunset.—C. Fryatt asks: "Could you inform me why it is the sun sets twenty-five minutes after the time stated in your Almanac; in fact, not only yours, but all the others I have referred to? I am, no doubt, awfully ignorant, but it has puzzled me greatly, and I have asked so many people, but they cannot tell me. I first discovered it about a month ago rushing home to photograph a glorious sunset, and ever since I have timed it when possible."

Nikoda Paper.—Chloro-platinate says: "A paper for matt printing called the 'Nikoda' has been frequently advertised in The British Journal Photographic Almanac and in other publications by a dealer named Mucklow. Can any of your readers let me know if they have had any experience of it? I have applied over and over again for prices and specimens of it, and twice sought to obtain it through dealers, and begin to think it must be a myth."

Defective Spirit Level.—J. Smith says in reply to "W. J. C.": "If you gently heat the level as hot as the hand will bear, and then immerse it in methylated alcohol, the expansion and contraction of the vapour it contains will suck in more spirit. If the first attempt does not introduce sufficient, the process can be repeated until the desired result is attained. If the aperture is very small, it will sometimes prove a very tedious job refilling, consequently every precaution should be taken to prevent leakage. To effect this, let the screw which closes the aperture be freely lubricated with indiarubber cement, and, finally, to make assurance doubly sure, paint it over outside with thick gelatine."

Magnesium Flash Paper.—W. B. writes: "P. Stow will find it a far better plan to first convert the paper into gun-cotton, or papyroxyline, to ensure its combustion. He can afterwards saturate it with chlorate of potash, if he likes to ensure more rapid and perfect action. Probably too much paste was used in its preparation, which, by burying the chlorate of potash, rendered it practically inflammable." In reply to the same query, Syntax says: "Let P. Stow immerse his paper, ordinary tissue paper answers best, in a mixture of equal parts of nitric and sulphuric acids, cooled down to about 80° F., for ten minutes. This will convert it into papyróxyline, which should be well washed to remove all excess of acid, and then dried. It may, in addition, be soaked, before drying, in hot saturated solution of chlorate of potash, which will assist in the rapid and perfect combustion of the magnesium. Apparently your correspondent uses some paste to cause the magnesium to adhere; this is not a good plan, as the sizing so applied operates against the combustion of the paper. Better to simply fold the

powder in the paper, or to gum the *edges* of two pieces, and place the powder between. Another plan I have adopted is to fold magnesium ribbon in strips of papyroxyline, to form a sort of spill."

Our Editorial Table.

Christmas and New-year's Cards, Calendars, &c.

C. W. Faulkner & Co., 41, Jewin-street, E.C.

Messrs. Faulkner have submitted to us a number of specimens of their Christmas and New-year's publications. First comes a series of platinotype and photogravure reproductions of popular pictures by well-known artists, the subjects being so chosen as to gratify popular tastes in the matter of humour and sentiment—Ludlow, Kilburne, Couldery, Henry Ryland, Slocombe, and Tarrant being among those whose works are reproduced. The photographs are beautifully done, and are in such sizes and styles as to make them eminently suitable for framing and presentation.

The Christmas and New-year's Cards of Messrs. Faulkner, of which they have about a thousand different designs, are bewildering in their beauty and elegance. There would appear, from the pretty specimens shown to us, to be still a considerable demand for cards in colours, and those before us are as varied as they are pretty. We are, however, more interested in the photographic cards, bearing what appear to be well-executed little pictures in platinum. The designs and printing of the mounts are always in good taste, the pictures are capitally made, and the series is one which, combining faultless selection with elegance of execution, is assured of great popularity amongst photographers, stationers, printsellers, &c. Illuminated calendars, with spaces left for advertising purposes, and cheap and amusing little games for both young and old, are also among the specialities to which Messrs. Faulkner have drawn our attention. With Messrs. Faulkner's assistance many a country photographer might make a corner of his window attractive and profitable next December.

Modern Developers.

Fuerst Bros., 17, Philpot-lane, E.C.

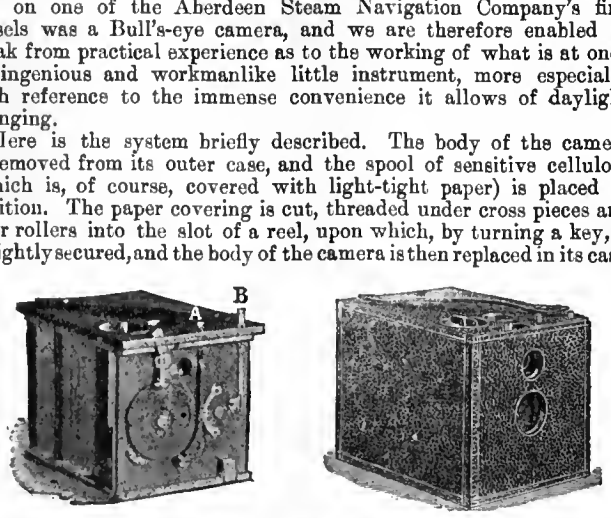
This little handbook, the compilation of Mr. J. Fuerst, concerns itself with Amidol-Hauff, Metol-Hauff, and Glycin-Hauff, the properties of each of which are succinctly set forth. Formulæ for their successful use are also given, both in cubic centimetres and grammes, and ounces and grains. There are many useful practical hints to be picked up from Mr. Fuerst's pages, which will repay careful perusal by those who work with "modern" developers, and are anxious to secure the best results therewith.

The Bull's-eye Camera.

The Eastman Photographic Materials Company, 115, Oxford-street, W.

Our photographic companion on the occasion of a recent brief river trip on one of the Aberdeen Steam Navigation Company's fine vessels was a Bull's-eye camera, and we are therefore enabled to speak from practical experience as to the working of what is at once an ingenious and workmanlike little instrument, more especially with reference to the immense convenience it allows of daylight changing.

Here is the system briefly described. The body of the camera is removed from its outer case, and the spool of sensitive celluloid (which is, of course, covered with light-tight paper) is placed in position. The paper covering is cut, threaded under cross pieces and over rollers into the slot of a reel, upon which, by turning a key, it is tightly secured, and the body of the camera is then replaced in its case.



A few more revolutions of the key are made until from the back of the camera it is seen, through an aperture of red glass, that No. 1 film is in position. The exposure is made, No. 2 is turned into position, exposed, and so on down the whole available length of the film. When the last exposure is made, film and paper are tightly wound round the reel, and are then removed from the camera, the gummed edge of the paper moistened and secured, and there is your reel of exposed film safely to be handled in daylight, the while a fresh spool of unexposed film is placed in the camera ready for use.

The little camera, which gives pictures $3\frac{1}{2} \times 3\frac{1}{2}$, is a cleverly thought-out piece of apparatus, and in use is the *beau idéal* of a simple and effective snap-shot instrument. It is fitted with a finder; a controllable shutter, and diaphragm plate. The convenience of daylight changing should make it a great favourite with those—an increasing number—of whom a hand camera of some kind is almost an inseparable companion.

Fallowfield's Christmas and New-year's Photographic Mounts.

Jonathan Fallowfield, 146 Charing Cross-road, W.C.

Mr. Fallowfield, as usual, shows us some samples of mounts suitable for holding photographs that are exchanged between friends at the Christmas and New-year seasons. The mounts are varied and effective in design, and are calculated to afford opportunities for the

gratification of many tastes. Some are plain embossed; others have inscriptions in silver and in colours, while a plentiful choice of colour as regards the mounts themselves is obtainable. Slip-in spaces for the photographs are provided, as shown in the illustration. These mounts will assuredly be popular with photographers and the public.

News and Notes.

Messrs. Gowans & Gray, Glasgow, and Messrs. S. W. Partridge & Co., London, will issue immediately a new handy-sized illustrated Bible, containing 135 views from photographs of the Holy Land.

Photographic Club.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock on Wednesday evening, November 4. Annual General Meeting.

We are asked to state that the latest date for the receipt of entry forms for the Hackney Photographic Society's Exhibition has been fixed for Monday, November 2, by which day they should reach the Hon. Secretary (Mr. W. F. Fenton-Jones), 12, King Edward-road, Hackney, N.E.

A young man who had been used for about four weeks as an object for demonstrating X-rays phenomena discovered to his surprise that his skin was peeling off at the places which had been exposed to the rays, causing sores in some places. He also began to lose his hair, and is now threatened with premature baldness.—*Elektroteohnische Rundschau.*

Mr. S. H. Fry, of 12, South Villas, Camden-square, N.W., writes: "In the report of the proceedings of the Photographic Club, which appeared in your columns last week, Mr. Naegali was stated to be the Chairman. This was an error. Mr. Stretton occupied that position, and I shall be much obliged to you for an opportunity of correcting the mistake."

The Syndics of the Cambridge University Press, says the *Publishers' Circular*, will shortly publish the *Autobiography of Sir George Biddell Airy*, edited by his son, Mr. Wilfrid Airy. The autobiography opens with his early school days, and contains chapters on his studies as an undergraduate at Cambridge, and his subsequent work at Cambridge Observatory as Plumian Professor, as well as a full record of his scientific labours during his long tenure of the office of Astronomer Royal. Abundant materials for the preparation of this book were available in the chapter of his autobiography which Airy had prepared in his annual reports to the Board of Visitors of the Observatory at Greenwich and in his correspondence on private and scientific matters, which he carefully preserved.

ROMFORD AND DISTRICT PHOTOGRAPHIC SOCIETY.—This Society will hold an Exhibition of photographic work in the Public Hall, South-street, Romford, on Thursday and Friday, November 26 and 27, 1896. There are several open classes, particulars of which may be obtained of the Hon. Secretary, Mr. A. John Ormiston, 4, Laurie-square, Romford.

ON Friday afternoon, October 23, Mr. J. F. Joplin, who lived at Ravenscliffe, Sutton Coldfield, met with a dreadful death in the park. He was riding, in company with Mr. E. Butler, near the Blackroot Glade, when his horse bolted, and running under a tree Mr. Joplin came in contact with a bough, which struck him off and killed him instantaneously. Assistance was called, and Dr. Evans summoned to the deceased, but it was found that his neck was broken and his skull smashed in. The body was removed to Ravenscroft to await an inquest. Mr. Joplin, who was well known in the photographic profession, was a partner in the firm of J. W. Beaufort, Birmingham.

THE Hackney Photographic Society's Annual Exhibition will be held at Morley Hall, Triangle, Hackney, on Tuesday, Wednesday, Thursday, and Friday, November 17, 18, 19, and 20, 1896. The Exhibition will be opened on Tuesday, November 13, at 7.30, and on the succeeding days at 12 noon. The Judges in the competitions will be Mr. F. Hollyer, Rev. F. C. Lambert, and Mr. E. J. Wall. Arrangements have been made for high-class concerts, under the direction of Mr. Hensler and Major C. Woolmer-Williams, and an orchestral band under the direction of Mr. Henry Bainton. A demonstration of X rays, *The Heart and Diaphragm in Action*, will be given by Mr. J. E. Greenhill, and also by Dr. Gerard Smith, seeing through hand, arm, and other objects with the naked eye. The cinematoscope (Birt Acres' patent), as shown at Marlborough House, by command of H.R.H. the Prince of Wales, will be exhibited; and, in addition to the foregoing, the competition slides will be shown through the oxyhydrogen lantern by Dr. Roland Smith and Mr. Albert Rose (Lanternist to Society).

THE ACCURATE DETERMINATION OF OXYGEN BY ABSORPTION WITH ALKALINE PYROGALLOL SOLUTION.—It was found repeatedly in my laboratory that during the absorption of oxygen from the Brin gas a considerable volume of carbon monoxide was evolved, although this did not occur in absorbing oxygen from the air. If the evolution of the gas was known to take place, and carbon monoxide was subsequently absorbed by cuprous chloride solution before reading off the residual nitrogen, the estimation of the volume of oxygen was correct; if this precaution was not taken, the estimation was open to serious error. Repeated trials with varying proportions of pyrogallol and potassium hydrate showed that the evolution of carbon monoxide might be entirely prevented by using a sufficiently large excess of potassium hydrate. With the following proportions no fear of this source of error need be felt, even when pure oxygen is being absorbed:—160 grammes of potassium hydrate and 10 grammes of pyrogallol in 200 c.c. of solution. This solution is prepared by dissolving 160 grammes of potassium hydrate in 130 c. c. of water, and then dissolving the 10 grammes of pyrogallol in the alkaline solution.—Professor FRANK CLOWES, D.Sc. (Lond.).

A WORD TO EMPLOYERS.—If you have a good workman, treat him right, pay him a fair price for his services, and let him feel that you regard him as something more than a mere machine for the mechanical production of some particular marketable product. To obtain good work from a machine, says a contemporary, an occasional oiling is necessary. It is the same with man; a bit of praise, a pleasant word, treatment that causes a man to feel that he is a man, all act upon the workman as does oil upon the machine. It costs nothing to treat a man right. No need to be familiar, that will often lose you his respect and lessen your control of him; get his respect by respecting him. The writer knew a man who made a business principle (?) of finding fault with the work, and bulldozing the spirit of his workmen at regular intervals, in order to discourage any attempt at advance, and to stifle any aspirations for better wages. He has failed several times, and is always complaining that his men are loafers. This business principle (?) of his has been the cause of all his trouble; a good man will not work for him. The men he does get go to him from the necessity of having work. They have no encouragement and no spirit to do for him more than is absolutely necessary, and they leave him at the first opportunity for a better master, and yet he thinks that his is the right and only way to treat a workman. The moral is plain: To get the best efforts from a man, you must first of all have his respect, and next his good will. Treat him as a man, and you will have both.

A PHOTOGRAPHIC LIBRARY.—Professor Reginald A. Fessenden, of Pennsylvania, says that it is possible to condense a library of 50,000 volumes into a box of one cubic foot capacity by means of photography. Professor Fessenden has used photography for several years in collecting scientific data, and has found not only this method is cheaper than the cost of paper on which to write the same amount of matter, but also that it occupies only one per cent. of the time required in copying by hand. From the results that he has obtained in this way he thinks that it is not impracticable to reduce a big reference library to a small bulk by the same method. Professor Fessenden says, as an illustration of what might be accomplished by photography, that it would be an extremely easy matter, for instance, to arrange the mechanism of a plate containing a German dictionary so that by the pressure of a couple of keys the page commencing with any given letter could be thrown on the screen. Professor Fessenden says he has overcome the difficulties arising from the necessity of accurate focussing, the expense of the plates, and the time required to put an object into a suitable condition to photograph. A special camera is employed, having a one and-three quarter-inch focus, and a lens of a quarter of an inch aperture. Suppose it is desired to copy a table which occupies a page of a technical journal. The paper is laid on the desk, and the camera, which is small and suspended on a bracket above the desk, is focussed so as to include the page. A plate-holder is then put into the camera and exposed for ten seconds, if the illumination comes from a student lamp of thirty-two candle power, placed on the desk opposite the paper, and one-tenth second if the exposure is by daylight. The plate-holder is then put away until a convenient opportunity occurs for developing. From the instant it is decided to copy an article until the time the operation is finished it need not be more than twenty seconds. When twenty-five or thirty plates are exposed, which may be within a week or so, they are all put in one tray and developed together. As all have made the same exposure, it is not necessary to watch them carefully, and in practice they may all be developed, fixed, and left to wash in ten minutes. The whole time spent in copying one article or table, including preparation for photographing, exposing, developing, fixing, washing, filing away, and labelling is less than one minute, according to the Professor's experience. These negatives may be filed away in small envelopes stuck to the backs of pasteboard cards. These plates used are only one-and-a-quarter inches by one one-and-a-half inches, and can hold upon them 2000 words, so that each word can be easily read with a small magnifying glass. This has the advantage of preserving drawings, which show with equal distinctness and also of preventing errors in copying. In case one does not wish to copy more than 400 or 500 words, this number can be read with ease by any person of average eyesight without the use of a glass. So convenient is this method, that Professor Fessenden states he uses it for copying all his correspondence.

"OPERATORS AND OPERATORS."—The art of photography to-day lies in the conception of an idea," says Abraham Bogardus, "and the lighting, posing, and execution necessary to carry out the conception. The old 'sit down there and keep still' will not answer for this intelligent age. Who gets the honours at our exhibitions and conventions? It is not the man who merely makes a good picture photographically. It is the man who exhibits pictures with the above qualifications, art in conception and execution. There may be occasions when he cannot display the art he may possess. For instance, when a bouncing mother brings a bouncing baby, wishing a group. The photographer may place the mother as gracefully as circumstances will admit, but the young hopeful will not be posed according to the rules of art or any other rules. Young as he is, he has a will of his own. Art don't trouble him. He is determined to slip off from the abundantly ample lap offered him, and, like some windy orators, 'take the floor.' A little force is now necessary. He don't like that. Then some squeezing is resorted to. To this he decidedly objects, and, although unable to raise a cyclone, yet he can, and does, raise a squall. Under the above circumstances, the operator is obliged to suspend all knowledge of art, drawing, or taste for beautiful lines. He is hoping for anything within the lines of propriety. We should not find fault with him or condemn his production. It is one of those unavoidable happenings to which human nature, in the pursuit of bread and butter, is liable. He is burdened with a weight of responsibility difficult to locate and impossible to control, while the financial probability is light and doubtful. In this emergency he is not supplicating for art. Dexterity and snap is the burden of his mind. Before he has had five minutes' rest, or time to gather his ideas, another very different situation presents itself. A beautiful lady, elegantly dressed, requires his attention. Now we shall see how much art there is in him. She is pliable in his hands, and willing to conform to his superior taste. He knows this picture will be subjected to severe criticism. He knows that success means more business, and a favourable recommendation to friends, whose patronage is desirable. At a glance he sees the style of picture which will be favourable, and at once proceeds to carry out his idea. Being a gentleman, he acts with dignity, carefully, promptly placing his subject. The picture must be graceful, and, at the same time, natural and easy. Just consider that sentence. It contains a great deal. Graceful, dignified, agreeable, and pleasing to the eye. Natural; it must conform to reality. Easy; it must not be constrained. If the picture represents the points named, it is a success. The expression will, in most instances, conform to such accompaniments. It is human nature to conform to environments. If your surroundings are pleasant, it shows in the face. Can a person be expected to look pleased when all around is dingy, dismal, and disagreeable? I do not believe in too much talk with sitters. An agreeable conversation as to sitters' wishes, and what you intend to produce, is well, but many sitters are disgusted with the continued 'gab' of shallow-headed pretenders, and rightfully *angry* when the results fail to fulfil *loud* promises."

Patent News.

THE following applications for Patents were made between October 14 and 21, 1896:—

CAMERAS.—No. 22,557. "Improvements in or connected with Photographic Cameras." W. TYLAR.

MAGAZINE CAMERAS.—No. 22,573. "Improvements in Magazine Cameras." S. D. WILLIAMS.

PHOTOGRAPHS IN WATCHES.—No. 22,614. "Improvements in the Inner Covers of Watch-cases to adapt them to receive Photographs." Complete specification. A. SALCHLI, L. KEMPF, and G. ZURFLUH.

SCREEN KINETOSCOPY.—No. 22,627. "Improvements in or relating to Apparatus for, taking Photographic Pictures of Objects in Motion, and for Exhibiting such pictures." H. J. HEINZE.

REPRODUCING PHOTOGRAPHS.—No. 22,732. "An Improved Method of, and Apparatus for, Reproducing Photographs, Sketches, and the like." N. S. AMSTUTZ.

EXHIBITING PHOTOGRAPHS.—No. 22,928. "Improvements in Apparatus for Taking or for Exhibiting Photographs." Complete specification. W. FRIESE GREENE.

PHOTOGRAPH STAND.—No. 23,013. "A new or Improved Stand for Photographs, and the like." J. W. MARRIOTT.

PHOTOGRAPHING MACHINES.—No. 23,039. "Improvements in Automatic Coin-freed Photographing Machines." A. G. ADAMSON.

ADVERTISING BY PHOTOGRAPHS.—No. 23,059. "Improvements in the Mode of Advertising by means of Photographs and the like." H. STEVENSON.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

November.	Name of Society.	Subject.
2	Bradford	*Economical Enlarging.* F. Nicholson.
2	Camera Club	Smoking Concert.
2	North Middlesex	Trial of Members' Slides.
2	Richmond	Lantern Evening, Members' Slides.

6	Croydon Microscopical	*Reduction and Intensification.* A. Roods.
7	Borough Polytechnic	Prize Slides.

ROYAL PHOTOGRAPHIC SOCIETY.

OCTOBER 27,—Technical Meeting, Mr. G. Scamell in the chair.

ACETYLENE.

Mr. C. HODDLE (Messrs. Thorn & Hoddle) gave a demonstration of the Incanto acetylene apparatus for portraiture and the optical lantern, dealing, in some preliminary remarks, with the question as to whether acetylene gas was safe in the hands of persons possessing no special knowledge of it. With ordinary care and a fair amount of intelligence, he said it was as safe to manage as an ordinary candle, provided a simple and effective generator was employed; but cylinders of compressed acetylene must be avoided. Acetylene would not stand much pressure, about 700 lbs. bringing it to a liquid, and, if this was exceeded, the machinery must break or the cylinder burst. He attributed the recent explosion in Paris to an attempt to fill a cylinder which was only partially empty, a danger entirely obviated by the use of a generator. The Incanto generator comprised a carbide container, and a gas and water container combined, and, upon charging the apparatus and turning on the stopcock, the gas would be supplied as required, the generation being automatically stopped when the lights were turned out. The generator was connected with the Society's optical lantern, and a number of slides (including Mr. Paul Martin's medalled series, *London by Night*) were projected, a disc of about five feet in diameter being excellently illuminated. The studio lamp, for portraiture, carrying twelve sixty-candle power burners in a parabolic reflector, was also shown, with specimen portraits taken by its means with an exposure of about four seconds. Mr. Hoddle confidently recommended acetylene as an absolutely safe gas to handle, and anticipated an early reduction in the price of calcium carbide as a consequence of the increased demand and the greater output from the works. A perfect burner had not yet been invented, but Bray's 4 O or 5 O were the best now obtainable, the former passing one foot of gas per hour.

The CHAIRMAN asked what the insurance companies had to say about the use of acetylene?

Mr. HODDLE said the companies were very ridiculous in the matter, and were making out that the gas was a great deal more dangerous than was really the case.

Mr. T. BOLAS pointed out that the kinetic position of acetylene was precisely the same as that of dynamite, and it was something with which one should be extremely cautious. As with a weight suspended over one's head, one knew that the danger was present, but did not know what would release the weight.

Mr. FERGUSON had understood that acetylene formed explosive compounds with copper and brass, and asked whether such could be formed with the fittings of apparatus?

Mr. BOLAS strongly deprecated the use of copper or brass in any form for acetylene fittings, although the action did not readily take place with clean metal.

Mr. HODDLE said Mr. Bolas was unnecessarily frightening his audience, and was referring to the gas as it was made twenty-five years ago rather than as it was at the present time. He had purposely tried to get an explosive compound with copper, but had not succeeded.

Mr. CHAPMAN JONES also thought that Mr. Bolas had taken an extreme view of the case. He believed the acetylene compound with brass was very rarely produced, though, doubtless, it sometimes arose by action on corroded metal, but even then the quantity was so very small that, if it were to go off, only a little puff would result. The compound caused by the action of acetylene on brass, &c., was of a fulminating character; but, although he had made the gas and experimented with it for many years, he had never had any sort of explosion, and the risk was so remote that it was practically of no moment.

Dr. OWEN asked whether it was necessary to limit the burners to two, as in the lantern fitting exhibited.

Mr. HODDLE said nothing was gained by increasing the number of burners; more light was obtained, but not much of the light passed through the lens. No smoke arose unless the pressure was insufficient. There was a particular height at which the flame smoked, but this could be remedied at once by turning it either up or down. When full on, no smoke was caused. The pressure at which he was burning the gas was about forty-tenths, coal gas being, in his opinion, usually supplied at about twenty-tenths.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

OCTOBER 22,—Mr. J. E. Hodd in the chair.

Mr. E. J. WALL considered it would be well to revive the old custom, which had been allowed to lapse, of formally introducing newly elected members, and he therefore had much pleasure in introducing Mr. G. H. James, who had promised shortly to give them a paper.

The CHAIRMAN announced that, it being an Open Night, the meeting would be devoted to the examination of objects of interest.

Mr. T. E. H. Bullen passed round a number of transparencies done on warm-toned lantern plates, sample packets of which he had brought up for those interested in lantern work for trial. The longer the exposure and the weaker the developer, the warmer was the tone obtained. Those shown were from dense negatives, and received from twenty-five to forty seconds' exposure to a No. 5 gas burner at twelve inches' distance. The plates would yield any degree of softness or density according to requirements.

Mr. EVERITT had been intrusted with a print which had been toned in a recently recommended toning bath containing sulphite of soda. Although left in this bath for two hours, the print still retained its original red colour of an untoned print.

It was generally agreed that the sulphite was in excessive proportion.

Mr. DRAGE said the least over-use of sulphite would stop toning altogether, and it was a thing which should be very cautiously used.

Mr. Bayston exhibited a print from a pocket Kodak negative, taken the previous night by moonlight with an exposure of an hour and a half.

The CHAIRMAN described a pocket camera, which did away with rollable films, dark slides being provided. It was fitted with finders, and time and instantaneous shutter. Glass plates could be used, and were of one-quarter the size of quarter-plates, to facilitate the cutting of which he showed a device so made that the diamond ran in fixed slots, and accurately divided the plate into four. He handed round an enlargement of one of the negatives by sixteen diameters. He also exhibited a new pneumatic flash lamp of high power, and an old photograph, done twenty-five years ago, very well preserved, and the process used in making which he wished to learn.

Mr. BANKS thought it looked like a collodion transfer.

Mr. H. Snowden Ward handed in an enamelled tile on which a photograph had been reproduced and burnt in. It was produced by a photo-mechanical, and not a pure photographic, process, by Mr. Grundy, of Derby, who had utilised the collotype process, the necessary depth of shadow being obtained by five or more separate printings on the same tile immediately after and on top of one another. This required very nice adjustment to ensure accurate register. After printing, it is glazed and fired in the usual way. The depth of shadow was all that could be desired, and the process allowed of any of the ceramic colours being used. They were being supplied on very reasonable terms, and were designed to compete with German-made goods.

A discussion ensued as to the necessity for very accurate register in the separate printings, Mr. EVERITT having discovered slight defects with the aid of a glass. He thought the use of glazed surfaces was to show to more advantage the finest detail, the preservation of which he thought a great thing.

Mr. JAMES said tiles were not to be confused with enamels of the usual type. They were purely decorative, and should be as "broad" as possible, with very little detail.

Mr. SNOWDEN WARD said the glaze was to facilitate cleansing; but, if preferred, it was possible to have a matt glaze, which would display as much detail as the glazed, but without the reflecting surface. It was liable, however, to retain dirt, which was not the case with a glazed enamel.

A desultory discussion followed upon the previous week's proceedings regarding the tanning action of pyro and bromine on gelatine, consisting of the most part of repetitions and restatements of opinions before given.

PHOTOGRAPHIC CLUB.

OCTOBER 21,—Mr. Crofton in the chair.

Mr. J. R. Williams passed round two old enlargements as objects of interest, one a carbon enlargement of a photograph of Bruges, made by the late Walter Woodbury, the other a portrait of the Prince of Wales, enlarged and printed on salted paper by Mr. Alfred Harman.

The CHAIRMAN read a letter from Messrs. Cadett & Neall, in which they stated they had sent samples of lantern plates for distribution among the members, and a copy of their new photographic instruction book for the Club library.

In view of the annual general meeting, fixed to take place a fortnight hence, the nominations of the several officers of the Club for the ensuing year were made.

Notice was given by Mr. Fry of a motion to enable the Committee to suspend the holding of the meetings during the summer months if the Committee thought it in the interests of the Club to do so.

Mr. F. YORK presented to the museum an old instantaneous shutter for a pair of lenses. This had been made for him thirty-five years ago.

Mr. Frank Haes passed through the lantern a few slides from negatives made by himself from objects collected by Professor W. M. Flinders Petrie at Thebes. These were of great interest on account, first, of the great age of the objects themselves; and, secondly, on account of their character. The most interesting comprised examples of iron tools dating from about 670 B.C., and

consisted of files, rasps, chisels, &c., of striking resemblance to the most modern instruments. Mr. Haes also showed copies of mural paintings illustraiting the art of a time some 3000 years B.C.

Borough Polytechnic Photographic Society.—October 21, ordinary meeting, Mr. A. Bedding (Chairman) presiding.—Mr. P. C. CORNFORD read a paper by Mr. Thomas Bolas on

THE INTENSIFICATION AND REDUCTION OF NEGATIVES,

which dealt chiefly with intensification by the mercuric chloride, ammonia, and potassium iodide method, and reduction by Howard Farmer's well-tried system of hypo and ferricyanide of potassium. Several slides were shown, illustrating the writer's remarks.

Brixton and Clapham Camera Club.—The opening meeting of the winter session was held Tuesday, October 20, Mr. J. W. Coade (President) in the chair.—There was a very large attendance of members to hear Mr. HORSLEY HINTON (Vice-President) read a paper on

PRACTICAL PICTORIAL PHOTOGRAPHY.

In his introduction Mr. Hinton said photography has numerous ramifications, of which pictorial photography is only one branch among many others. Our Exhibitions, however, bear evidence of the attention it is receiving at the present time, and an ever-increasing body of workers are devoting time and energy to its pursuit. As an amusement, photography can easily be beaten. Carrying heavy weights for hours along dusty roads, at the end footsore and weary, waiting with patience an hour or more to secure the photograph, afterwards subjecting oneself to a voluntary imprisonment, trying alike to eyesight, health, and temper—the imprisonment of the dark room—is certainly not sufficient reward to tempt one to take up photography as a pure amusement. What, then, is the inducement? It is the hope that in the after-results will be the recompense for the labour spent. These expectations, alas! often end in bitter disappointment. Entering into his subject, Mr. Hinton gave a complete and masterly exposition of the meaning of pictorial photography and its difference from "the usual thing." Illustrating his remarks with diagrams, lantern slides, and prints, he explained clearly the essentials of a true picture, and the principles necessary to successful picture-making by photography. His address received the closest attention, and must have made a deep impression on his hearers. Much was given to think over, and many must have gained knowledge which will confer upon them the power to work with more success in the attempt to portray the pictorial possibilities of photography. Unfortunately, time permitted of no discussion, desirable as it would have been, Mr. E. Dockree in particular being anxious to obtain Mr. Hinton's reasons for a statement he made respecting the merits of lantern slides as pictures. The recent Exhibition, it was mentioned, has been an unprecedented success, both as regards the quality of work shown and the support given by the public. Ten new members were nominated.

Croydon Camera Club. — The usual Wednesday evening meeting, on October, 21 was devoted to

AT HOME PHOTOGRAPHY,

which was expounded by means of a lantern lecture composed by Mr. W. Thomas, F.R.P.S. The lecture was one upon which amateur was written large, both matter and manner being of the unprofessional order. Unfortunately, Mr. Thomas was unable to attend and read his paper, as had been hoped, hence the duty devolved upon the PRESIDENT (Mr. Hector Maclean), who gave it with a vivacity which at times seemed to be much appreciated by a large gathering of members. The lantern slides in illustration were skilfully projected on to the screen by means of a newly acquired biunial lantern, which was in charge of Mr. Isaac. At the termination of the reading, Mr. Maclean stated he trusted members had received gratification and instruction from what had gone before, and that they were not like the beadle depicted in to-day's *Sketch*, who told the "meenister" that he disliked the good man's "sairmon" for three reasons. "Fairstly, ye read it; secondly, ye did n'a read it weel; and, thirdly, it wasna' worth readin'." He (the speaker) felt sure that, at any rate, Mr. Thomas's paper was worth careful attention, for more than one reason. At the same time, exception must be taken to a good deal of what had been rather too dogmatically brought forward in the lecture on the subject of composition. Mr. Maclean at some length analysed what were the points alluded to. He also questioned the exposure advised for a figure taken in the most brilliant sunlight possible with stop *f*-11, six seconds being correct. An interesting discussion followed, in which Messrs. Wratten, Kough, Richardson, and Ibbetson took major part. The PRESIDENT announced that Mr. Edwin Dockree had accepted the Club's invitation to show and describe a choice selection of his slides at the first public lantern show. Prints of varied interest were shown by Messrs. Maclean, Rogers, Isaac, Noaks, and Kough, the last-named exhibiting a remarkable snap-shot depicting a man shooting a wild duck, the latter being seen falling in mid air. Amongst the other prints were some amusing and clever flashlight photographs taken by Messrs. Noaks and Isaac at the Dolphin costume swimming entertainment. A few lantern slides by members were put on the screen, including a set of Dorking scenes by Mr. Elkin, and a fine series of interior and exterior views of the Municipal Buildings by Mr. Jenkins.

Hackney Photographic Society.—On October 20, Mr. J. O. Grant in the chair, the HONORARY SECRETARY announced particulars of the forthcoming Exhibition. Members' work was shown by Messrs. Dunkley and Hensler. Mr. Fleetwood showed results of his experiments with the X rays. Exposures had been made through various thicknesses of opaque material with excellent results. In the absence of the writer, Mr. A. MACKIE read a paper on

INTENSIFICATION AND REDUCTION,

by Mr. E. J. Wall. The paper dealt most thoroughly with the different methods, commencing with the advice that a print should be taken from the negative before intensifying or reducing, as it was difficult to judge of the printing density without trial. In the discussion which followed the reading of the paper, the CHAIRMAN said that, when dealing with a too thin negative, if time were no object, it was a good plan to make a positive transparency from it, and another negative of the required density from that. This plan had the further advantage of not interfering with the original negative, which might possibly be of correct density for enlarging from, but not for printing direct.

North Middlesex Photographic Society.—October 26, Mr. C. Beadle in the chair. Messrs. Bacton & Hambly were duly elected members of the Society. The President (Mr. Mummery) called attention to the special competition, Outdoor Figure Study, the prints for which are due next Monday, November 2, also the annual Exhibition to be held on November 30, and December 1 and 2. Mr. J. A. SINCLAIR then proceeded with his demonstration on the Artigue system of

CARBON PRINTING WITHOUT TRANSFER.

He said it was really the oldest form of carbon printing, slightly modified. He went very fully into the method of sensitising and using the paper, and laid special stress upon the fact that it was essential to keep the temperature of the sensitising bath below 60° Fahr., and also the paper in drying. He developed a couple of prints which turned out successful. Under-exposure, he said, gave a flat grey image, and over-exposure too dense blacks, with too white high lights. The time of sensitising, and the strength of the sensitising solution had a good deal to do with the quickness in printing and the gradation. The paper darkens considerably on drying, and it was necessary to allow for this in development. After washing, the print should be put into an alum bath. A vote of thanks to the lecturer concluded the meeting.

Putney Photographic Society.—October 12, Dr. W. J. Sheppard in the chair.—On this occasion a set of architectural slides, ecclesiastical and domestic, was shown. These included examples of Saxon, Norman, Early English, Decorated, and Perpendicular styles of architecture in this country now existing, which illustrated, in an interesting and instructive manner, the gradual transition of each style into the succeeding one. Among the slides shown were several very beautiful views of cathedral interiors.

OCTOBER 22, Dr. C. Wyman in the chair. A lecture, by Mr. Chapman Jones, on

NEGATIVE-MAKING,

was read by the Chairman to a large audience. The paper proved to be a very valuable one, containing much information on exposure and development, and was greatly appreciated by those present. Some of the members expressed the hope that the paper will be published on the completion of its rounds among the societies, in order that they may have an opportunity of studying it at their leisure. After a short discussion, a hearty vote of thanks was accorded to Mr. Jones for his interesting paper. Owing to the increase in the secretarial duties, the Council have elected Mr. W. J. Colebrook to be Joint Hon. Secretary with Mr. William Martin, who has for some time carried on the duties of Hon. Secretary and Treasurer.

Woolwich Photographic Society.—October 21.—The Rev. F. C. LAMBERT, M.A., began the first of a series of three lectures on

ART PHOTOGRAPHY.

beginning with (1) The General Nature of Pictorial Composition; (2) Selection and Arrangement, with special reference to Lines, Forms, and Mass. Mr. Lambert very ably described his lecture by means of sketches on the board, and, by the help of the lantern, he showed some of Turner's and other artists' work, which he described with reference to their pictorial and other qualities. The meeting was very well attended, and, judging by the applause given to Mr. Lambert after his lecture, was well appreciated. Mr. W. H. Dawson kindly acted as lanternist.

Leigh Photographic Society.—October 22, Mr. S. L. Syms presided.—A discussion, introduced by Mr. W. HAMPSON, on the development of special rapid plates and dark-room illumination, proved of great interest, and was enthusiastically taken up by the members; and Mr. Hampson exhibited some splendid negatives on these plates, which were everything to be desired. The Country Village Competition was held, and Mr. Herbert Isherwood took off the first prize, presented by Mr. W. Hampson, who gained the second prize. Messrs. P. Seddon, W. R. Moore, T. Haddock, and Dr. Joseph Jones were the unsuccessful exhibitors.

Liverpool Amateur Photographic Association.—October 22.—Mr. GEORGE HOLDING, of Liscard, gave a paper and demonstration on the

ART OF SCULPTURE,

doing a lightning model of Mr. Gladstone's head in clay, and afterwards taking a cast of the hand of Mr. William Tomkinson, one of the members. The demonstration was a departure from the beaten track of the Society, and constituted an agreeable change, which seemed to be much appreciated by a large audience.

Photographic Society of Ireland.—October 23, the President (Mr. Alfred Werner) in the chair.—Mr. R. M. INGLIS gave a practical demonstration on

ENLARGING.

During the evening the lecturer described and showed his enlarging lantern, and how it was possible to adapt his ordinary camera as a front for holding the negative, and, of course, the lens. He used the incandescent gas light, which was very steady and bright, and always exposed his enlargements through an aperture of *f*-24. He preferred using developers such as metol or amidol to the ferrous oxalate, as he thought it was possible to obtain by their use softer images, with less harsh blacks in the shadows, than when the iron developer was employed. Mr. Inglis's lecture was interesting and instructive, and delighted the audience, which comprised about seventy members and their friends. Several questions put by members to the lecturer were thoroughly dealt with. Afterwards Mr. L. R. Strangeways (Vice-President) showed the Autocopyist, which proved of interest to a large number present. Mr. W. O. Stanley was elected a member.

Port Elizabeth Photographic Society.—Annual General Meeting.—The following are extracts from the annual report:—The meetings held during the session are 20, and the average attendance 15, the largest number at any one meeting being 25. Your membership roll began the session with 52 members. To this was added during the year 20 new members, making a total of 72. Out of this number 9 have become country members, but still take an interest in the doings of the Society, while 8 have resigned. This makes the roll 55 active members, with 9 country members. The Treasurer's balance-sheet shows a substantial credit balance. The annual outing in October, 1895, took place at Springfield, a few miles beyond Uitenhage. Although the scenery was not adapted for taking a variety of photographic views, still some good prints were produced, and all who took part in the outing, whether naturalists or photographers, came back looking all the better for their trip. The ride by bullock waggon from Uitenhage formed a pleasant break in the journey. A field day at Cuyler Manor, fifteen miles from Port Elizabeth, was also arranged by the members, where some excellent photographs were taken. Mr. Davies was very successful with a photograph of some ostriches near to the dam at the farm house, which made a very pretty picture. This photograph was, much to his surprise, reproduced as a half-tone block by the weekly illustrated paper, *Black and White*, shortly after, under the misleading title of *Ostrich Farming in the Transvaal*. This fact your Committee wish to bring before your notice as a warning to members not to indiscriminately give away prints. In February, 1896, the Society inaugurated a new departure in lantern lighting. In place of the usual four-inch paraffin lamp, there was adapted to the lantern one of Welsbach's incandescent mantles with gas mountings. This light was found to give a clearer light than the paraffin, and better definition of objects. Lantern slides which, with the ordinary oil lamp, looked smoky, came out on the screen under the incandescent lamp clear and distinct. Our relations with other societies in South Africa continue to be of the most friendly nature. During the year competitions have been judged by both Kimberley and Capetown societies. Your Committee, with deep regret, have to record in this report the sad death of Mr. Norman Edwards, aged nineteen, the youngest member of the Society, who was brutally murdered by the Matabeles a short time since. He was well known to many of you here this evening, as it is not so long ago that he was personally amongst you all, a promising young member doing capital work in the Society. To his parents the Committee expressed their sympathy for the sad loss they had sustained immediately after the news became known to them. The CHAIRMAN, in moving the adoption of the report, congratulated the members upon the flourishing condition of the Society, not only in having good workers and energetic members, but in having financially such a substantial balance to the good. He doubted if many similar societies were upon such a sound basis. He noticed that a good number of members had gone to other towns, but he did not consider that as altogether against the Society, for they could undoubtedly speak in such good terms of it as to induce other young men coming to the town to join. He wished to state that a full set of apparatus for the production of Röntgen's rays was now in his hands, and this he placed at the full disposal of the Society for the purpose of their making an exhibition of this wonderful discovery. He hoped that, now the Athenæum was completed, it would become a home to the young men of the town, a place where instructive and scientific pursuits could be developed and maintained. He therefore moved the adoption of the report, which was seconded by Mr. RICHARDSON. Mr. ALCOCK proposed, seconded by Mr. FOREST, a very hearty vote of thanks to their President for the unceasing interest he had taken in arranging the affairs of the Athenæum. What he had done was beyond a duty, it had become more a personal matter with him, and members must feel grateful for his energy and perseverance. This was carried with acclamation, all members rising to their feet. The election of office-bearers resulted as follows:—*President:* Mr. A. Walsh.—*Chairman:* Mr. W. Alcock.—*Vice-Chairman:* Mr. F. West.—*Committee:* Messrs. Jackson, Mathews, Richardson, and Scruton.—*Hon. Treasurer:* Mr. J. Lewis.—*Hon. Secretary:* Mr. W. A. Brown.

FORTHCOMING EXHIBITIONS.

1896.	
Oct. 30, 31	Southport Social Photographic Club.
,, 30-Nov. 7	Photographic Salon, Dudley Gallery, Piccadilly. Alfred Maskell, Dudley Gallery, Piccadilly.
,, 30-Nov. 12.....	Royal Photographic Society. R. Child Bayley, 12, Hanover-square.
Nov. 12	Dulwich Photographic Society.
,, 17-20	Hackney Photographic Society. W. F. Fenton-Jones, 12, King Edward Road, Hackney.
,, 26, 27.....	Romford and District Photographic Society. A. John Ormiston, 4, Laurie-square, Romford.
,, 30-Dec. 1, 2 ...	North Middlesex Photographic Society.
December 3, 4.....	Aintree Photographic Society. E. P. Heron, 2 Tilney-street, Orrell Park, Aintree, Liverpool.
,, 28-31.....	Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.
Dec. 1896-Jan. 1897	Bristol International. Hon. Secretary, 20, Berkeley-square, Clifton, Bristol.

Correspondence.

THE ARTIGUE PROCESS.

To the EDITORS.

NTLEMEN,—The enclosed price list of M. Victor Artigue will perhaps help you in your promised answer to "Alum Hypo." It was given me by M. Artigue when I visited him about a fortnight ago at his factory in Bordeaux, where he was kind enough to demonstrate the printing and development of the paper to me. The results of the process are of extraordinary beauty. The maximum of contrast is obtained without a suspicion of hardness. In a reproduction of a well-known oil painting, *La Main Chaude*, by Roybet, the high lights stand out with wonderful vividness, though there is not a spot without gradation. M. Artigue explained that this brilliance is due to the slightly satined surface of the paper. The sharpness of detail is remarkable. In a small reproduction of an old woodcut illustrating *L'Ecole des Maris* every touch of the graver's tool is perfect.

The preparation of the paper and the sawdust is M. Artigue's secret. All the materials can be sent by parcel post, where the Postal Convention extends. It is not easy to send small quantities by sample post, as such parcels must be packed so as to be easily opened for inspection by the authorities, and the paper, though non-sensitised, may receive damage.

M. Artigue's address is 114, rue Terre-nègre, Bordeaux.

I may say that the development is practically identical with the directions given in the last paragraph of Mr. Pretzl's article of last week, except that, instead of being laid on glass, the paper is clipped to a strip of wood. Great modifications can be obtained by varying the temperature of the water, and the quantity and fineness of sawdust in suspension, by taking from the top or bottom of the container.

If you would care to see the specimens given me by M. Artigue, I shall be happy to send them for your inspection.—I am, yours, &c.,

St. Mary's, Poole, October 23, 1896. AUGUSTIN MORFORD.

[We are much obliged to our correspondent for his letter and enclosure. There are excellent specimens of the process in the Exhibitions of the Royal Photographic Society and the Salon.—EDS.]

UNFAIR COMPETITION.

To the EDITORS.

GENTLEMEN,—Will you allow me space to call attention to the latest dodge to increase the circulation of a halfpenny London morning paper. Not content with cigarettes, bicycles, and jumble puzzles, the journal in question is now in a position to supply, to the first 1000 of its readers, "a beautiful three-quarter life-size crayon and ink portrait," for the unheard-of sum of six shillings and sixpence. Should the reader order one from the "poor photographer," the usual price will be from two to four guineas. This is in no sense a case of fair competition, but sheer, underselling, and tends to depress the wages of the photographic workers to starvation point, for at the present time, with the trade in such a depressed condition, photographers have quite enough competition to meet without this halfpenny journal making matters worse. Thanks to this paper and the well-known firm of diarists of whom we have heard so much lately in the columns of THE BRITISH JOURNAL OF PHOTOGRAPHY, photographers will soon have to put up their shutters and retire to the workhouse. I am sure that, when a London daily enters into competition without side trades, it must in some way "feel the pinch." Let us hope we shall never see the good old BRITISH JOURNAL OF PHOTOGRAPHY retailing soap and flea powder.—I am, yours, &c., VICTOR THOMAS.

11, *Munster-road, Fulham, S.W. October* 20, 1896.

THE CARRIAGE OF GAS CYLINDERS.

To the EDITORS.

GENTLEMEN,—The lantern season has arrived, and we are face to face again with the (to my mind) senseless restrictions *re* carriage of cylinders. One would have thought, after the Board of Trade report, that we should have been allowed to carry them as passenger's luggage, provided they were properly packed in either boxes or other covers. The railway companies are evidently not disposed to take off the restrictions, and, if anything is to be done, *we* as lanternists, both professional and amateur, must move in the matter. Cannot we unitedly petition or memorialise the railway companies? The commercial travellers have got special facilities of a most beneficial kind by *united application*, and I think we might do something in the matter instead of merely grumbling and paying. To one who travels 15,000 to 16,000 miles each winter with the lantern, as I do, cylinder carriage is a serious item.—I am, yours, &c., JAMES W. GARBUTT,

Lanternist to the Gilchrist Lectures.

Armley, Leeds, October 19, 1896.

AN INDEX TO SCIENTIFIC PERIODICALS.

To the EDITORS.

GENTLEMEN,—The *Catalogue of Scientific Papers*, compiled and published by the Royal Society of London, was intended to serve as an index to the titles and dates of scientific papers contained in the transactions of

societies, journals, and other periodical works. This Catalogue is highly valuable to all technical inquirers, and it is a matter of deep regret that the International Conference, held under the auspices of the Royal Society of London, has decided that the *International Catalogue of Scientific Literature*, which is to begin with 1900, is to relate to pure science only, applied science being strictly excluded. It is possibly too late to remedy the position, which is probably due to the absence of representatives of technical societies at the International Conference.

It would seem desirable, further, that there should be a conference of technical societies to discuss the publication of a subject-matter index to technical and scientific periodicals. This institution has had for some time before it the question of the publication of such an index of subjects of interest to mining and metallurgical engineers; and probably a comprehensive index to engineering and other technical papers would prove more valuable.

This suggested Conference of Technical Societies might also consider other questions which interest technical societies individually, but which they are unable to obtain owing to want of concerted action. Thus, such an association might approach the Government on such questions as the excessive cost of postage of transactions, as there can be no valid reason why they should not be placed in the same position—although their transactions are issued at varying intervals of time—by a short Act of Parliament as an ordinary weekly newspaper.

And there are many other matters which, no doubt, crop up in connexion with the carrying out of the objects of individual societies in which concerted action would produce valuable results.—I am, yours, &c.,

W. Walton Brown, *Secretary*.

The Federated Institution of Mining Engineers, Neville Hall, Newcastle-on-Tyne, October 21, 1896.

THE PHOTOGRAPHIC SALON.

To the Editors.

Gentlemen,—In your issue of the week before last there appeared a letter from Mr. Charles Moss in defence of an attack that had been made on the management of the Salon.

While appreciating Mr. Moss's good intention, it is necessary to say that no Exhibition can be carried on strictly on the lines he infers. It is true, as he says, that all works are submitted to a committee of those best qualified to judge pictorial photography; but, were it thought that the simple merit of the picture was the only consideration, I am afraid that those responsible would have some very awkward questions to answer, and their ability might at times be seriously questioned.

It should be obvious to all that there must be a certain number of individuals—really there are only a few—who have to be treated apart from the strict merit of their works. Some there are whose services to photographic art have been invaluable in the past, but who cannot keep pace with the advancing ideas of the day; some whose labours on our behalf we could ill afford to spare; and some who, from their position in the world, must be studied. A glance round the walls of the present Exhibition, the finest collection of works of pictorial photography yet brought together, will convince any one of intelligence that these slight deviations from the strict rule affect its excellence to only an inappreciable degree.

I hope Mr. Oliver, to whose letter Mr. Moss replies, will not take his rejection to heart. We sometimes have to reject better pictures than some we accept. Notoriously there is a certain amount of luck in the matter, and the most honest selecting committee can make mistakes, and grievous ones. Let him forget his disappointment, and try his luck again.—I am, yours, &c.,

M. L. R.

To the Editors.

Gentlemen,—As one of the Linked Ring, allow me to say that I hardly agree with the criticisms that "Cosmos," in your last number, passes on what he terms the "attitudinisations" of some of those with whom I share membership, although it has before now struck me as strange that, when a few men ally themselves together in the Cause of Art, they usually take up a position of superiority to those who are intellectually below them. Why is this, sir? The Linked Ring and the Photographic Salon serve a Noble Cause. Generations yet unborn will bless them for their efforts in the advancement of Pictorial Photography to a place among the arts. They must be—nay, I know they are—conscious of this, so why should they sully their dignity by looking down upon a worthy but inoffensive institution, such as the Photographic Society undoubtedly is, and whose only fault is that it so strenuously carries out the terms of its charter that it can afford to ignore both the artistic and scientific sides of photography? I beg my fellow-members of the Linked Ring to desist from these uncharitable attacks upon the Royal Photographic Society. The Royal and Ancient Order of Buffaloes, the Foresters, and the Oddfellows, with their grotesque rites, regalia, and other paraphernalia, may excite the derision of a few members of the community who have no need of them, but is it not conceivable that to others, especially of the industrial class, such institutions may have their uses? I enclose my card, but I ask you to let me sign myself—

Yours, &c., A New Link.

To the Editors.

Gentlemen,—Some months ago, when you published a paper on photographic art that criticised the Salon and its adherents, "Cosmos" twitted the author with giving the Linked Ring's Exhibition a cheap advertisement. It occurs to me that this is just the effect which your contributor's gentle references to the Salon and its members, that appears in your last issue, will have—much against the design, I am sure, of so consistent an opponent of the Salon as "Cosmos" has all along shown himself to be. As one who agrees in the main with "Cosmos" that the Salon does not monopolise exhibited pictorial photography; that it is distinctly a rival show to that of our own Society (the Royal Photographic Society); and that personal pique and vanity are at the bottom of the actions and utterances of those members of the Linked Ring who are warmest in their praise of the Salon, and loudest in their unfavourable criticisms of the Royal and its Exhibition; may I suggest to your contributor the wisdom of, in future, leaving the Links and their doings severely alone? I don't suppose your contributor and others will at first appreciate this advice, the more especially as silent indifference would not by any means be relished by the Salon "young men," whom to attack is to exalt in their own estimation and to advertise to the photographic world generally; but "Cosmos" will at least agree with me, I trust, that the notice he and others take of the Salon is calculated to give it a prominence it does not deserve. That being so, why not, as the Americans say, "let it rip?"—I am, yours, &c., A Royalist.

London, October 26, 1896.

Answers to Correspondents.

*** *All matters intended for the text portion of this* Journal, *including queries, must be addressed to* "The Editors, The British Journal of Photography," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post. Questions are not answered unless the names and addresses of the writers are given.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* Henry Greenwood & Co., 2, *York-street, Covent Garden, London.*

Photographs Registered:—

William Bond, 53, London-street, Norwich.—*Photograph of four-in-hand team, with passengers.*

A. G. Lewis, 62, Shaw-heath, Stockport.—*Photograph of Stockport County Association Football Club.*

Alexander McHarrie, County Studio, Stranraer, N.B.—*Photograph of Sammy Tamson, holding his gun.*

John Munro, Dingwall, Ross-shire, N B.—*Photograph of herd of deer taken at bore of Ben Wyvis, in February*, 1895.

J. Blain Scott, 18-22, Devonshire-street, Carlisle.—24×18 *direct negative of Sir Thomas Grainger Stewart, of Edinburgh. Photograph of C. P. Colnaghi, Esq., of London.*

Received.—F. H. Evans; J. Lewis; Wallace Bennetto; L. E. Morris; Toning; Magic Lantern. In our next.

F. W. Robinson; W. Rutledge. We will communicate as desired.

A. C. Wright.—We have a vague recollection of the substance you mean. By next week we will endeavour to obtain the information you require.

Light for Lantern.—T. Fisher. We know of no kind of light, whether paraffin or gas, that will equal the lime light as a lantern illuminant.

Americus.—We do not reply to questions sent anonymously. If you care to give your name and address, or call upon us, we shall be happy to advise you.

Coating Machines for Dry Plates.—R. W. We are not quite sure as to whether Mr. Cadett still supplies coating machines. Why not write to him and ask the question?

Lens.—H. Watson. If the combination is symmetrical, it matters not which lens is used as a single lens, but, whichever is used, its convex surface should be next the focussing screen.

Interior.—A. Bryant. The fault is in the negative. It is frightfully underexposed. Instead of three minutes, such a dark interior, with the plates used, would require half an hour at least with the stop employed.

Acetylene.—W. Symonds. The acetylene light at present will not compete with the lime light in the lantern. It, however, will compete well with the best of the oil lamps. For a twenty-feet screen we should recommend the lime light, certainly.

Portrait Lens.—W. Foley.—One of the great faults of the Petzval portrait lens is astigmatism. If it could be got rid of, that would be the best form of lens of all, for extremely rapid work, by reason of its large angular aperture, which is not surpassed by any other lens.

ZAENSDORF SELF-BINDING ALBUM.—W. TURNER. We are not quite sure if this album is still in the market. Fallowfield used to be the agent. Write to him.

BLISTERS ON GELATINE PAPER.—W. S. J. We cannot understand that brand of paper blistering; it has never done so in our hands. Possibly you have made some departure from the ordinary method of working? From your letter we can form no idea of the source of the trouble, as it gives no details.

COPYRIGHT.—C. W. It by no means follows, as has been pointed out many times before, that by joining the Photographers' Copyright Union you must take half a guinea for the use of your photographs. You simply agree not to take less than that amount. You can take as much more as you can get; there is no limit in this direction.

COST OF LENS.—W. POOLEY. It does not follow that, because a lens is sold for a small price, it many not be good. Sometimes a low-priced lens turns out to be a good photographic tool; but, of course, many don't. By buying of a good maker you ensure a good instrument, and, as you are a novice, that is what we advise you to do.

DRYING BOX FOR COLLOTYPE.—BEGINNER. Gas may be used for heating the box, but care must be taken that the products of combustion do not gain access to the plates, as they have an insolubilising action on bichromated gelatine. Instead of gas we should recommend you to have one or two paraffin stoves. The fumes from them will be inert.

G. PRESTON.—1. We have no experience of the developer referred to, but we should imagine that the crystallisation out was due to the fact that you had dissolved too much of the salts. Why not dissolve them in the cold? 2. Nothing is simpler than intensification with mercuric chloride, followed by blackening with either ammonia or sulphite of soda.

FACTORY ACTS.—AN ANXIOUS INQUIRER. Photographic establishments certainly come within the Factory Acts, just the same as all other businesses. The Inspector under the Factory Acts in your district will furnish you with all particulars, or you can obtain the rules, &c., from the Office of Factory Inspectors, London, S.W., by writing for them.

PHOTOGRAPHING CHURCH.—Yes; the rector can forbid your photographing the interior of the church; but he cannot do so with the outside, unless, perhaps, if the camera is placed in the churchyard, and there is not a public way through it. If the camera is placed outside the church property, the rector has no power to prevent the photographs being taken.

STUDIO LIGHTING.—C. GREY. As the stippling was only put on the glass to stop out the midsummer sun at mid-day, an advantage would certainly accrue from clearing it off now, and applying it again next year. Moreover, it is more than probable that the paint has acquired a yellow and non-actinic tint by the exposure, and therefore stops off more light (actinic) than is apparent to the eye.

PHOTOGRAVURE.—COPPERPLATE says: "You would greatly oblige me by informing me which is the best book published on photogravure, together with price and publisher."—In reply: The best book on photogravure is that by Mr. Herbert Dennison, himself a master of the process. The book is published by Messrs. Iliffe & Son, St. Bride-street, E.C.; price, we think, 5*s.* or 3*s.* 6*d.*

CLEANING OFF OLD NEGATIVES.—PICKWICK. Soak the negatives for a day or two in cold water, and then put them, one by one, into hot. The gelatine will then dissolve off freely. With some plates, after a day or two's soaking, if the film be loosened from the edges of the glass, it can be rolled off in one piece, then the glass will be left clean for future use. No maker will purchase the plates for recoating.

OLD MANUSCRIPTS.—W. SMALL. There is no special treatment that you can apply to the manuscripts, or, if there were, the owner would not allow you to apply it to valuable and irreplaceable documents. If the parchment is thin, it is sometimes advantageous to back it up with white paper before copying. If it is yellow in colour, it will be advisable to employ plates sensitised to the yellow rays, such as those prepared with cosine.

RESIDUES.—R. & CO. The old developing solution is certainly not worth saving, notwithstanding the large number of plates developed daily. There is no silver in it to recover. The case is quite different with wet-collodion plates. That was well worth saving, as it contained a good quantity of silver. You have been doing wrongly by adding the developer to the chloride of silver residues, because the ammonia in it is a solvent of chloride of silver.

COLOURING IN OILS.—B. W. writes: "1. Kindly give me your opinion as to the best way to prepare photographs (albumen prints) for painting in oils. I have seen them mounted on wood, and sometimes on millboard, but do not know how to prepare them. 2. Would you be prepared to criticise my pictures as regards posing and lighting, and general effect, if I send some?"—In reply: 1. Albumen prints require no preparation for colouring in oils. They can be mounted on wood panels or millboard, or anything else. The material on which the prints are mounted makes no difference in the colouring. 2. We shall be pleased to give our opinion on the pictures.

THE "UNITED" LENS. B. B. C. says: "Having recently bought a lens (half-plate) will you kindly let me know, first, if you ever heard of, or saw, Marion's United R. R. lens; the one I bought is engraved as above, but I never saw any advertisement of such a lens; any information you could give me of its qualities and price will oblige. Second, who supplies apparatus for underground photography, that is, the lighting outfit?"—In reply: 1, The lens mentioned figures in Messrs. Marion's catalogue. A simple test or two with the camera will tell you what are its qualities. 2. Messrs. Marion & Co.; Perken, Son, & Rayment, and numerous other firms, supply apparatus for magnesium flashlight work.

THE KEW CERTIFICATES.—L. G. P. says: "I am desirous of obtaining Kew certificates for two or three lenses. Would you kindly tell me to whom they should be sent and with what fee?"—In reply: Address the Superintendent of the Observatory at Kew. We think, but are not sure, that the fee is 2*s.* 6*d.* per lens. If you are interested in the method employed at Kew, you will find in our volume for 1892 an exhaustive paper on the subject by Major Leonard Dawson.

ACTINIC FOCUS.—A. PAGE. If as sharp an enlargement is not obtained as is shown on the cardboard upon which the image is focussed, it is due to the optical and chemical foci of the objective not being coincident. That is the case with many objectives made expressly for the lantern: indeed, for projection purposes, better results are secured when the foci are not coincident. Substitute for the lens with which the lantern is fitted a photographic lens, such as an ordinary *carte* or a quarter-plate lens.

SALARY.—W. J. C. writes: "I have just bought a business. My predecessor paid the lady in the reception-room (who has been in the business since it was opened) 25*s.* a week and a commission, which brings it up to about 27*s.* Is this not an exorbitant salary? I may mention that she keeps the books, and generally manages the business in my absence. She says she will not take less."—We should say she would not. As she has had the management of the business for so many years, we should say that she is under, rather than over, paid.

SILVER IN PAPER.—T. H. H. asks how much silver is consumed in sensitising a sheet of albumenised paper?—This is a question, as it is put, that it is impossible to answer, as the quantity depends upon several things. For example, the larger the proportion of chloride in the albumen the more will be the silver required for its conversion. Again, the more viscous the albumen used, the more will be the chloride in it. Further, as there is always a quantity of solution remaining on the paper, the stronger that is, the greater will be the silver on and in the paper, &c.

TONING.—E. J. H. says he "would like to know, through your columns, the cause of sulphur toning, as some of my silver—albumen paper—prints, after staying in toning bath for about ten minutes, get what I call sulphur toned, the tone being of a bricky red, although paper has had silver washed well out of it before toning. Acetate bath is used."—If the ordinary acetate toning bath is used, there will be no sulphur toning of the prints. Our correspondent is in error when he says there is sulphur toning, that is, of course, supposing that the usual acetate toning bath is employed.

LENS.—R. FOTHERGILL writes: "With some very antiquated apparatus I have recently come into possession of is a lens I do not understand. The back lens is much smaller than the front; it bears the name of Horne & Thornthwaite, Newgate-street, and on it is 'caloscopic lens.' None of my friends can tell me anything about it, and there is no such firm in Newgate-street. Can you enlighten me on the point?"—The caloscopic is merely another name for the old orthoscopic lens. This form of lens is a good one, but it has been supplanted by others of more modern construction.

OIL ON LARGE PLATINOTYPE.—H. B. (Leeds) says: "My boy yesterday let two or three drops from the oil can drop on a large platinotype I have to frame. Instead of saying anything about it at the time, he allowed the oil (sweet) to spread in the paper. Is there any way of taking the grease out? Would soda and water do it?"—No. The oil may be extracted (we have little doubt, as we have never failed to do it ourselves) in the following way: Let a few drops of pure benzole drop on the spots, and, after it has been on a few seconds, blot off closely with clean blotting-paper. Repeat the treatment till the last trace of the grease is extracted. The benzole, if pure, will not leave a stain; if not, it may.

YELLOW PRINTS.—SOUTHSEA writes as follows: "I herewith send you one or two of my photographs, to see if you can explain the cause of the whites of prints going such an objectionable tint. They have been shown in a good north light (no sun) for about three weeks, and it occurs in some recent prints, while others I have, that have been printed for two or three years, are still pure and will stand any light, but the ones that are subject to it commence within a week or fortnight. It is evidently in manipulation, and, as it occurs only occasionally, I feel, with your advice, I may prevent it. I may add, I am most careful to see my printer gives full attention to instructions to washings between chemicals, but I somehow fancy the alum bath might be the cause, but anxiously await your opinion."—There seems but little question that the trouble is due to the manipulations, but, without seeing them carried out, it is impossible to say how. In all probability it arises from insufficient washing after the prints are taken from the alum bath; that should be complete. Try more complete washing at this stage, or omit the alum bath altogether.

WOODBURYTYPE.—T. writes: "I would be obliged if you would at some time inform me what is the largest size that is worked commercially, *i.e.*, can, say, 15×12 Woodburytype be produced, or has the process limitations which prevent it being worked to such a size? I have never met with any prints above whole-plate, but I have no means of ascertaining whether a larger size is workable, given, of course, suitable plant of increased power. Also, can you inform me what is the lowest workable pressure per square inch at which the hydraulic press must be run? On this point books are rather vague, saying from two to four tons per square inch."—The sizes produced commercially rarely exceed 10×8 to 12×10. Theoretically, there is no limit to size; but, in practice, the difficulties in working the process increase materially as the size is increased. The Woodburytpye process is better suited for small sizes, from a commercial point of view, than it is for larger ones. From two to four tons per inch is about as definite a pressure as can well be written, because it depends upon the metal used. If antimony or some other metals are added to the lead to give hardness, more pressure is required than when lead alone is used.

EX CATHEDRÂ.

The Exhibition of Portraiture that is now on view at the Camera Club comprises nearly 150 examples of work, and is well worth visiting. The collection cannot fail to be instructive by reason of the fact that chronologically it almost covers the whole ground of photographic portraiture, and exemplifies the various processes that have been employed. Thus there are examples of Daguerreotype and collodion positive portraiture, as well as a series of calotype portraits of well-known artists and others made by D. O. Hill, in the year 1846. Examples of Mrs. Cameron's art, with which many of our readers are familiar, bring us down to more recent times, and we pass by easy stages to the well-retouched portrait of the show-case, that appears to be having somewhat of a bad time at the Exhibitions just now, until finally we come to the "heir of the photographic ages"—the portrait according to Hollyer or Craig Annan.

* * *

There is so much that is really interesting as well as instructive in this collection that it is a pity it must be dispersed. Especially eloquent are the fine portrait studies of D. O. Hill. They tell us that, after fifty years, the very best among our portrait photographers do not excel him in mastery of pose and lighting. So, too, may it be said of Mrs. Cameron's work, that, as studies for the portrait photographer, they are full of power and suggestion. It is not our intention to devote any lengthy remarks to this admirable Exhibition. In all probability it contains most of the best work that has been done in photographic portraiture during the last fifty years. There are some Taber bas-relief portraits on the walls; but, without this additional attraction, a visit to the Camera Club just now will well repay the time spent. Every credit is due to Mr. George Davison for his work in organizing the Camera Club Exhibition of Photographic Portraiture.

* * *

Mr. Maskell writes us: "May I be allowed to announce that the Photographic Salon will close on Saturday next, November 7, at 9 p.m. Pictures may be removed from the gallery on the evening of that day, between the hours of 9 p.m. and 11 p.m. provided that no packing or wrappers are brought in. Notice of arrangements for the delivery of pictures which may not be so removed have been sent to the exhibitors or to their agents."

* * *

This (Friday) evening there will be a Meeting of the General Committee of the Traill Taylor Memorial Fund, at the Royal Photographic Society's Exhibition Gallery, 5A, Pall Mall East, at 7.30 p.m. The business is to receive the report of the executive committee with reference to the disposal of the funds in hand.

* * *

Gelatino-chloride paper is suggested by a correspondent as having a use not usually accredited to it, viz., that of being a test for damp sheets. Our friend, who is obviously a commercial traveller, and, therefore, not without sympathy for his colleagues, writes to us as follows: "Having occasion to sleep in country hotels at frequent intervals, I always dread the idea of being put in a damp bed. The watch-glass dodge for testing the sheets is all very well in theory, but I find it difficult to judge by this method. Upon taking some gelatino-chloride printing-out paper out of a damp box, I was immediately struck with the idea of using it as a test for hotel beds. Of course, all photographers know gelatine is very susceptible to damp, and if a piece (say half-plate size) of gelatino printing-out

paper is placed *in a dry condition* between the sheets for a few minutes, it should be quite crisp if the sheets are dry, but, if damp, the paper will be quite limp. If it is damp weather, the paper can be dried over the gas or candle before placing in the bed. I send you this little tip, as I think photographers do their fair share of travelling, and often have to put up with all sorts and conditions of accommodation."

THE FUTURE OF PHOTOGRAPHY (?).

THE Forty-first Annual Exhibition of the Royal Photographic Society, which closes next week, may well be said to mark a new epoch in the history of photography. During the time it has been open, varied indeed have been the expressions of opinion we have heard regarding its merits. Some persons have strongly affirmed that it is the best show the Society has ever had. On the other hand, not a few have denounced it as being just the reverse, some going so far as to say that some of the work now most extolled would certainly have been rejected in the pre-Salon days. In some respects both are right in their ideas. The one looks at the show from an art point, and the other from a technical point of view.

When the unfortunate split occurred in the Society a few years back, and the Salon was started, it was alleged that some of the Linked Ring prognosticated that the yearly Exhibitions of the Photographic Society were doomed, if not the Society itself. What has happened? The Salon struck out with a new style of work, which, at the time, was freely condemned by the general body of photographers, by many ridiculed. This year it must be confessed that the Photographic Society, by its Committee of Selection, has copied the Salon. It has rejected some hundreds of technically excellent photographs, and has accepted a very large number of what, from a technical point of view, are very imperfect ones. Those who hold the opinion that the present Exhibition is, technically, a failure are termed by some "Philistines."

Without expressing any opinion whatever as to the merits of the two sides, we shall, for the nonce, consider the Exhibition entirely from the Philistines' point of view, and at once ask if it tends to advance photography, which is one of the chief functions of the Society? Its first law reads thus: "The object of the Royal Photographic Society shall be the advancement of photography, and the branches of science and art connected therewith." Does the present Exhibition tend to carry out that rule? The Jena glasses, for instance, have put new powers in the hands of opticians, who can now give us lenses that were unheard of before; but of what good are such lenses, if the type of photograph, as shown at Pall Mall, is to be the photography of the future. By far the larger proportion of the work shown there might just as well be produced by the most primitive form of lens, or, indeed, by no lens at all—a tolerably large pinhole would have answered the purpose. In many instances, lenses of high quality were, doubtless, used in taking the negatives; but the sharpness of the image has been lost, or purposely destroyed, in the prints. The general idea of the Society, some say, with this year's selection, seems to be that sharp pictures are not art, neither are bold and vigorous ones.

There is no gainsaying the fact that sharp and vigorous photographs may be artistic. Take, for example, the work of Colonel Gale, both at Pall Mall and at the Salon; it is both good photography and good art. These pictures are sharp and bold, and are quite distinct from the majority of the others, which are made in a low tone, and many from negatives that, at one time, would have been cast aside as failures. Which, then, of the two types will be the photography of the future? This is a somewhat important question, as it has a commercial side, and that must not be overlooked, as a large proportion of the Society is composed of professional photographers. Does the general public appreciate unsharp pictures in a low tone, and on rough paper? Will sitters, for example, who pay for portraits be content with their own counterfeit presentments if they are of the character of many in the two Exhibitions shown as "a portrait of a lady," study of a head, &c., or will the public purchase, say, landscapes or views of places of interest of the misty and fuzzy-type order, however artistic they may be according to the impressionist school? The general public do like, and, doubtless, will for a long time to come, a photographically good picture, and one that is at the same time also good artistically.

As we have just remarked, according to the first rule of the Society, its province is to advance photography, and the branches of science connected with it, as well as art. How is that served by the present Exhibition? There is not a single collotype shown; photo-engraving is represented by three or four very small pictures; scarcely any reproductions of works o art—a most difficult branch of photography, now mostly in the hands of foreigners—are there; no "process work" is shown, except the small illustrations in the catalogue; photo-chromotypography, chromo-collotype, or the three-colour processes, are not represented at all. It may be that none were sent in. But it may be asked is it not the province of the Society to obtain examples, in order to show the existing state of such important phases of photography? Most workers in these branches, at home and abroad, would, no doubt, be only too pleased to supply examples of what they are doing, if specially invited to do so.

One thing is certain, namely, that the Royal Photographic Society cannot please all, or ever will; but it may be a question for its future consideration as to whether it should not hold two Exhibitions annually, one to be devoted to the art side of photography, and the other to the technical side of it, or perhaps combine the two in one by having two distinct sections, separated entirely from each other. In this article, as we have said before, we express no opinion of our own, but simply echo the opinions that many others have freely expressed.

To Detect Formaline.—Some new and simple methods have recently been proposed to this end. One of them is by means of milk. One drop is added to the solution under examination, and the mixture is poured carefully on to a quantity of sulphuric acid in a test tube. The presence of formaline is shown by the production of a blue ring.

Standard Solutions of Hypo.—The reciprocal action of hypo, or, more correctly, thiosulphate of soda and iodine, and the usefulness of one for quantitatively estimating the other, renders any process of easy standardisation of considerable value. To standardise the hypo solution, Herr E. Rieglar uses iodic acid. On treating a solution of hypo with this chemical a certain reaction occurs ($6Na_2S_2O_3+6HIO_3=3Na_2S_4O_6+5NaIO_3+3H_2O$) and the smallest excess of iodic acid liberates iodine. Since this acid can be obtained absolutely pure, and can be completely dried over sulphuric acid, is not hygroscopic, and remains unchanged for a long time when dissolved in water, decinormal solution is a very serviceable reagent for standardising hypo solution.

Balloon Photography out-distanced.—We have on previous occasions described some results of scientific kite-flying, but quite lately, at Mr. Rotch's observatory at Bene Hill, near Boston, some extraordinary results in this direction have been obtained, as described in two successive numbers of *Science* last month. The kites employed were not the familiar toy of our childhood, furnished with yards of tail, but were the tailless Eddy kites and the Hargrave box kites, seven of the former and two of the latter being used, piano wire taking the place of the usual "string." The greatest pull on the wire reached as high as ninety-five pounds when the kites had reached their greatest altitude—8750 feet! On the occasions referred to, a large number of self-registering meteorological instruments were taken up by the kites, and many interesting records were brought down. There is very little doubt that, in lieu of the apparatus named, it would be quite possible to send up a photographic camera with arrangements for instantaneous self-exposures at intervals, or, possibly, exposure by electrical means. From its lightness, and the absence of the cumbrous arrangements for the use of gas when balloons are employed, it is obvious that kite photographs might play a most important part in military operations, and enable small parties to survey an enemy's country or strategical positions with an ease and celerity far outstripping balloon possibilities.

X-Ray Photographs from a Bulb without Terminals.—Mr. F. J. Smith, writing in *Nature* last week, describes some very remarkable experiments he has recently been making in this direction. Upon a protected plate a hand was placed, and four inches above it a Crookes' radiometer. "The terminals of Tesla coil were placed about half an inch from the bulb on either side of it, inclined to one another at an angle of 120°, the vertex of the angle being in axis of the radiometer. The Tesla discharge was allowed to bombard the bulb for four minutes. On development, a clear picture of the bones of the hand appeared. I failed entirely to get any X-ray results when only the usual induction sparks bombarded the bulb, these sparks often destroying the vacuum. My Tesla apparatus gives a spark three inches long in air at the normal pressure." After describing certain perceptible changes brought about without the radiometer, he goes on to say, "Thinking that the vanes on the radiometer might have played a considerable part in producing the X-ray photograph, I replaced the radiometer by a well-exhausted bulb, 4 cm. diameter, made of soda glass; the bulb was placed in respect to the conductors from the Tesla coil in the same position as the radiometer in the former experiment. I found that, with the same exposure and distance, a good X-ray photograph of the bones of the hand was produced. During the experiment the bulb was lit up with a bright and yellowish-green glow." Mr. Smith's experiments open out an entirely new field for experiment; but, in view of the fact that in the early period of Röntgen ray work it was stated that X-ray photographs were producible from the spark alone of an induction coil, Mr. Smith's observations would be still more interesting if he could say whether his photographs could not have been produced without any bulb whatever. Perhaps we may yet be informed on this point.

ON THINGS IN GENERAL.

The burning question—no pun is intended—for the season will undoubtedly be acetylene, whether to adopt it or not. The Editor has done wisely in drawing attention to the position taken by insurance offices in regard to its employment, the replies from the insurance offices, given in last week's leader, being eminently unsatisfactory. I can only hope with him that the advice given will not fall on deaf ears. Mr. Bolas's simile of a suspended weight is a just one. Acetylene, though it may be perfectly safe in the hands of experts, is by no means to be likened to coal gas; in fact, a stored chamber of mixed oxyhydrogen is in some respects safer. It is just one of those bodies which have an unhappy knack of exploding in most unexpected manners, but for which untoward behaviour the simplest and most natural explanation is immediately available—after the event. Then, perhaps, for the first time in his life, the victim reads his insurance policy—how many are there who have read their policies any further than the amount insured?—and he finds he has been acting against the agreement, and forthwith becomes very angry. Against himself? Oh, no, against the insurance company for putting in the prohibitory clauses. However, notwithstanding all this, acetylene is such a valuable agent that there is little doubt the whole bearing of the case will be thrashed out, and reasonable conditions eventually offered by the offices. There is no reason why some such apparatus as has recently been fully described in these pages should not be employed with perfect safety. The chief danger, it appears to me, lies in the possibility of some hitch in the application of the water occurring; a very small quantity only, for example, gaining access to the carbide, the consequences from which might be of the utmost seriousness. I should like to express my great appreciation of Mr. James Swinburne's treatment of the subject in his lecture before the Society of Arts—that is to say, if he is still alive; for after reading what he had to say about the feminine element in connexion with the use of such novelties, I felt a sympathetic shudder as to his fate when his remarks came to the ears of some of his lady friends. "Women," he says, "are wanting in the faculty of understanding things, and they have the unreasoning conservatism and conventionality belonging to the undeveloped mind as seen in boys and savages." Really, Mr. Swinburne, you are a very brave man! But to return to my topic, he does well to point out the false analogy so often drawn between the cost of acetylene as made on the spot and ordinary coal gas as delivered at one's doors; in fact, even at existing prices there are few gas companies anywhere who would make much show on dividend day if it were not for the residuals—the tar and ammonia, &c.—they sell. There are no residuals of much value in acetylene making, and, if it had to be made like coal gas at a central station and then delivered, a very different tale as to its price would have to be told.

I have been quite pleased to read the last issue of this Journal in comfort, for I have so much been occupied lately in picking out the few grains of photographic interest, that I almost forgot it was not the *Chemist and Druggist's Journal* I was reading. What a mighty pother has been raised because some little-needed chemical has had to be purchased from a registered chemist, instead of a photographic dealer! A photographer can buy his plates, his hypo, his pyro, his gold chloride from any stock dealer he likes, but has to go to the chemist for his corrosive sublimate. The unfortunate chemist and druggist is the only tradesman who has to go through a series of stiff examinations before he can open shop in a proper manner; surely he should have his reward—even if it is only in matters photographic—the power to sell a few annual shillingsworth of poison.

Now, if the complainers had to face such a state of things as, according to the extract in this Journal a fortnight ago, he has to do in the United States, they might have some case to go upon. With hypo over sixpence an ounce, and carbonate of soda two shillings a pound, we might fairly expect to see bichloride at a guinea or two a pound! But even here there is another side to the question. A first-class chemist prides himself upon always buying the best chemicals he can, and his prices must be compared, not with the class of chemical that the photographer is content with, but with the high standard of the shop in question. I have before me, as I write, a wholesale price-list (prices that the chemist would himself have to pay). I find the best hypo costing a shilling a pound, and the same price for best carbonate of soda crystals.

So much for the chemists. Let us look at the photographic dealers. I have often seen chloride of gold quoted at 14*s.* a dozen fifteen-grain tubes, and, when single tubes are bought, 1*s.* 6*d.* or 1*s.* 9*d.* has been asked for a similar tube. Where is the honesty here? Chloride of gold, or the double chloride, has so long been sold of a recognised quality of seven grains metal to a tube that any deviation from that quality is a distinct fraud. If this is to be permitted, there is no limit whatever to the reduction in the quantity of gold present in a tube of gold. When it is considered that a sovereign, which, of course, contains a pound's worth of gold, only weighs about 123 grains, and contains 113 grains of gold, it is very easy to reckon how much gold is obtainable for fourteen pence.

Certainly not fourteen pennyworth, even if the containing tubes were stolen, and the cost of manufacture and acids were *nil*.

It is quite possible that some discrepancy of this sort may account for the trouble of "Printer," who in the Correspondent's column, asks why he uses fifty per cent. more gold than is used by a relative of his employer for a similar number of prints. The Editor's answer is, in all probability, the correct one; still, the above consideration must be taken into account, as also the possibility of the expensive one of the two not trimming the edges of his prints before toning.

What a fund of interesting reading is to be found in those columns! Another example: a photographer who has purchased a business, wants to know whether the reception-room lady is not asking an exorbitant price in wanting 25*s*. per week and a commission, which would bring it to about 27*s*. All I can say is, that if the inquirer knows so little of his business as to ask the Editor what he ought to pay for the salary of his chief assistant, the sooner he ceases to run a studio the better it will be for his pocket.

I have heard surprise expressed in many quarters as to the finding of the County Court Judge, who gave a verdict in favour of the plaintiff who had sent some plates to a customer's order, the plates eventually being delivered smashed. If every dealer is expected to insure his goods before dispatching them, the price of many of them would rapidly "go up." It is perfectly just for the dealer to take the position that when he delivered the goods to the railway, and so long as the packing is efficient, and the nature of the goods declared, any loss must be borne by the consignee. This is both law and justice!

FREE LANCE.

DIGRESSIONS.

XI.—"THE BEARINGS LIE IN THE APPLICATION."

FOR several years I have been endeavouring to show that, if the student is to get all out of pictorial photography that can be got, he must go at it in a whole-hearted manner and not be tempted from the path by side issues. In doing this I have had to say pretty strongly that a great deal of time and talent has been wasted on that which has no more to do with pictorial photography than the manufacture of colours and canvas has to do with the painter; in fact, just as much and no more. Somehow or other, sometimes by misunderstanding, and sometimes wilfully, this has been gradually interpreted to mean a "hatred of science" on my part, most condemnable. I think the time has come for me to make as serious a reply to—I won't call them my detractors—as such a curious mistake will allow.

The title to the first article I ever wrote on photography was *On the Simplicity of the Collodio-albumen Process*, and I think it may fairly be claimed as characteristic of nearly all I have written since, which has had for object the endeavour to clear away as much as possible all difficulties, complications, and hindrances to the photographer getting straight to his proper work, leaving all else to those whom it may concern. In doing this, I have had to deprecate the necessity of the photographer having anything to do with the manufacture of his materials, or to enter into chemistry, or other science, further than was required for him to understand the use of the tools he employed; surely enough knowledge for any artist. Time was when the photographer, like the painter, had to make most of his materials, simply because there were no makers to supply him with them, but now there is almost something comic, if the waste of time were not tragic, in the earnest photographer troubling himself with what can be done better and cheaper for him. He may as reasonably cook his own dinner, or black his own boots.

It was different until about 1880. Before that year every man had to be his own chemist; since that time there has been no use for any photographer (I don't mean experimentalist) to understand, as I have always put it, more of technique than *the efficient use of his materials*. If he is a photographer only, what more does he want to know about his materials than how to use them? What more would further knowledge add to the effect of his result? Of course, I credit him with the usual modern school education. Nearly all the rest he will find on the packet of plates or paper he uses, or in any of the handbooks; and, in fact, the nearer he keeps, as a rule, to the instructions of the manufacturers, whose interest it is for his goods to be successful, the better will be his results from a technical point of view, and the more time it will allow him for the mental part of his art.

I have only one object, and that is to see photography flourish; and by photography I mean what the word means, not process nor emulsion-making, nor modification of developer, nor any playing at science whatever. I reiterate, as I have done again and again, that I have a very great respect for real science, even abstract science; but I look upon it as a thing apart, a thing we could not have done without in the past, which should certainly be cultivated, and will surely be useful in the future, but will always be the work of a separate mind from that of the artist who uses the processes of photography.

There are several of our—shall I call them abstract—photographers for whom I have the greatest respect, and read with admiration much of what they write; I dont mind mentioning names as types—Abney, Bothamley, Pringle—but, as a pictorial and practical photographer, I look upon the subject from another standpoint. It is when science is watered down to what we usually get, the stuff that is manufactured to "fill up an evening," or to be an excuse for certain poor articles that are written, that I cannot help thinking it does absolute mischief by distracting the student with unnecessary trivialities. And I must ask my reader to bear in mind that it is not the bad scientist alone that I object to, as seems to be commonly supposed, the bad artist is quite as objectionable to me as the sham scientist. I have frequently said that what is represented symbolically by scales and weights is not a help, but a hindrance, to the pursuit of photography, when the art is properly understood. Will any of those who think I am too severe on science in relation to our art refute me? It may easily be done if the material is at hand, as those who have objected to my teaching should have made sure before they spoke. Will they send me the names of any scientists who have succeeded in photography—I mean the photography which is not something else? I am quite aware that many of them are successful in making pretty photographs, and I have known two or one rare instances of one or two getting a little beyond "the usual thing," but not very far; and, what is more, they don't expect to get further, for most of them seem to take pleasure in saying thay know nothing about art, and how can anybody expect to succeed in any subject he knows nothing about? Yet, strangely enough, they never hesitate to give their opinions about art, and, indeed, sometimes undertake to judge pictorial work as if they *did* know something about it! Now, on the other hand, we pictorial photographers, although we have never boasted that we know nothing of the subjects, have never had the presumption to read papers, since we were boys, on mathematics, optics, or chemistry, or any of the abstruse subjects that are made to belong to photography. Scientists waltz in gaily, where artists modestly creep on tiptoe.

And thus, in trying to make things simple for artists who use photography, and clear away some of the irritating hindrances that have grown up around the art, I believe I have got a sort of evil reputation for a hatred of science. Only lately an American writer, in a very kind and appreciative article, headed, "Can we learn too much?" is quite sure I am wrong in saying the photographer—the pictorial photographer, it must always be remembered—need know little more science than how to efficiently use his tools, and that it is not possible to learn too much. He says he does not believe that I would (I quote his words) "really undervalue necessary knowledge, and think his (H. P. R.'s) recommendation to leave it alone arises from a fear that the student will be tempted on its account to neglect the study of the higher phases of photographic picture-making—art itself. But the fear is unfounded. Those who go in for photography as they would for any other amusement may, and probably would, but I do not speak of or write for them. The man who is worthy of photography does not regard it as a plaything with which to pass a leisure hour, but as a means of realising and showing to others something of the emotions and impressions that nature produces in his own mind, and he knows, and the higher up the ladder that leads to success he gets the more thoroughly he knows, that the goal at which he aims can only be

approached, never perhaps altogether reached, by patient, persevering study."

This is good, and agrees with all I have ever written. The pastime photographer is not worth troubling about, and the man who has the compelling influence towards picture-making is safe, it is the next rank that wants warning against illusions, and strengthening with good advice. There is not only the fear, but the knowledge that science, the showy pseudo science we meet with among photographers, is so exceedingly easily acquired, and picture-making of the advanced kind so difficult, that it is easy to lapse from the pursuit of one to the other.

Perhaps I ought to explain what I mean by science in this particular. I do not mean the higher branches of science, but the pretentious sham kind with which our art abounds. As an illustration of the sham scientist might be mentioned the man who has tried all the developers, and talks of nothing else except similar trifles. This man would be useless as a picture-maker; he is lost in the shallows. He may be a capital paddler, but could never have a good swim in the depths. The man who can give you advice on all subjects, both particular and minute, in learned language is a lost photographer. The suspicion usually is that he knows this, but must make a reputation at all costs; so is the one also lost who passes his time inventing little things. I have often repeated that a profound knowledge of science either cramps the artistic faculty, or, what is more probable, shows an order of mind to some extent inimical to a feeling for art. Both faculties are rarely found to exist in the same person. What I assert is the result of long observation, and lately I have searched carefully through the last four years' catalogues of the Salon and the Pall Mall Exhibition for a picture made by a scientist; I have done this with every desire to refute myself and to find what I looked for, but I met with as much difficulty as, and had no more success than, Diogenes, when he searched for an honest man in the daylight with a lantern.

It is not true science, but too much of it for the purpose, that is objected to. I don't deny that photography is the result of science, so are nearly all our great inventions, and some of our discoveries, but the practice of pictorial photography does not require so great a name. It is now reduced to a simple matter, that need never go beyond the use of easily used tools. For the present our tools are adequate for our purpose, notwithstanding which we are ready to accept improvements when they are offered to us by proper and responsible persons; but it is not for pictorial photographers to turn from their true path to go worrying after them, and we don't want scientists worrying after us with *supposed* little improvements, of which we have had to discard such quantities the last ten years.

Taking all these things into consideration, I still feel that I am doing my duty when I entreat those photographers who want to succeed in pictorial photography to go straight to their object, turn deaf ears to all distracting studies and those which are not essential, and then they may in time succeed.

The following will illustrate and help to confirm what I have written.

A letter-writer in a contemporary some time ago, in relation to another matter, gave a quotation from Mark Twain's *Life on the Mississippi* that exactly shows the effect of too much fact, and science is the art of fact.

"Now, when I had mastered the language of this water, and had come to know every trifling feature that bordered the great river as familiarly as I knew the letters of the alphabet, I had made a valuable acquisition. But I had lost something, too. I had lost something which could not be restored to me while I lived. All the grace, the beauty, the poetry had gone out of the mighty river."

Then he goes on to describe the gorgeous sunset, and wondrous beauties of the river, too long to quote. He describes how, as the facts came in the poetry went out; and the splendid effects began to be looked upon after this fashion: "This sun means that we are going to have wind to-morrow; that floating log means that the river is rising; that slanting mark on the water refers to a bluff reef which is going to kill somebody's steamboat one of these nights; those trembling 'boils' show a dissolving bar and a changing channel there; that tall dead tree is not going to last long, and then how is a body ever going to get through this blind place at night without the friendly old landmark," &c.? All the poetry and beauty were gone, and knowledge brought nothing but cold facts.

H. P. Robinson.

FOREIGN NEWS AND NOTES.

Eikonogen and Para-amidophenol.—Dr. Andresen gives the following as the best formulæ for these developers, both for plates and papers:—

Sodium sulphite	2⅔ ounces.
Potassium carbonate	1 ounce.
Eikonogen	288 grains.
Boiling water	20 ounces.

The solution should be placed in bottles whilst still hot and immediately corked. It will keep for any length of time, and, if it acts too energetically, should be diluted with a corresponding quantity of water. If very delicate negatives are required, the above quantity of potash should be reduced by one-half. If over-exposure is feared, development should be begun with very dilute developer to which some potassium bromide has been added. For bromide paper the developer should be diluted with five parts of water. A two-solution developer can be made as follows:—

1. Sodium sulphite	1½ ounces.
Water	20 „
Dissolve and add eikonogen	150 grains.
2. Sodium carbonate	3 ounces.
Water	20 „

For use mix 3 parts of No. 1 with 1 part of No 2.

For para-amidophenol he suggests for a two-solution developer:

1. Para-amidophenol	192 grains.
Water	20 ounces.
2. Sodium sulphite	576 grains.
Potassium carbonate	576 „
Water	20 ounces.

For use, mix 1 part of No. 1 with 2 parts of No. 2.

For a one-solution developer dissolve 5 ounces of potassium metabisulphite in 20 ounces of water and add 800 grains, and add saturated solution of caustic potash till the precipitate first formed is redissolved. This will keep for a long time, and for use should be diluted with from 10 to 30 parts of water.

Tricolour Projection.—M. Marguery suggests the following baths for obtaing the self-coloured images for projection:—

For the Red Sensation.

Carmine	5 parts.
Ammonia	15 „
Water	100 „

For the Green Sensation.

Saturated solution of picric acid.

For the Blue-Violet Sensation.

Methylene blue	10 parts.
Water	100 „

Glass coated with plain gelatine should be soaked in a three per cent. solution of bichromate of potash, and then dried and exposed under the negatives, developed with hot water, and then soaked in the above baths.

Newspaper Imprints.—It is well known that plates wrapped in newspaper will show on development all the printing, which is extremely difficult, if not impossible to remove. According to the *Photographische Rundschau*, this impression can be entirely removed by bathing the plates before development in a two per cent. solution of acetic acid and well washing with water, and then treating with an alcohol bath.

Neutral Developers.—Professor R. Namias has been experimenting with neutral developers made with magnesia and sulphite, and finds that, though slow, they act well. The equations representing the chemical reactions he states to be as follows: The hydrobromic acid set free by the reduction of the silver bromide sets free sulphurous acid from the sulphite—

$$2HB_2 + Na_2SO_3 = 2NaBr + H_2SO_3,$$

and the developing action is lessened. If now magnesia MgO is

added, the sulphite is neutralised with the formation of magnesium sulphite.

$$MgO + H_2SO_3 = MgSO_3 + H_2O.$$

In this manner the developer remains neutral the whole of the time. If developers are used in which the acid of the radical is not completely saturated, the magnesia will neutralise this and the developer be more energetic. Magnesia developers have less tendency to oxidise, and no ill effect is produced on the gelatine. Pyro, eikonogen, and metol are suitable for this kind of development, but hydroquinone loses all its developing power. Such developers are best prepared by using double the normal quantity of developing agent with the corresponding quantity of sulphite, and adding about fifteen parts of magnesia to every 1000 parts of solution. After use it can be poured into a bottle for repeated employment.

Keeping Developers.—Coconari sugges the addition of one or two small fragments of calcium carbide to developers when they are to be kept, so that the air may be driven out and acetylene take its place. The disadvantage to what seems a perfectly feasible plan is that calcium hydrate would be formed, and this would react with any alkaline carbonate, and, forming the alkaline caustic and carbonate of calcium, be precipitated; and, further, acetylene has a reducing action on the salts of silver.

Cyanine as a Colour Sensitiser.—Schumann, who is so well known for his researches upon spectrum photography, points out in Liesegang's *Photographischer Almanac* that most of the difficulties met with in using cyanine as a colour sensitiser are due to the employment of plates of too high an initial sensitiveness, and to keeping the plates too long. He states that a plate sensitised with cyanine must be used at once, and that, even after a day, it does not give such clean negatives as when used immediately it is dry. The developer should be of moderate strength, and with plenty of bromide.

Metol.—Schienol states that metol by itself is not a developer, but that in the presence of sulphite, although it works slowly, it is excellent, and he ascribes it to the too free use of an alkali. He affirms that a developer composed of five to six per cent. of aqueous solution of sodium sulphite, with the addition of one per cent. of metol, will give denser negatives than one with a lot of alkali; further, that the plate may be left in the developer for some considerable time without becoming fogged or suffering in any way. The development is necessarily slow, but, with an addition of one per cent. of washing soda, it may be hastened, but not with superior results.

Banded Spectra.—Wiedermann points out that it is generally considered that complex molecules give banded spectra, whilst atoms give line spectra. But this, he says, is not quite correct, as proved by Eder and Valenta's researches upon the spectra of mercury vapour; and also, according to Schmidt, cadmium and zinc in a vacuum tube, with low power, and plenty of these vapours give bands in the violet. Potassium and sodium also give in vacuum tubes continuous spectra in the red and green, which are similar to the continuous spectra first observed by Warburg, and they also give a fluorescent spectrum, which, in the case of sodium, consists of a series of bands in the blue and green, of which the more refrangible mainly consist of single lines, but the less refrangible cannot be thus resolved.

Sodium Tribasic Phosphate.—Dr. Max Kortüm strongly recommends the use of this salt to replace the ordinary alkalies, and suggests the following developer:—

1. Water	400	parts.
Sodium sulphite	40	"
Hydroquinone	5	"
2. Water	200	"
So[illegible] tribasic phosphate	32	"

have a
his materials. parts. He further states that the action of the salt
to know about rption of carbonic acid from the air, and its con-
would further kno into sodium carbouate and phosphate.
I credit him with the usual modern sc
rest he will find on the packet of platoal Work.—Helheim
of the handbooks; and, in fact, the never been very successful

with zinc, on account of the difficulty of burning it in, as the zinc begins to melt or crystallise. He has overcome this difficulty by applying the commercial forty per cent. solution of formaldehyde to the enamel film, and also adds a little to the etching fluid. He suggests the addition of a little formaline to the ferric chloride solution for photogravure in order to obtain greater contrast.

A Universal Developer.—Kastner, of Vienna, suggests the following glycin developer as the universal developer. In a bottle capable of holding a pint place 16 ounces of water, and add 1 ounce of carbonate of potash and ½ ounce of glycin, and, when all has dissolved, 1½ ounces of sodium sulphite. This costs about one shilling, and may be used over and over again both for negative and positive work.

Yellow Screens.—Fleck suggests the following as the best yellow screen for use with erythrosine-sensitised plates. Dissolve 10 parts of acridine yellow in 150 parts of alcohol, and 5 parts of fuchsin in 100 parts of alcohol. To 100 parts of two per cent. raw collodion, add 20 parts of the acridine solution and 7 to 8 parts of the fuchsin solution.

DYES AND PIGMENTS IN PRACTICAL PHOTOGRAPHY.
IV.

The practice of film-staining has now become a recognised method of securing not only freedom from halation, but also a more perfect rendering of colour values. Unfortunately, a great difficulty is encountered when we attempt to explain the exact influence of the dye in the production of orthochromatic effects. This difficulty consists in the uncertainty which exists as to the precise action which takes place. It is not yet definitely established whether this action is physical or chemical—that is, whether the light vibrations absorbed by the dye are transferred to the sensitive silver salt, or whether the dye itself is decomposed, so as to act as a kind of developer to the silver salt. A complete discussion of the arguments in favour of these rival theories would be beyond the scope of this article, but certain facts have been established which undoubtedly guide us in the selection of suitable colour sensitisers. We are here again confronted, however, with somewhat conflicting evidence on account of the great variability of the commercial samples of dyes employed by different workers.

In the first place, the colouring matter combines with the silver salt to form a lake, the colour of which is not always that of the dye. For instance, Carey Lea observed that some blues dye the silver salt lavender, while methyl green produces pink. The behaviour also is not the same with the different haloids. Those dyes which do not form these lakes are useless for producing orthochromatic effects, for which reason the aniline dyes are useless for this purpose.

The majority, if not all, of the dyes which are useful as sensitisers are unstable in sunlight. Even those which are apparently stable are probably fugitive in thin films. In this connexion Abney has shown that the fugitive dyes only bleach when exposed to the rays which they absorb, and they may be kept for an indefinite period if protected from those rays.

It is difficult, if not impossible, to establish any connexion between the sensitising action of dyes and their chemical composition, although there is undoubtedly an agreement in the behaviour of bodies of analogous constitution.

To produce any sensitising effect upon any kind of ray, the ray in question must be absorbed by the dye. Hence the absorption spectrum of the dye is the key to its behaviour as a sensitiser. Unfortunately the absortion spectrum of dyes is influenced by other considerations, such as the nature of the solvent, the density of the medium (causing, by Kundt's law, a displacement of the absorption band towards the red), and the impurities present in the gelatine tending to form lakes with the dye. Then, again, the quantity of dye necessary to produce a sensitising action is so extremely minute that its behaviour in a gelatine film may differ entirely from its properties in mass. It is not always possible to predict, therefore, what will be the precise nature of the absortion spectrum of a dye when present in an attenuated condition in a gelatine film. Nevertheless, in estimating the probable behaviour of different commercial samples of dyes, it may generally be taken that, other things being equal, those which have the same absorption spectra will have the same sensitising action, although mixtures of dyes do not always produce an effect equal to the sum of their separate actions, one dye sometimes neutralising part of the effect of the other.

Although a large number of substances have been found to possess the property of behaving as colour sensitisers, comparatively few have actually come into general use for this purpose, the most important being the phthaleine group and its related compounds, the quinoline dyes. Of the phthaleines, the most active are eosine and erythrosine; and, of the quinoline group, cyanine (quinoline blue), quinoline red, and azaline, a mixture of these two dyes, have been found most effective.

In practice, the photographer will find it advantageous to purchase ready-dyed plates, of which the exact constitution is a trade secret. There may be occasions, however, when it may be necessary to dye ordinary plates by the bath process, when the following method may be followed:—

Prepare stock solutions of cyanine, one part, in alcohol, 2000 parts; or erythrosine, one part; water, 1000 parts. For use, take one drachm of either, and add ten drachms of water. If cyanin is used, it is necessary to add one drachm of a ten per cent. solution of ammonia. The plates in this case must be used within two days; but ammonia is not necessary for erythrosine, and the plates thus prepared will keep several weeks. The plates are simply immersed in the solution and dried in the dark. The duration of the immersion is important, two or three minutes being enough. Too short a time produces inequality, and too long an immersion reduces sensitiveness, owing to the presence of an unnecessary amount of colour in the film.

The study of the absorption spectra of dyes, and their action as colour sensitisers, is readily accomplished by means of an ordinary optical lantern with a spectroscope attachment.

Gelatine films, coloured with various dyes, are interposed in the path of the rays from the spectroscope, and the position of the absorption bands noted. Bromide paper, dyed with any of the colours, is then submitted to the action of the pure spectrum for a few minutes, and, during the exposure, the limits of the spectral colours are noted by a pencil mark on the bromide paper. On development, the positions of maximum and minimum effect can be readily compared with that of an undyed plate.

When using gelatine emulsion, only those dyes can be used which are soluble in water; certain dyes, such as chlorophyll, soluble in alcohol, can only be successfully used with collodion emulsions. Some samples of eosine, in which the metal potassium is replaced by the ethyl or methyl group, are also insoluble in water.

A great deal of the discrepancy which has been found to exist in the results of different workers is, no doubt, to be traced to the difficulty in obtaining commercial samples of the dyes of uniform purity and composition.

J. Vincent Elsden.

FLEXIBLE FILMS.

[London and Provincial Photographic Association.]

Film photography is not a subject of to-day, of the year even, like the X rays, but it originated in one of the very earliest efforts of photography—with the Talbotype process, for which Fox Talbot took out a patent in 1841.

Briefly, the process was to select a paper of fine texture, and brush it over evenly with a solution of nitrate of silver. It was then dipped in a solution of potassium iodide, converting the nitrate into iodide of silver. The paper was then rinsed in distilled water to remove the bye-products —excess of iodide and potassium nitrate—and then dried. Prior to exposure it was brushed with a solution of nitrate of silver, acetic and gallic acids. The paper was then ready for exposure, and development was effected by brushing it over with a further solution of nitrate of silver and gallic acid.

As this process now is purely historical, I have not attempted to produce any specimens, for in this particular form it is not likely ever to come into use again. However, with this process excellent results were obtained. As the paper was made semi-transparent with waxing, the process may fairly be credited with having suggested the paper-negative process referred to later on.

Glass shortly afterwards was introduced for use in connexion with wet collodion negatives, which is beyond the scope of this paper. Scott Archer, in 1855, introduced and patented a method of coating collodion negatives with a solution of guttapercha in benzole. When dry, it was stripped from the glass support; but I am unable to find that Archer used paper, and I refer to this invention as it leads up directly to the experiments made by Dawson and Warnerke in 1868.

The latter made a film of alternate layers of collodion and rubber, coating it with a film of dry collodion emulsion. These films were made up in pads, like a blotting pad, orange paper being inserted between the films to protect the one underneath from light during exposure in the camera, the whole being backed with a piece of sheet zinc to fit into the camera dark slide. Mr. Warnerke, who, unfortunately, is not well enough to attend here to-night, has kindly sent me some negatives taken on these early collodion films, and I pass them round for examination. These films bear Mr. Warnerke's own description and the dates when taken, in 1876 and 1877

On the introduction of gelatine emulsion, greater facilities were offered to the landscape photographer, and manufacturers at once commenced to seek for a substitute for glass, which hitherto had been a necessity in connexion with wet collodion. Glass always was, and, unfortunately, still is, very heavy, as well as brittle, and during the seventies was very costly.

In 1879, Ferrier, in France, made a film of gelatine, and waterproofed it with coatings of collodion. Balagny, in Paris, used at this time a collodion base for a gelatine film; and Stebbing (also in Paris) a gelatine film, hardened with alum.

About 1886, we find that the Eastman Company, and, in 1880, Morgan & Kidd, introduced a modification of the Talbotype process. They used a Saxe or Rives paper, coating it with gelatine emulsion. After exposure in the camera, development, washing, and drying, the paper was treated with vaseline or castor oil, to make it transparent, and so hasten the printing.

This Society has already in its possession some fine paper negatives evidently made in this manner; it was not therefore necessary to make specimens, for you are all familiar with their character and quality. These paper negatives give excellent prints, but even when waxed or oiled do not print so quickly as a glass negative, and the oiling process is a dirty, messy operation. We cannot consider, then, that paper prepared in this manner for negative work is satisfactory.

As to the texture of the paper being objectionable, excepting for very small negatives the defect, if any, is exaggerated. However, in 1881, plain paper as a substitute for glass is put on one side, and various films of gelatine are suggested. The Eastman Company introduced their gelatine stripping film, still sold, I believe, by them under the name of Transferotype. This is a film of gelatine emulsion, somewhat hardened, that is, coated on paper previously covered with a very soft, soluble gelatine, melting at a low temperature in warm water. The negative is exposed, developed, washed, and squeegeed on to waxed glass, allowed to rest a few minutes, and put into warm water. This tepid water dissolves the soluble gelatine, leaving the emulsion film on the glass. A skin of plain gelatine is then pressed over it, the whole allowed to dry, and then detached. This film was exposed in the camera, in a film carrier as sample [shown], or used in a roller slide which was at this time introduced by them, and another form by Warnerke. At the same period Froedman introduced a gelatine film, sold as the "Vergara" film, consisting of a collodion base coated with bichromated gelatine, exposed to light, and washed in water and dilute sulphurous acid. As this film is not likely to be reintroduced, I have not prepared any specimens on it.

In 1881, Warnerke introduced a gelatine film, made on paper. This was exposed, &c., and dried. When *dry*, it was detached easily from the paper support, and you then had a rigid gelatine film, as transparent as glass and equal to same in every respect—superior in some. I pass round specimens made by me on paper prepared in this manner, only partially stripped, so that they may be detached by you and examined. This process I certainly have a great liking for myself, and where time is not an object, it is a process that gives everything that can be desired. The great objection to gelatine films is, however, that, so far as is known at present, gelatine can be only made insoluble, but not impervious to water.

In the necessary operations of developing, washing, &c., a large quantity of water is absorbed, and thick films of gelatine consequently take a very long time to dry.

With our recent knowledge of formaline, an improvement in this could be made; but gelatine films of themselves cannot compare with celluloid —to which I now refer—for simplicity of working, although superior in other respects. The first mention I find of celluloid is in a paper read by Fourtier before the Paris Photographic Society in 1881. But it is to America that we have to credit the greatest advance made, both in the manufacture of celluloid and films on celluloid. Carbutt appears to have at once taken up the idea, and certainly had the start of English manufacturers. Celluloid films at the present time are sold in two forms—rigid for slide work, and in rolls for roller slides and cinematographs. But to this subject I shall return later on.

Warnerke at this period (about 1881-1882) introduced various processes for film work. One was the use of vegetable parchment; another that of tissue paper, made quite transparent prior to coating. For these processes he coated his paper *on both sides*. At a meeting of the Royal Photographic Society, held in June, 1885, he stated that the double coating was designed to obviate the imperfections of all grain in the paper, and "to render the quality of the print even superior to one obtained from a glass negative in roundness and pluck." Such negatives I pass round. The print on the double-coated tissue paper is very good, and could hardly be improved. The texture of the paper is not discernable, and the rapidity of printing is nearly equal to a negative of equal pluck and density on a glass plate. A very ingenious form of carrier for these films was devised also by Warnerke—a piece of 3-ply veneer, having a piece of soap plaster attached to the face. On this the paper was simply pressed, and then placed in the dark slide.

Another paper for which he took out a patent has been discussed at the last two meetings of this Society. I allude to his "Wash out pro-

cess," based upon the action of pyro on a sensitive gelatine emulsion that is exposed to light.

Those portions that are exposed are acted on by the pyro, and become insoluble; those not acted on dissolve in warm water.

Paper is coated with a gelatine emulsion—bromide or chloride—exposed, and developed with pyro-ammonia. Before fixing, it is squeegeed on to glass. After three to five minutes, the glass is placed in warm water, the paper is dissolved off, and the soluble portions of the film washed out.

I have made a positive by this process on paper I prepared myself, and it will more clearly explain the advantages of the method for process work, where it is necessary in the high lights to have bare glass. This paper is still prepared by Warnerke, and is sold exclusively for process work. The positive can be transferred to zinc or copper, and the gelatine relief inked up to form the first resist to the etching acid.

I can fairly introduce now a form of film prepared by the Gem Plate Company for collotype work, or any process where a reversed negative is required. This is a very clean and dense-working, slow emulsion, suitable for copying purposes, that is specially coated on prepared glass to allow the film to be stripped after development, fixing, washing, and drying. Usually a coat of collodion is given to strengthen the gelatine film, and this is so thin that the stripped film can be used from either side without distortion.

Another form of film, with a paper support, has also been suggested—a sensitive film coated on a starched paper. After exposure and before development, it is placed in water, and at once pressed on to a sheet of clean glass. After allowing it to partially dry and become firmly attached to the glass, it is placed in cold water, and very shortly the starch substratum dissolves and allows the sensitive film to be developed from the back.

This is hardly a practical method, as it necessitates a stock of cleaned glass to be always at hand.

The only other film I have to mention is of very recent date, namely, the Wellington film, made by Wellington & Ward. According to the instructions they issue with the films, they can either be left on the paper on which they are coated, or stripped whilst *wet* and *transferred to a prepared glass plate*.

Having now exhausted the historical portion of the subject of the paper this evening, we should consider what are the requirements of a perfect film support for the sensitive emulsion we require.

1. A film that is as transparent as glass.
2. A film that is made rigid for cut sizes, or that can be made flexible for roller slides.
3. A film that does not require the backing of paper or other substance as a support at any time.
4. A film that is impervious to water.
5. A film that remains flat during and after development, and will dry without being attached at any time to glass.
6. A film that has no prejudicial chemical action on the sensitive salts of silver.
7. Lastly, a film that is as cheap as glass.

A pure gelatine film on paper detachable when dry, meets all the requirements named excepting conditions 3 and 4. It must be supported by paper, and is not impervious to water, consequently such a film (as I have shown to-night) takes a long time to dry.

Of gelatine films I consider it the best, for being able to use the paper as a support from the exposure until *dry* is a great advantage. Yet celluloid being quite impervious to water offers yet further advantages, although in celluloid we meet several disadvantages.

It is practically as transparent as glass. It can be made rigid or flexible, and does not require any support at any time. It is quite impervious to water, but it does *not* remain flat during development or when dry. It has a prejudicial chemical action in many cases on the emulsion, and the price is so high that it is quite impossible for manufacturers to sell celluloid sensitised films at the price of glass dry plates.

The solvents employed in the making of celluloid are ether, alcohol, or amyl-acetate—all very expensive chemicals. Consequently, the price is double that of glass and is likely to remain so.

Yet celluloid, for the want of a better material, is very largely used for films. I hope, however, that the new material I shall now introduce will shortly take its place, for the reason that it meets all the requirements essential to a perfect film that I have already enumerated.

It is the outcome of considerable work on the part of a member of this Society—Mr. Banks—and the specimens I shall show are not from the commercial finished article, but from experimental coatings that have passed just out of his hands, and were annexed by me for the purpose of assisting to illustrate the paper this evening.

From the specimens I hand round, you will notice that it is quite transparent. That it is rigid, so as to be suitable for cut sizes—it can also be made thinner for roller-slide work. It is not supported at any time by paper. It is impervious to water. It is perfectly flat during all processes of exposure, development, and drying. It has no chemical action, theoretically, on the emulsion. And lastly, it will be placed on the market almost at once, at the price of glass.

At this time of the year, it is very difficult to start out with a camera and make a dozen specimen negatives in a given time, so I have brought mostly transparencies to show this evening, together with a few negatives.

The negatives also, it should be noted, are made on chloro-bromide emulsion, as for experimental purposes it has been found more easy to work.

To develop the negative the process is very simple. Take the film, moisten it in a dish of clean water, or under a rose tap. Use plenty of developer, and put the developer in the dish before the film. Place the moistened film in the developing dish, and rock it well. It is important that the film is not allowed, during development, to stick to the bottom of the dish, as it is coated with emulsion on both sides. Fix, wash for half an hour; place for five minutes in a bath of glycerine, water, and alum; hang up and dry.

T. E. H. Bullen.

THE WELSBACH INCANDESCENT BURNER PATENTS.

[Invention.]

The decision of the German Supreme Court in the invalidity suits against the Welsbach patents, which we referred to in our issue of October 10, is fully dealt with in a long article in the *Vossische Zeitung* of Berlin, from which we extract the following:—

"The Supreme Court says a method for the production of incandescent bodies for incandescent gas burners remains patent property of Dr. A. von Welsbach or his successors in law, this method to be charact rised by four principal features, as follows: (1) There are produced nitrates, sulphates, or equivalent combinations of substances or mixtures of substances; (2) the salts thus formed are dissolved according to patent; (3) the solution is introduced into the tissues designated; (4) the mantles thus produced are transformed by being turned into incandescent bodies according to patent. The main question for the industry now is: Can the German Gas Glow Light Company, the present owner of the patents, restrain its competitors from the further production of incandescent bodies for incandescent gas burners? The question can be answered only as regards certain incandescent bodies. The industry produces and sells only such incandescent bodies as according to our present knowledge combine the highest light-emitting power with the highest power of resistance. In this direction the numerous suits instituted by the German Gas Glow Light Company have been of enlightening influence. The analyses by Fresenius have shown that both the patent owner and all his competitors impregnate the tissues with nitrates of thorium and cerium oxides, and that the mixture with slight deviations consists throughout of 99 per cent. of thorium and 1 per cent. of cerium.

"The reason why all the manufacturers select this mixture is mentioned in the opinion of the Court: It is the mixture which, without dispute, produces the most luminous and the most durable incandescent bodies. Other incandescent bodies which are impregnated with other nitrates, or in which the ratio of thorium and cerium materially differs, cannot compete with the former, and are not in the market for that reason. Apart from the question whether the Court would sustain the patent at all, the interest of all parties concerned was centered upon the point whether the patents would be sustained so that incandescent bodies impregnated with a mixture of thorium and cerium in the ratio of about 99 to 1 would be covered by it. The reason of this is, that all the other features of the Auer patents were really never disputed seriously. But there can be no doubt that all the features mentioned are found in incandescent bodies that are put upon the market by Welsbach's competitors. The dispute was really only whether the mixture of about 99 per cent. of thorium oxide and about 1 per cent. of cerium oxide was covered by the patents. The importance of this question was fully recognised by the Court.

"There were three patents to be considered: the original patent, 39,162, and the additional patents, 41,945 and 74,745. By the last-named patent the mixture is undoubtedly not covered, because the Patent Office limited this patent to the mixture of thorium and uranium oxide, and it is not among the mixtures protected by the original patent. Thus there is but the additional patent 41,945 left, and of this Claims 3 and 5 have here to be considered. In Claim 5 the mixture (99 to 1) is not mentioned plainly, while by Claim 3 there is protected "the use of incandescent bodies produced from oxide of thorium according to the process described in Claim 3 of the original patent." Here only incandescent bodies are referred to that consist of oxide of thorium, while we are interested in those in which oxide of thorium is mixed with a small quantity of oxide of cerium. The Court now explains, and this is the most important point in the opinion, that under the term "thorium oxide" that substance should be understood which was known by that name in 1886, when the patent was applied for. The oxide believed to be pure at that time was, in fact, not absolutely pure, present methods of analytical division not being known then; it was impure. It follows that in case of Claim 3 oxide of thorium should be considered which is not pure, but the question could be raised whether the foreign substance may consist of oxide of cerium. The Court here points to the fact that thorium and cerium occur jointly in minerals, especially in monazite, from which thorium is chiefly obtained to-day; for this reason it can hardly be disputed that there was a slight admixture of cerium oxide in the thorium oxide of 1886. According to authorities cited by both parties, pure oxide of thorium with a slight admixture of oxide of cerium furnishes excellent incandescent bodies. Supposing the so-called pure

oxide of thorium of 1886, that is, the slightly impure article, furnishes the same result, it should be concluded that the protection of Patent 41,945 concerning oxide of thorium should also extend to the mentioned admixture of 1 per cent. of cerium to absolutely pure thorium oxide.

"The hypothetical way of expression is explained by the fact that the definition of the patent claims according to German law is not admissible in invalidity proceedings, but only in infringement suits. It should be noted, however, that the Supreme Court is also the last court of appeal in infringement suits. That all incandescent bodies now put upon the market by other manufacturers infringe upon the Welsbach patent, says our Teutonic contemporary, is the practical meaning of the German Court decision."

PROPERTY IN UNPUBLISHED PHOTOGRAPHS.

It is well known that the preamble to the Fine Arts Copyright Act, 1862, recited that the authors of photographs (amongst other artistic works) had then no copyright therein, and that the Act proceeded to confer such right upon those who complied with its requirements as to registration. The right endured from the making of the photograph until seven years after the death of its author; but it is not, we think, so generally known that, in addition to this statutory copyright, which is based solely upon this Act, authors of photographs have, *until publication*, certain rights or property therein based upon the ancient custom of the common law, and known generally among lawyers as "common-law copyright." Strictly speaking, it is not copyright, for that was defined by Lord Chancellor Cranworth, in 1854, as "being the exclusive right of multiplying copies of a work already published," and is, therefore, as regards photographs, created and governed entirely by the Act of 1862; but this property in unpublished photographs is founded upon the same principles as, and is identical with, the rights of ownership a man possesses in personal effects, such as the clothes upon his back or the furniture in his house; it is absolute and perpetual unless and until it is waived or divested by the owner. The celebrated case of Jefferies *v.* Boosey, which gave us the standing definition of statutory copyright before quoted, also gives us the tersest and most unequivocal statement of the author's possession of this property in unpublished works. The whole matter was thoroughly and finally threshed out before the House of Lords, and, in his judgment, Lord Brougham declares that "the right of the author before publication we may take to be unquestionable; he has the undisputed right to his manuscript, he may withhold or he may communicate it, and, communicating, he may limit the number of persons to whom it is imparted, and impose such restrictions as he pleases upon the use of it; and the fulfilment of the annexed conditions he may proceed to enforce, and for their breach he may claim compensation."

Lord Brougham referred only to manuscripts, but the principle applied, as was pointed out in the same case, to all literary and artistic work; indeed, it had been applied five years before in the leading case of Prince Albert *v.* Strange, where the Court restrained the defendant from attempting to exhibit some drawings and etchings made by the Queen and the Prince Consort, of which a few copies had been struck off on a private press and distributed amongst their friends. It was doubted, however, whether the statement in the preamble of the Act of 1862 did not supersede this common-law property by substituting for it the statutory copyright. Good authorities inclined to the opposite view, and their contention has of recent years received judicial confirmation. Thus it may be taken as settled law that, before publication, the author of a photograph has an absolute property therein, enabling him to do as he pleases with his own, and to prevent any one making any use whatever of it; between making and publication he has, in addition to and co-existent with this property, statutory copyright as provided by the Act of 1862; and, after publication, he has that statutory copyright alone.

The question then naturally arises, What constitutes publication? And the only answer that can be given is but a judicial dictum, the Copyright Acts themselves containing no definition. Publication is stated to be "the making a thing public in any manner in which it is capable of being communicated to the public." This would generally be by offering the thing itself, or copies of it, for sale in such a manner as to make it accessible to all who choose to obtain it, freed from any restrictions imposed by the author, and subject only to the general law of the land. Perhaps we shall get a better notion of the matter by considering briefly what acts have been held not to constitute publication. Communication of a photograph or other artistic work that is partial, restricted, and conditional, for a limited purpose only, is not sufficient, nor is the making of copies for private circulation and their distribution amongst friends and acquaintances. Copies even may be assigned under an express or implied undertaking on the part of the assignee not to publish, without losing the common-law copyright, though in this connexion it must be remembered that the statutory copyright is irredeemably lost if, when a photographic negative is first sold, there is no agreement in writing granting the right to the buyer or reserving it to the seller. The loan of a photograph for an engraving to be made from it, which engraving is intended to be published, is not publication of the photograph itself, nor is the exhibition of a copy at an Exhibition, similar to that of the Royal Photographic Society. At all such Exhibitions it has been held there is a condition, implied if not expressed, that the public may come to see but not to copy, although this implication may, of course, be negatived by the fact that copying is, indeed, actually allowed. It is better always to do as the Royal Academy does, and expressly forbid copying by a note in the catalogue, which, however, we fail to find in the catalogue of the Pall Mall Exhibition.

The waiver of these rights constitutes a divestive fact, and the thing then becomes public property. The question whether it is or is not of any pecuniary value is immaterial, but there is never, at any time or under any circumstances, any property in immoral, seditious, or blasphemous works. Judging from the correspondence columns of this and other journals, it is of the unpublished and generally unregistered photographs, belonging to amateurs with whom they are acquainted, that unscrupulous editors and others make the most unauthorised use. It is evident that this is often done on the mistaken assumption that non-registration under the Copyright Act saves them from liability; but that this is not so would be quickly shown were they confronted by an action for damages and an injunction founded upon this common-law property.

Ernest J. Richards.

The Inquirer.

*** *In this column we from time to time print questions that may be addressed to individual contributors to our pages, or such as are sent to us with the view of eliciting information from a variety of sources. We invite the co-operation of our readers in rendering this feature of the* Journal *useful and instructive.*

Ammonia in Gelatine Emulsions.—Historicus writes: "Can you, or any of your readers, refer me to the first mention of ammonia in connexion with gelatine emulsion? I have heard its introduction variously ascribed to different individuals, but I should like to learn the truth."

Tectorium.—Colonel O'Hara writes: "In answer to H. P. in Inquirer column, October 23, 1896—'Tectorium'—let him try The New Wire-wove Roofing Co. Direction (used to be), 75A, Queen Victoria-street, London. Material called 'Durotine,' price about 6½*d.* per square foot."

Tectorium.—W. H. Stoneman says: "Referring to 'H. P.'s' query in the Inquirer column of the 23rd ult., *re* 'Tectorium,' if you have not already received replies, the address he wants is the Patent Wire-wove Waterproof Roofing Co. (Allport's patent), 108, Queen Victoria-street, E.C."

Xyloidine.—Ignorance inquires: "What is the difference between xyloidine, celloidine, and pyroxyline? I believe they are all similar substances, but should like to know the difference, and if they possess individually any special features that recommend them in any particular departments of photography. Papyroxyline, I suppose, is pyroxyline made from paper intead of cotton?"

Conversion of Printing Bath.—J. Phillips asks: "Can I in any way utilise a quantity of old silver printing bath that I have no longer any use for as a bath for negatives (wet process)? I have tried it for the purpose in its present state, but can get nothing but fog."—The thing can be done, but we leave it to our readers to suggest the most economical and convenient plan. Our own suggestion is, Send the old bath to the refiner's.

Metabisulphite of Potash.—Process says: "Will any of your chemical readers give me the relative quantity of alkali to be added to this salt in order to exactly neutralise it for developing purposes? That is, how much alkali must be added to bring the solution into the same condition as if the neutral sulphite had been used in making it up? As it is, the use of metabisulphite is very confusing unless you stick to a fixed developer and trust to Providence."

Cleaning Glass.—In reply to "Young Amateur," J. Robson writes: "I have found nothing better for the purpose of cleaning for *all* purposes than Brooks's soap. A soft rag rolled into a pad, well wetted and rubbed on a block of the soap, and then applied vigorously to the glass, will remove not only all grease and chemical impurities, but also particles of film, either gelatine or collodion, if the plate has been previously used. It then only remains to rinse the glass thoroughly in hot water for preference, to dry with a clean linen cloth, and polish in the usual way. If a plate cleaned in this manner is good enough for the wet process, I think it ought to do for opalines. If not, the operator had better look in some other direction for his failure."

HYDRIODATE OF POTASH.—SENEX, in reply to "Novice," says: "This term is a survival of the old nomenclature, under which the haloid salts were known as 'hydriodates,' 'hydrobromates,' and 'hydrochlorates,' or 'muriates,' instead of, as now, 'iodides,' 'bromides,' and 'chlorides.' There does not seem to be any good reason why these names should have been dropped, since the corresponding names of the acids have been retained, although it is true the salts contain no hydrogen."

WOODEN BATH.—WET PLATE writes: "Will any of your readers, who may have had experience with wooden baths for silver solutions, give me their opinion on the relative value of the following different methods of waterproofing: (1) Shellac (*a*) in the form of varnish, (*b*) spread with a hot iron; (2) Paraffin wax, and how best applied; (3) Lining with ordinary glass, and how best to cement the lining? I shall be very glad of any practical information as the bath I am constructing is of large size, and I do not want to make a failure."

THE ACTION OF ALUM ON GELATINE.—C. E. F. writes: "I see in last week's columns a query on the subject of the difference in action between ordinary and chrome alum. As I understand it, ordinary alum, when added to gelatine in solution, precipitates it, however small a quantity may be added; whereas, chrome alum may be, and is, added to gelatine solutions and emulsions in considerable quantity without causing precipitation or coagulation, but the gelatine when once set cannot be remelted. From this I take it that the action of ordinary alum is immediate, that is to say, that, when applied to a gelatine film in sufficiently strong solution, it at once renders it insoluble; whereas, in the case of chrome alum, the full action is not performed until the film has been dried. Ordinary alum would appear to be the better for use on films, chrome alum in emulsion, and so, I believe, they are usually employed."

CARBON PRINTING QUERY.—EMULSION says: "Your correspondent, J. E. Behrend appears to be dreaming of *Utopia*. I don't know whether he has had any experience in emulsion making; but, if he has, he must know that it is sometimes trouble enough to get a decent emulsion when only gelatine, silver, and bromide are used. What must be the added trouble, then, if we throw in a handful of finely powdered soot or lampblack, or any other colouring matter? I don't mean to say it is impossible to so combine colouring matter with an emulsion without spoiling the properties of the latter; but where is the use? The light could not penetrate into such a film to a sufficient depth to form a satisfactory image unless the exposure were enormously prolonged, and then it is questionable if the result would be anywhere within measurable distance of ordinary carbon printing."

STAINED GELATINE NEGATIVES.—EDGAR BULLARD writes: "In reply to 'Phœnix,' I was for a long time troubled in the same way as himself, as I do all my printing in the open air, and was constantly getting negatives wet and stained. No matter what preventive means were taken, the stains always appeared after exposure to light, until one day I took the opportunity, whilst it was wet, of intensifying a negative that was rather deficient in force, and it was the only one that did not subsequently show the stain. This gave me the hint. Of course, it is not all negatives that will bear mercurial intensification; but where such is not the case, if they are bleached with chloride of copper, very thoroughly washed, and redeveloped with pyro, or any other developer, as may be preferred, the original image is restored without any fear of the stain reappearing. Of course, this treatment must be applied after the preliminary course of salting and fixing, and before any stain has shown."

Our Editorial Table.

LUMIÈRE'S ORTHOCHROMATIC PLATES.

Fuerst Bros., 17, Philpot-lane.

WE have been favoured with a sample of the B series of these plates, which are sensitised for yellow and red. Our test was somewhat severe, and included the purple and blue tints of some black grapes, red and yellow tints of the fading foliage, and some bright reds of the flowers of the geranium and fuchsia, and the berries of the mountain ash. The exposures were made through a screen of pale yellow glass, and the results fully equalled our expectations. The plates exhibited considerable sensitiveness for red and yellow, and should be of great value to those enaged in orthochromatic work. The grain is fine, and the emulsion is very clean and free from fog. Instead of the formulæ recommended by Messrs. Lumière, we used pyro and carbonate of potash, and obtained images of remarkable vigour and gradation. We understand these plates are especially suitable for radiography.

CATALOGUES RECEIVED.

Gibson & Son, King-street, Nottingham.

BROMIDE enlargements on paper and opal, carbon enlargements, and finishing in oils on paper or opal, are among the specialities of Messrs. Gibson, whose prices appear to be reasonable.

Holmes Bros., 24, Southall-street, Manchester.

MESSRS. HOLMES, formerly known as Holmes, Sadler, & Holmes, have sent us a copy of their catalogue of photographic materials, specialities, &c. It extends to 167 pages, and is well printed and got up. A glance through its pages indicates that an enormous variety of photographic goods are listed. The catalogue appeals to photographers, dealers, and the trade generally.

J. C. Drummond & Co., 14, Henrietta-street, Covent Garden.

MESSRS. DRUMMOND'S specialities are photogravure, collotype, line and half tone, platinotype and carbon printing. Accompanying their list are some admirable specimens of line and half-tone work.

The British Photographic Company, New Walk, Leicester.

THIS Company's list gives the prices, which appear to be moderate, for enlarging, finishing, developing, retouching, printing, mounting spotting, &c.

News and Notes.

A TEST.—Mr. Hojack: "Miss Tenspot must be surpassingly beautiful." Mr. Tomdik: "Indeed! What makes you think so?" "She looks well even in an amateur photograph."—*Life.*

PHOTOGRAPHIC CLUB.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock on Wednesday evening, November 11. Members' Open Night.

ROYAL PHOTOGRAPHIC SOCIETY.—Ordinary Meeting, November 10, the Gallery, 5A, Pall Mall East, at eight p.m. *A New Form of Apparatus for Measuring the Light reflected from Prints*, by Mr. Chapman Jones; *A Theory of the Röntgen Phenomena*, by Mr. Charles E. Benham.

OXFORD CAMERA CLUB.—The Third Annual Exhibition will be held on Thursday, November 12, 1896, in the Holywell Music Room, at 2.10 p.m. Various exhibits will be shown, including the X rays, the acetylene light, &c. Tha lantern slides sent in for competition, and others, will be exhibited on the screen at eight p.m.

WEYMOUTH AND DISTRICT CAMERA CLUB.—The Second Annual Exhibition of Photographs will be held on January 14 and 15, 1897, in the Public Library, Weymouth. Seven silver medals, seven bronze medals, and nine certificates of merit are offered for competition among photographers in Somerset, Devon, Cornwall, Dorset, and Hants. The Hon. Secretary is Mr. E. C. Bennett, 10, Newberry Terrace, Weymouth.

THE WOOLWICH PHOTOGRAPHIC SOCIETY'S TECHNICAL LECTURES.—The Hon. Secretary (Mr. F. W. Machen) writes: "The idea of having a series of connected lectures delivered by a specialist was commenced by us last winter, when Mr. Gear gave our members and other friends in the district instruction in the technical side of photography. These proved a great success, and were attended by large audiences. We felt that instruction in the art of picture-making naturally followed, and we have secured Mr. Lambert to carry it out. He has delivered his first lecture, which was much enjoyed."

THE SALE OF RAT POISON.—At Bow County Court, last week, before Judge French, Robert Potton, a seaman, the branch secretary of the National Seamen and Firemen's Union, was summoned by the Council of the Pharmaceutical Society, that he, not being a registered chemist, did sell a packet of "Hammond's Remedy for Killing Vermin," at 29, Tidal-basin-road.—Mr. Grey, who prosecuted, said that this was a very serious matter. The vermin killer, when analysed, was found to contain enough arsenic to poison 150 people. A number of children had been poisoned by rat poison containing arsenic, in the neighbourhood, during the past few months, and it was difficult to find where it came from. He pressed for the full penalty of 5*l.*—Judge French (to defendant): What do you say? are you a chemist?—The Defendant: I ain't no chemist. I'm a working man. I am the branch secretary of the Union. Mr. Gibbs, who makes this rat cake, used to have offices at the Union-building. A lot of letters came for him, and I gave them to him to oblige. One day a gentleman I thought was the manager of large works called. He said he wanted 2*s.* worth of the poison. I asked Mr. Gibbs for it. He called again, gave me 2*s.*, and I gave up the money to Mr. Gibbs.—Judge French: Did you have any of the 2*s.*?—The Defendant: Not a penny.—Judge French: How do you make him liable?—Mr. Grey: The Act says we must go for the

person who actually sells it.—Judge French: Why not go for the man Gibbs? He is really the guilty person. If you had made proper inquiries, surely you would not have gone against this poor man?—Mr. Grey: The Act does not allow us.—Judge French: Then it is a bad Act. It is your own Act; the sooner you get it amended the better. Are you going to press for the full penalty?—Mr. Grey: I am afraid we must.—Judge French: You are liable.—The Defendant: I can't see I am.—Judge French: Their Act says so. Have you a family?—The Defendant: My wages are 30*s.* a week. I have a wife and four children.—Judge French: Do you press for the full 5*l.*?—Mr. Grey: I do.—Judge French (sharply): Then I order him to pay the 5*l.* and costs at the rate of 1*s.* a month. That will take over eight years for him to pay.—(Laughter.)—Mr. Grey: I must, in the public safety, ask for a larger order. This will have a very bad effect.—Judge French: And it is still worse effect to take proceedings against a man who was not in the habit of selling the poison, and only gave it out on one occasion to oblige a neighbour, as he thought.

Patent News.

The following applications for Patents were made between October 21 and 28, 1896:—

Dark Slides.—No. 23,132. "Improvements in Dark Slides for Photographic Plates." A. E. Hopkins.

Development without Dark Room.—No. 23,232. "New Arrangement and Dark-slight for Development of Exposed Photographic Plates by Day or or other Common Light without Dark Room." E. Klupathy.

Screen Kinetoscopy.—No. 23,279. "Improvements in Apparatus for Taking and Projecting Animated Photographs." E. B. J. Hunebelle.

Mounts.—No. 23,507. "An Improved Mode or Method of Uniting Paper to a Cardboard or other Support particularly Applicable to the Art of Manufacturing Photographic Mounts." Complete specification. J. W. McCabe.

Retouching Desk.—No. 23,547. "An Artificial Light Retouching Desk." A. McNab.

Photographic Lamp.—No. 23,683. "Improved Lamp or Lantern for Photographic Purposes." H. G. Moberly.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

October 29,—Mr. E. J. Wall in the chair.

The Chairman formally introduced, with a short speech, Mr. Paul Martin, who has attracted some amount of attention recently by his series of pictures, *London by Night.*

Mr. T. E. H. Bullen read a paper on

Flexible Films [see p. 711].

Mr. Bedding inquired whether the new film would stand any degree of heat—that of a warm climate, for instance?

Mr. Mackie asked the object of coating the film on both sides.

Mr. Everitt felt bound to say that a film like that under consideration would be a great boon if it could be placed on the market at the same price as glass plates. One advantage of a film like this, coated on both sides, although, perhaps, for another purpose, was that one had an opportunity of printing either way.

Mr. James inquired what was the limit in the size at which the film would keep flat?

Mr. Sinclair said it appeared to be a very promising film. There was no difficulty in getting a slow film to give good technical excellence, but he had found the reverse in getting a rapid film that would keep. His recent experience with plates and films exposed indiscriminately had set him against films, finding, as he did, on development, that, while the plates were good, the films were totally useless. It was important to get a film with better keeping qualities, and one the material of which had no effect on the emulsion.

Mr. Beckett hoped they would not split. He had found on one occasion, after developing a dozen films, that two dozen were in the dish. He had also found them very erratic, and, though theoretically they did not lose sensitiveness, if they were not developed soon after exposure, they often lost the image.

Mr. Teape had been greatly troubled with dark, almost opaque, spots.

Mr. Bullen, replying to those and other remarks, said he could see no good reason why the films should not stand a warm climate as well as any sensitive plate. Mr. Banks told him they would stand a temperature of 150°. In reply to Mr. Hodd, he had not found that alcohol had any influence on the films. With reference to some remarks on various faults in the specimens, he reminded the meeting that these specimens were not made from the perfect commercial films, but from those in the experimental stage, and it was easily understood that an unfiltered emulsion would account for the roughness discovered by Mr. James. As to the price of the finished films commercially, he said there were no expensive solvents used in their manufacture, and consequently there was no reason for a high price. The largest size that had been made was four and a half feet by twenty inches, and this remained perfectly flat. In reply to Mr. Mackie, he thought the flatness presented by the film was sufficient explanation for coating on both sides. There was equal tension on either side, and so the film remained flat. He could not answer for their keeping qualities yet from experience, sufficient time not having elapsed since their origination. He would say, however, that there was certainly nothing used in their manufacture that should have any ill effect on a sensitive silver salt. Replying to a remark by Mr. French, he said the films should not stick to gelatine papers any more than other types of negative.

The Chairman said they were indebted to Mr. Bullen for a very good historical sketch of film-making, and for some extremely promising specimens. How long would this film take to dry?

Mr. Bullen said that, as two surfaces were exposed, they took no longer to dry than a single surface. The body of the film was not affected by water, and the surfaces only had to be dried.

PHOTOGRAPHIC CLUB

October 28,—Mr. Snowden Ward in the chair.

Mr. Burrage was proposed as a member of the Club.

Mr. Welford introduced Mr. Liesegang, a son of Dr. Liesegang, of Düsseldorf.

Mr. D. Hill presented to the Club library a copy of Puyo's *Notes sur la Photographie Artistique.*

Dr. Charters White delivered a lecture upon

Switzerland,

illustrated with a series of lantern slides, mainly from his own negatives. Mr. White took his audience through some of the most interesting scenery and towns of the country, and described his adventures with characteristic humour. He was heartily thanked for a very interesting evening's entertainment.

Amherst Club Photographic Society.—This Society was started on Wednesday evening, October 28, when the first General Meeting was held at the Amherst Club, West Hackney. The names of gentlemen desirous of joining were taken, and the rules agreed upon. Mr. C. C. Paine was elected President, and Mr. Walter Potter Vice-President, Mr. E. M. Groundwater being appointed Treasurer, and Mr. J. Douglas Hon. Secretary. Meetings are to be held on the second and fourth Wednesdays in each month at the Club house, where the Society has most luxurious rooms for its meetings, and is having a capital dark room, fully equipped and furnished, provided by the President, free of expense to the Society.

Croydon Camera Club.—The meeting on the 28th ult. was a Lantern Night. There was a crowded gathering at the Club-rooms to inspect slides shown by Messrs. Richardson, Myrtle, Underhill, G. W. Jenkins, Taylor, Costar, A. J. Noaks, Holland, Isaac, Platts, Elkin, Lock, Kough, Allbright, and Rogers. The best of the above, which illustrate the festivities and procession in connexion with the visit of the Prince and Princess of Wales, and an admirable series of the interior views of the Municipal Buildings, will be selected for display at the public lantern show, to be held on the 11th inst. In the course of the evening the President (Mr. Hector Maclean) referred to a newly invented camera and projection apparatus, called The Grand Kinematograph, which had just been perfected by the firm of which their member, Mr. Victor Bender, was one of the leading partners, viz., Messrs. Bender & Co., of Croydon. The apparatus in question was in many ways a great advance upon those machines hitherto shown; the negatives were double the size of any

other camera of the class; the vibration was much reduced, as also were the noise and clatter which usually accompany the projecting apparatus when in action. The President was also able to announce that, by the kindness of Messrs. Bender & Co., Mr. Adolph Langfier had promised to show the Grand Kinematograph in action at the Lantern Show of the Club, to be held on January 13, 1897.

Hackney Photographic Society.—October 27, Mr. W. Rawlings presiding — Mr. Dunkley showed results produced by placing two spectacle lenses in front of a single landscape lens of five and a half inches focus, thereby increasing the focus of the lens to eight and a half inches. The Rev. F. C. LAMBERT spoke strongly in favour of using non-achromatic lenses for portraiture, the non-coincidence of the visual and chemical foci giving a soft, harmonious image. A paper on

INTENSIFICATION AND REDUCTION,

by Mr. T. Bolas, was read by Mr A. BARKER. Slides were shown on the lantern screen to illustrate the relative degrees of intensification produced by the various formulæ. A discussion on the subject of the paper and of the after-treatment of negatives in general took place. Mr. GRANT repeated his advice given at a previous meeting, that, instead of using an intensifier, it was a good method to make a positive transparency from the negative, work up the transparency, if necessary, with pencil stump, and then make another negative from it. Mr. HENSLER thought that a certain amount of detail was lost in copying. The Rev. F. C. LAMBERT agreed, but thought that it might be of advantage in some cases. Personally, on the question of working up or "faking," he had no objection to it whatever. The object was to get an effective picture, and the end justified the means. In the course of the discussion, a point was raised as to length of time necessary to wash negatives after fixing. A certain amount of difference of opinion was revealed, some being for long washing, others for short; but it was finally pointed out that the effectiveness of the operation depended not so much on the duration of the washing as in the manner of it, a few minutes under the tap being better than prolonged soaking. The Rev. F. C. LAMBERT thought that thorough fixation was of more importance than the after-washing, and for this reason it was desirable to use a supplementary fixing bath.

Richmond Camera Club.—On the 26th ult., Mr. F. P. Cembrano in the chair, Mr. ALFRED WATKINS gave a lecture on

SYSTEMATIC DEVELOPMENT.

He pointed out that, an exposure having been given, the various tones of a negative appeared in a settled ratio, and there is very little power of altering the ratio by development; also that the density of the various tones was built up as development proceeded in a ratio which progressed by definite rules, and could not be altered by modification of developer (fog and a limited power by variation in bromide excepted); that variations in the amount of developing agent or alkali merely altered the speed of development, although a strong pyro developer attains density in a quicker ratio after appearance than a weak pyro developer. In the case of variation in amount of bromide, a certain alteration of gradation was shown in some cases; but, to gain full effect, the alteration should be from commencement. The uselessness of previous soaking in alkali or in pyro and bromide was illustrated, and also the fact that such widely different developers as metol and hydroquinone gave exactly the same result if carried to the same stage. Great emphasis was laid on the power of altering gradation by length of development, the same exposure, giving soft, plucky, and hard results, being shown on the screen. The power of control for variations of exposure by mere length of development was illustrated, prints from exposures of half to sixty-four seconds, developed together in one dish for times indicated by the Eikronometer method, all showing much the same gradation. The difficulty of judging stage of development by looking through the negative was alluded to. The lecturer advocated the control of results by timing only, the basis being the time of first appearance of the image, a given multiple (according to developer used) of this time being given. Thus, Ilford pyro soda (the weaker formula) requires about six and a half times the appearance of the image. The timing could be done by watch, but the Eikronometer, a specially designed clock for the purpose, was much more convenient. The lecture was fully illustrated by lantern slides.

Bradford Photographic Society.—On October 26, Mr. Walter Booth (Vice-President) lectured before the members of this Society on the platinotype process, and treated the subject in a very lucid and instructive manner. As the lecture was specially prepared for beginners, the lecturer began his discourse by explaining the nature and special properties of platinum, which made it one of the most desirable materials for photographic printing. He gave a short sketch of the various discoveries in connexion with the process, and explained the why and wherefore of the calcium tube, and gave details of a good system of gauging the exposures. The demonstrator then developed prints on various papers, gave formulæ for blue back, warm black, sepia, blue, and other colours, by development only, and particularly recommended the thick papers, both rough and smooth, of the Autotype Company, and the c. c. of the Platinotype Company. Mr. Booth had numerous examples of his own work in platinotype on various grades of paper, and the series of architectural studies he showed were much admired, these efforts alone being sufficient to at once stamp him as a worker of the most advanced school, his pictures displaying not only excellent technique, but a thorough knowledge of the elementary principles of art.

Leeds Camera Club.—The third of a series of elementary lectures for beginners was given by Mr. A. Gaunt, on Wednesday evening last, at the Club's rooms, Grand Restaurant, Boar-lane, the subject taken being

PRINTING.

Mr. GAUNT confined his remarks to those printing processes that come within the range of a beginner's efforts, and in the course of his lecture he threw out a few useful hints as to the preparation and treatment of the negative before and during printing, explaining his method of "blocking out" (using a fine drawing pen and Chinese ink for outlining), printing in skies, &c. At the close Mr. Gaunt answered a number of questions, and an interesting discussion followed on the relative merits of albumenised *versus* gelatino-chloride papers, which eventually led to a challenge by the lecturer, which was promptly accepted by a member present, and eventually two other contests were arranged, the decisions to be given at some future meeting Notice was given by the SECRETARY of the postponement of the Annual Dinner to November 11, to suit the convenience of several members interested in the municipal elections. The dinner will be held at the Grand Restaurant, followed by a smoking concert. Stockwell's patent single lantern for dissolving effects was exhibited and described by its inventor—a member of the Leeds Camera Club—and elicited great praise from all lanternists present. A demonstration is to be made with it on November 18, when all interested in lantern work are cordially invited to be present.

Newcastle-on-Tyne and Northern Counties' Photographic Association.—October 27, Annual Meeting, Mr. J. P. Gibson (the retiring President) occupying the chair.—Mr. JAMES BROWN (Hon. Secretary) read his report, which stated that the Association had had a successful year. The membership on October 1 stood at 109—a decrease upon the previous year's figures—but new members continued to be enrolled. The indoor meetings had been very well attended, but the outdoor meetings had been practically failures. Mr. Fred Park (Hon. Treasurer) reported a balance of 15*l.* 8*s.* 10*d.*, as against 3*l.* 19*s.* 8*d.* at the beginning of the year. The election of officers resulted as follows:—*President:* Mr W. Parry.—*Vice-Presidents:* Messrs. J. S. Bell, J. P. Gibson, J. Hedley Robinson, and John Watson.—*Council:* Dr. Blacklock, Messrs. W. E. Cowan, J. E. Goold, William Graham, George Hall, J. J. Kirkwood, Edgar G. Lee, T. O. Mawson, Captain Sayers, and Mr. G. L. Snowball.—*Hon. Treasurer:* Mr. Fred Park.—*Hon. Secretary:* Mr. James Brown.—*Assistant Hon. Secretary:* Mr. Parker Brewis. Awards in the members' competition were announced as follows:—Landscape: silver medal, Mr. James Brown; bronze medal, Dr. Smith. Marine and instantaneous: silver medal, Mr. James Brown. Portraiture: bronze medal, Mr. Burton Graham. Hand-camera work: bronze medal, Captain Sayers. Lantern slides: silver medal, Mr. W. Errington Cowan. Enlargements: silver medal, Mr. Burton Graham. In all, seventy-eight sets were submitted, which contained much meritorious work. Messrs. W. Milburn, President of the Sunderland Society, and J. Blain Scott, of Carlisle, acted as Judges.

Oxford Camera Club.—October 28, Colonel Impey in the chair.—The SECRETARIES gave further information as to the arrangements for the Club Exhibition on November 12, stating that there would this year be no restriction on the sale of tickets. The competition slides would be shown at eight o'clock. A lecture on

THE TREATMENT OF FIGURES,

by the Rev. F. C. LAMBERT, was then read, and illustrated by lantern slides. The members were invited to add their criticisms to those of the lecturer, and some points of general interest were brought out. It was announced that it was proposed to hold an examination at the end of the season on the subject of these lectures, and there would be prizes for the best papers. A vote of thanks to Mr. Joyce for lending and working the lantern closed the proceedings.

FORTHCOMING EXHIBITIONS.

1896.

Correspondence.

☛ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

ORTHOCHROMATIC PLATES WITHOUT A SCREEN.

To the EDITORS.

GENTLEMEN,—In the final paragraph of an article by Mr. W. K. Burton, in your last issue, reference is made to an old suggestion of mine in the direction of rendering orthochromatic plates altogether independent of a coloured screen, when the maximum effect is desired.

Speaking from memory, however, I do not think I ever proposed a separate coating of coloured collodion, which would present other difficulties besides that of expense. My proposal, I think, was to take

an emulsion properly colour-sensitised in the ordinary way—that is to say, with the sensitising matter chemically combined with the silver salt—and to mechanically stain either the emulsion or the film with a suitable dye to produce the desired effect. The effect of dyeing the film of dry plates was shown, years ago, to have the effect of lowering the general sensitiveness in pretty well the same manner as a coloured screen used with an ordinary plate would act by reducing the action of the blue and violet rays. If, however, a film specially sensitised for any particular class of rays were so treated with a proper dye, it seems to me that, while the more active rays would be considerably weakened in their action, those specially sensitised would not be proportionately so. In a few experiments, made at the time with collodion emulsion, I found such to be the case, but did not follow them out. Of course, it must be understood that the dye used to replace the screen must have no chemical action on the film itself or its constituents.—I am, yours, &c.,

W. B. Bolton.

THE BANKSIAN THEORY OF DEVELOPMENT.

To the Editors.

Gentlemen,—Whilst admiring the clever reasoning of Mr. Banks's paper—published by you on p. 677—I cannot help feeling a little regret that he did not give a summary of the researches and writings of others, so that we might have gained a better idea of the novelty, or otherwise, of his results, which hardly seems to have been called in question at all by those present at the meeting.

The idea of a rearrangement of the molecules of the silver salt is by no means new, as it was suggested by Davanne in 1857, and the first, or one of the first to suggest an electrical action was Marié Davy in his work *Hauptinhalt der Untersuchungen über die Elektricität*, a little-known, if not quite forgotten work, published, I believe, in 1860.

Cherrill, in 1867, suggested that the action of light was to polarise the silver haloid, and the metallic pole was turned in the direction whence the light came.

W. B Bolton published in The British Journal of Photography, 1870, p. 397, a paper supporting the electrical theory, and stated that he believed that the action of light was not chemical but electrical, and that the latent image was formed of molecules which were in a state of electrical excitation; and that in the case of the collodion plate with acid silver development, the metallic silver was electrically attracted in *statu nasceadi*, and in the case of alkaline development the decomposition of the molecule was produced by the hydrogen set free in the developer.—I am, yours, &c.,

A. D. Pretzl.

ACETYLENE.

To the Editors.

Gentlemen,—I see in your last issue that Mr. Chapman Jones, whom most of your readers would consider an authority, considered there was little or no danger in using acetylene with brass or copper fittings. Having had a considerable experience with acetylene, may I venture to warn your readers that copper, or alloys containing copper, are *highly dangerous* with acetylene?

In the course of a long series of experiments, having found no apparent action, I was using copper connecting pipes and brass fittings, when one day, without any warning, one of these pipes fired with a brilliant flash and loud report. An examination of the fittings afterwards showed that all of them were very badly eaten away from the inside; but a still more important point was, that the whole of the generator was thickly coated with soot, and very hot, the ignition of the copper and brass fittings having evidently caused a decomposition of the gas itself. Fortunately my generator, being an ordinary steel compressed gas cylinder, was able to withstand the force of the explosion, else the result must have been disastrous. Mr. C. Jones says, "doubtless, it sometimes arose with *corroded* metal." Will he and your readers please note that the above occurred with bright, new, copper tubes and brass fittings, *which had never been used before!*

It may perhaps be news to your readers, as I have not seen it mentioned before, that acetylene gas generated from carbide of calcium *is not pure*. In the course of my investigations I found it to contain compounds of sulphur and phosphorus. I made several estimations of the sulphuretted hydrogen, and found it present to the extent of 1½ per cent. in volume, the actual average being 413 grains of sulphur in the form of sulphuretted hydrogen per 100 cubic feet of the gas! This figure may be better appreciated when you consider that ordinary coal gas in London has to be *absolutely free* from sulphuretted hydrogen, and the total sulphur present seldom exceeds 15 grains per 100 cubic feet. Perhaps, however, the most serious impurity is the phosphorus, which is present in the form of hydrides. One of the hydrides of phosphorus (phosphorous dihydride) which is nearly always produced with the other hydrides, has a very unpleasant property, in that it renders other gases *spontaneously* inflammable. Possibly it is the presence of these impurities in a greater or less quantity which brings about the apparent uncertainty of acetylene made from carbide. Certainly it can never be safe with phosphides present.—I am, yours, &c., A. E. Knowles.

The Birmingham Oxygen Co., Ltd., Saltley Works, Birmingham, October 30, 1896.

P.S.—I ought to add that silver (as would occur with plated fittings) is still more dangerous than copper. Acetylide of silver is terribly explosive. I have been unable to dry it, as it has always exploded spontaneously. It will explode with the slightest touch *under water!*

PHOTOGRAPHY IN NATURAL COLOURS.

To the Editors.

Gentlemen,—I have read the article on *Single Transparencies in Natural Colours* (p. 674), and I should like to make a few remarks:—

The method therein described of producing transparencies in colour in no way resembles my own, which are as easy and certain to produce as an ordinary silver print, and, as far as I have been able to prove, are absolutely permanent; and I do not think it possible for pictures produced in aniline dyes to possess that important property. The method you describe I worked out five years ago while engaged in the management of a well-known studio in Dublin, and was discarded by me in consequence of serious defects and difficulties. I have before me as I write my "notes and experiments" for that period, and I will reproduce some of them here. Under the heading of "Notes, March 3, 1891," are the following experiments, which I reproduce as they are entered:—

No. 2. Try the effect of power and gradation of aniline dyes (3*), red, yellow, and blue, as compared in the same manner with artists' pigments.

No. 3.* A gelatine plate sensitised with bichromate of potash—print and try the *absorption* of same with *dyes*.

No. 4. Same, and try dusting on powder colour.

No. 5. Transparencies developed with pyro, or hydroquinone, afterwards converted into red, yellow, and blue, these to be upon *celluloid*.

No. 8. Make from the test screen negative of three colours three prints in carbon in identically the same colours (red, blue, yellow); develop the first upon glass, the next two upon celluloid, and transfer accurately upon the first.

The above experiments were all carried out in one *day*, the materials having been previously prepared. No. 3 was afterwards carried out with celluloid, but I did not trouble to join up the films with balsam or other adhesive, as the method has serious defects which I will point out: there is great difficulty in getting perfect gradation in a plain film of gelatine by development with hot water, as the light in printing has a spreading action, and frequently renders the film insoluble right through; but a much greater defect is due to the actual image caused by the bichromate, which is of a brown colour. Now, if you take three such images as produced by Mr. Ives upon celluloid and without immersing in any dye whatever, you will find that, upon joining them up, you will have a brown positive of considerable vigour, and which, when coloured with the dyes, entirely destroy the truth of the original colours, a disagreeable monochrome running throughout the whole picture. The same defects are met with in making carbon prints as described in my No. 8 experiment, the brown image of the bichromate spoiling the purity of the colours. The above and similar methods were carefully tested and abandoned by me in 1891, and since that time I have succeeded perfectly upon different principles. I have not seen Mr. Ives's results, but it would be impossible by such a method to produce such gradation, purity of colour and detail, as my pictures possess. As to when I shall make known my method, I reserve to myself the right to do so, at what time and in what manner I feel disposed. I have a jewel, and may surely decide its setting before it leaves my hands; and, if another method should yet be found, I am not afraid of the lustre of my own.

During the years I have been working at this problem I have occasionally been startled with statements and announcements in different journals to the effect that the problem of colour photography has been solved; but, while I yield all honour to Lippmann for the interferential method and to Ives for his photo-chromoscope, I still possess my soul in peace, and not even the exquisite pleasantries and sarcasm of "Cosmos" disturb me from the even tenour of my way.—I am, yours, &c., Wallace Bennetto.

The Studio, Newquay, Cornwall, October 27, 1896.

THE TRAILL TAYLOR MEMORIAL.

To the Editors.

Gentlemen,—A Meeting of the General Committee of this Fund will be held at the Exhibition Gallery, 5A, Pall Mall East, on Friday, the 6th inst., at 7 30 p m., to receive the report of the executive committee.

All subscribers to the fund are invited to attend.—I am, yours, &c.,

Alexander Mackie,

Hon. Secretary to the Fund.

SCREEN NEGATIVES DIRECT FROM NATURE.

To the Editors.

Gentlemen,—I see in your issue of Friday, October 22, a very ful

report of a paper on the above subject read at a recent meeting of the Royal Photographic Society by Mr. Gamble.

It is but very little that can be done in the way of photographing direct from nature with the cross-line screen for various reasons, but especially on account of the smallness of the latitude permissible in the use of diaphragms. Something may, doubtless, be done in the house in the way of photographing statues and suchlike still objects, but the large process camera, with its long-focus lens and ponderous accessories, are far too cumbrous to be dragged about the country for landscape work, and, moreover, the smallest stop which would give proper contrast to the picture would be found too large to give the proper depth of focus for most landscapes, while, on the other hand, the largest stop which could be used with the line screen would be found far too small for successful portrait work. For working direct from nature a different form of screen is absolutely necessary.

The extra rapid screens which I am now making for this purpose, while they can be used in the ordinary way as slow screens with wet plates, admit, when desired, of being used with any intensity of light up to sixty times as much as would be available with a line screen in the same circumstances. The screen negatives from which the enclosed scraps were obtained were all taken from life in the house in a rather poor flat light, with an exposure of *two seconds*, while I was using Ilford Special Rapid or Red Label plates, and an intensity of light equal to about thirty times what I could have got with a line screen. The same thing could have been done with Ordinary Ilford plates with an exposure of from six to eight seconds, and with Ilford process plates in about one minute, the exposure in the last case being much too long for portrait work, but quick enough, certainly, for the still objects and copying purposes. With process plates or wet plates in good condition, about half an hour's exposure would have been required with a line screen. Each of these portraits had about the same amount of detail, and decidedly more pluck and roundness than ordinary photographs taken in in the same circumstances without the screen. For this mode of working, any kind of lens that will take a decent photograph, and any kind of camera, will do, and no elaborate calculation is necessary for adjusting the screen. All that is necessary is to lay the surface of the dry plate against the screen, and put both together into a double dark slide, the screen next the lens, and the black cardboard division in behind the plate to keep all tight, and give about four times as long exposure as would be required without the screen. The proper gradation of the picture is secured by the construction of the screen mesh, and the contrast may be modified greatly as desired during development, especially if pyro be used. By this mode of working a process operator could do about three dozen screen negatives in a day, a task which most would find it difficult to perform in a week in the ordinary way, especially in winter. When the time of exposure can be thus reduced to from one to three seconds, I see nothing to prevent portrait photographers from making screen negatives of their sitters direct from life, and furnish them with proofs by the hundred in permanent printing ink. A boundless field for the application of photo-engraving could thus be opened up, and an excellent opportunity afforded to people of filling scrap albums with portraits of their friends.

These rapid screens have also other uses. On account of the intensity of light available, they can be used for transferring the picture to the zinc or copper direct from the original negative, both the ordinary photographic print and screen negative being dispensed with.—I am, yours, &c.,

3, *Waterloo-place, Edinburgh.* A. MANN.

THE PHOTOGRAPHIC SUPPLIES INDUSTRY.

To the EDITORS.

GENTLEMEN,—To grasp this subject in its present aspect seems to me an impossible and invidious task, yet, on behalf of a numerous unoffending class of paterfamilias, I am drawn into the whirlpool.

In the early dawn of photography, one had to silver his own plates, make his hypo and his cigar-box camera, and construct his periscopic lens. Timely aid came from Mr. Robert Hunt, of the Royal Cornwall Polytechnic, who first published, through Griffins, of Glasgow, his work on practical photography, and which was then the only available guide in those dark ages, and was wonderfully useful. The fortunate owner of that book, if he compares it with the last number of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, 1896, may ask himself the question, Whence all these thousands of advertisements, and to what cause am I to assign their growth?

Much nonsense has been written about amateurs. Why, in 1840, we were not even qualified for that distinguished title. We were fiddlers or experimentalists; but, all the same, we are the legitimate fathers of that modern prince, if you will, the self-dubbed professional.

In scanning the list of modern photographic advertisements, one is struck by the contrast of 1840 and 1896. In the former we had to grope our way in every direction, and it took both time, brains, and money to coax his Majesty the Sun to become our delineator. Now, alas! for our pride of heart, the great sun himself waits patiently and obediently upon the human figure or the "penny in the slot," and asks for neither brains, time, nor certificate; he makes pictures broadcast by the aid of the dry-plate automatic camera, exposure meter, and self-acting developer, and all the rest of it. What a contrast! Yet (aside), have these picture-makers cause for glorification anything like the sparkling fire that lit up the enthusiasm of a Fox Talbot, Sir John Herschel, or Robert Hunt? I opine not. A German organ-grinder imitating Jenny Lind explains the contrast.

Oh, what a gush rushes to the heart when you tread the virgin soil and forest, and feel that you are the first human visitor! Any one who has had this delightful experience can well understand the emotional twitchings of delight when these pioneers first traversed the unknown regions of the *dark-(room)* ages, and brought forth for the first time mimicries of Nature herself.

Who could have divined that, in a weak moment, our best friend, the sun, would have so given himself away?

The autocrat of the universe has become republican, and one of ourselves; he is subservient to our requirements, and *strikes* not against our wage remuneration! Surely the millennium is in sight!

But to my text. The wants and the luxuries of the would-be photographer, what are they in his various conditions of development, the *embryo*, the *full-feathered*, and egg-laying? They have brought into existence sprucely donned, white-aproned waiters to minister to their craving appetites, and, according to the old law of supply and demand, we have a goodly choice; indeed, to the outsider, a comical one.

Lenses! What is a lens in present-day optical nomenclature? Jena glass, iris diaphragm, anastigmatic, *f*-12–5, Zeiss, *f*-18, aplanatic, group, rectilinear, concentric, baby, instantaneous, and all the rest of them. In glancing over this huge list of lenses, I defy the ordinary intellect to select the best lens for his immediate requirements. This should not be, seeing that we have societies by the hundred, which meet and sit, like so many ambassadors to Turkey, dumb and tongue-tied down either by personal interests or afraid to speak in favour of *one* instrument, lest they should endanger the reputation of a certain maker who has always been very kind. Then we come to the cameras by the thousand, from the Penrose process, the feather weight, the aluminium Zephyr to the Presto, press the button and the stable-boy does the rest. Well, surely there is no rational demand for such a conglomeration of contrivances, except this, that what was formerly understood as human brains has emigrated to Mars or elsewhere, and that these figaries are supplied to fill the vacuum, *vice* the mind, made necessary by promotion of the latter.

Automatic is in the air. We breathe it, digest it, it is the vitality of present-day life. The nature's gentlman spurns the dogma that "*he* must earn his bread by labour." And so he is impelled by desire, all he needs must be prepared ready to his hand, like the prince sportsman, who was driven to the wilds to shoot tigers. Attendants were placed in advance, driving in the animals, and others had a ready supply of guns, cocked triggers, which they handed to the prince at a given signal, and who simply *let fly*. That was newspapered tiger hunting, and the prince was highly bepuffed for his "gallant daring in the jungle." Now, this is a true reflex of the modern open-air photographer, who gets his exposures developed and printed by the professional. "But, why," some one will ask, "what are you raving about? Is it not quite right we must have our conveniences to assist us in our work?" Yes, quite right; but you ask to have the work done that you may reap the glory which you filch from the experienced man who *does* the whole work for you. In fact, the nature's gentleman, and, of course, woman, is included, not as it used to be, a matter of dress. Sex doth not now perplex our classification of humanity. The duplex man, therefore, is a creature, a vacant space, ready to be occupied by vapours or substantials, according to his appetite and his tastes.

The circumstances of the moment are the ruling elders in that church, hence we must expect that such an employment as making pictures of nature by auto[]machinery would ensnare humanity of every stage of development and progress, causing them to hover around the light after the manner of the midnight moth, who flies around the lamp flame until he is drawn in.

When the young moth gets entangled in the literature of photographic hydrophobia, he appeals to *pater* for a cheque, then to Dr. Photo Supplies for a cure! Oh, to read the diagnosis and the prescription is a proper caution! Another flame is dazzled before the eyes of the patient. A plethora of delights—snap-shot cameras, teetotal stands that always keep their feet, dry plates, open-air studios, changing bags, retouching air brushes, and a thousand other attractions, all dangled before the eyes of the embryo photoist. What is he to do? Bewildered at the extent and reality of his disease, he plunges back to his admiring dad to change the cheque for a much larger amount. Now, this amiable dad nets his cash in a very different trade, yet he feels that he should part with some of it if only to suit the whim of his darling offspring, and so the bigger cheque is drawn, and the photo-supply doctor prescribes accordingly. The patient feels apparently better, but not much wiser. There we have a side light which to those who read may find "a fitting cap." I have no quarrel with those who desire to provide aids and facilities for the legitimate requirements of the photographer; but, when inventors of lenses, cameras, and the thousands of other things, meddle with substitutes for brains, it is full time to put the scientific foot down, and say, *Stop!* lest you turn to nought and annihilate the remaining remnant of *esprit-de-corps* existing among the worthy community of *bonâ-fide* photographers.—I am, yours, &c.,

JOSEPH LEWIS.

Dublin, October 28, 1896.

SALON-IC ETHICS.

To the EDITORS.

GENTLEMEN,—Your kind insertion of the following may possibly interest your readers, and bring me the satisfaction I have vainly sought at the hands of the Salon's Hon. Secretary.

I sent six pictures to the Salon in response to the usual invitation, three of my own work, and three of my friend's, F. Holland Day, of Boston (whose work I introduced to the Salon last year), these being my own property, and sent by permission of Mr. Day.

I received a rejection notice for two pictures, and sent for them on the appointed day. I found, on attending the Exhibition, that I ought to have received a rejection notice for four pictures, as only two out of the six were hung.

I wrote and asked what had become of the missing two pictures, and why I had had no rejection notice for them. To this I received the reply that I "*had* had a rejection notice, and that I had received the pictures, they being signed for by So-and-So; but, if they were not so received, then they would be at Messrs. Dicksee's, in accordance with the conditions of the entry."

As this took no notice of my question as to why I had only received a rejection notice for two, instead of for four, I wrote again, reiterating this, and saying that I could not send again for pictures, and must look to them to return the missing two, and at their own expense, as the error was entirely on their side.

Unfortunately, before this reached the Hon. Secretary, he had, on his own initiative, had the pictures sent to me, and on which my housekeeper had to pay 2*s*. I have written twice for this 2*s*. to be refunded, or have a justification of its charge. The reply I get from Mr. Maskell is the one I now quote:—

"*October* 10.

"SIR,—In reply to your letter of October 1, demanding the return of expenses paid by your housekeeper on two pictures by Mr. Day, of Boston, I have to inform you that I see no reason for complying with a demand of the kind. "Yours truly,

"ALFRED MARSELL, *Hon. Secretary*."

I don't think I have ever received a letter that has so "riled" me. Its absurd attitude of superiority, the non-necessity of any condescending to reasons or argument implied in it, indicate a lack of the first principles of courtesy that should govern every action or letter of an official (be he a paid or a honorary servant), that is at least surprising when coming from Piccadilly. I replied to this, but got no response whatever.

I therefore publicly ask the Salon to say by what by-law or condition of entry their Hon. Secretary justifies the non-sending of a rejection notice, the return of the pictures, and the charge made for them? Is an exhibitor who receives a rejection notice for two pictures, out of six sent in, to suppose that there will be others at a later date which he must pay a fee for the return of? I could easily have had all my rejected pictures on the proper date, when I sent for them, in strict accordance with the entry form. The Salon will not miss any work I may withhold from it in future years—there are plenty of good workers to fill its walls—but I certainly shall not again risk being subjected to the extremely discourteous treatment they have seen fit to mete out to one who has been invited to show from the very first.—I am, yours, &c., FREDERICK H. EVANS.

19, *Buckingham-street, Adelphi, W.C., October* 20, 1896.

To the EDITORS.

GENTLEMEN,—Mr. Charles Moss, in his defence of the management of the Salon, goes rather beyond what the circumstances of the case justify. Mr. J. C. Oliver's original letter was a protest against the unfairness of the Salon Committee, in sending invitations to contribute so worded that the only inference that intending exhibitors could draw would be that all work of sufficient merit would be accepted, instead of openly and fairly specifying that they only want a few to fill up the space that the members of the "Linked Ring" and their friends have not already appropriated. The invitation is similarly worded to that sent out by the secretaries of most photographic societies, with the additional intimation that the work sent in is to be submitted to a selecting committee. Merit alone does not secure admission to this Exhibition, and that the absence of merit does not of necessity involve rejection a glance at the walls each year will show. The catalogue gives the information that this year's Exhibition contains 339 frames. Of these, 189 are contributed by 43 members of the "Ring;" 48 by 24 foreign exhibitors, who are non-members; and only 98 by 61 British workers, non-members, or an average of roughly 1½ each. (There is one exhibitor who contributes four frames, whose residence is not given.) Mr. A. Horsley Hinton, a member of the Salon Committee, stated in the *Amateur Photographer* that about 1100 pictures were sent in, which involves about 750 rejections. Now, very few of these rejections were the members' own work, and it is quite safe to assert that *nearly* 700 *of non-members' contributions were rejected against* 100 *accepted*. Is it reasonable or fair to ask photographers, who are fully as enthusiastic in the development of pictorial photography as the members of the "Ring," to send in their best work when it has so little chance of acceptance? In the ordinary sense of the term the Salon is not an open exhibition. No one would object to this if the members would only admit the fact, instead of sending out invitations broadcast and contending that a certain standard of merit will secure admission irrespective of who the sender may be, as in other exhibitions.

Why is it that Mr. Charles Moss, like many members of the "Linked Ring," cannot write a word about the Salon without adding sneering remarks about the Royal Society and its Exhibition? "A New Link" is following the example of his older brethren in this respect, and he has already expressed his adherence to the only one article of faith in which there appears to be unity of opinion among the Links, that is, that the "Ring" is the only exponent of pictorial photography, and the only Exhibition where artistic photographs are to be seen is at the Dudley Gallery. Would "A New Link" also kindly explain how the members of the "Ring" are to perform the impossible feat of looking *down* on to the Royal Photographic Society?

Being an ardent "Royalist," I cordially endorse "Royalist's" letter in your last issue, but I have been somewhat puzzled to reconcile with "Cosmos'" consistent and well-merited criticisms of the attitude taken by prominent members of the Ring, the fact that while in your paper you devote two long articles to the Salon Exhibition, one is considered sufficient for the Royal. Whatever may be the relative merits of the two exhibitions, the latter is certainly far more representative, and of more interest to British photographers.—I am, yours, &c.,

Hastings House, Norfolk-street, London, W.C., HENRY W. BENNETT.
November 3, 1896.

To the EDITORS.

GENTLEMEN,—I notice a letter in your current issue, signed "A New Link." It purports, I suppose, to be written by a member of the Linked Ring, and that is the impression your readers would gather from it. Without further evidence, may I ask the latter to discredit its genuineness? You, Sir, may easily have been misled, for no list of members of this private Society has ever been published. The Society is an absolutely private one, and if a member of it had a grievance, he would, at least first of all, as a gentleman, bring it before his colleagues. He certainly would not write to the public press in terms which might easily be misunderstood, and lack the courage to sign his own name.

With the late forged letter, purporting to be from Sir William Harcourt, still in our recollection, some reference to the one in your columns becomes a necessity, otherwise I should not have taken the trouble to notice it.

Your other correspondent, "M. L. R.," is, of course, entitled to express his views; but, not having the *entrée*, as one may say, behind our scenes, his opinions can only be taken for what they may be worth.—I am, yours, &c., ALFRED MASKELL.

63, *St. James's-street, S.W., November* 3, 1896.

RE UNFAIR COMPETITION.

To the EDITORS.

GENTLEMEN,—From the letter published in your issue of October 30, in which the writer calls attention to a halfpenny morning paper's scheme of supplying the public with life-size enlargements (24 × 19) at 6*s*. 6*d*. each, it seems that not only photographers, but newspaper proprietors, have a hard struggle for an existence. This scheme has very naturally excited a great deal of unfavourable comment among the profession, and is acting, and will act for some considerable time, as a powerful detriment to the business of London photographers, and, of course, greatly help to lower the photographic profession.

I am amazed to see the proprietors of these two papers (for the same offer is held out to the readers of a halfpenny evening paper, issued from the same office) resorting to such illegitimate means to increase their revenue. Not satisfied with supplying 2000 readers of these two journals, the editor has increased, "at the very earnest request of our readers," the offer to 10,000; taking the two papers together, brings the total to 20,000. Should they secure this number of orders, the money taken would amount to between 6000*l*. or 7000*l*.—a nice little sum to take out of the professionals' pockets at this time of the year, when it is a well-known fact that, with the present rates, they do scarcely earn as much as expenses amount to. These six-and-sixpenny "beautiful three-quarter, life-size, crayon and indian ink portraits," cannot last, for to-day photography is judged by a double-edged standard, in which the finest requirements of science and art are blended; a standard that lacks even standing-room, for hit-or-miss class of work, rushed through by the hundred, can have no comparison with work turned out by first-class firms. Last week the editor of the papers in question tells us he has had "hundreds upon hundreds of orders." Can it be wondered at, considering the ample means of extensively advertising these "things of beauty, joy for ever?" No doubt, in time the editors' rooms of these papers will have all the charms of a bazaar.—I am, yours, &c.,

October 31, 1896. A PHOTOGRAPHER'S DAUGHTER.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post. Questions are not answered unless the names and addresses of the writers are given.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2, *York-street. Covent Garden, London.*

RECEIVED.—W. J. BARKER; F. E. G.; A. RIVOT & Co.; K. BELL; PRINCESS PEACE; F. CLARK. In our next.

LENSES.—BOSANQUET. Yes to both questions.

C. A. COLYER.—You had better call upon us some morning between ten and one, and we will advise you.

APPARATUS.—H. A. LOCKINGTON. It is against our rules to recommend particular makes of apparatus, but we are always glad to be of assistance on specific points.

EXHIBITING OTHERS' WORK.—BOURNE writes as follows: "Would you kindly tell me if it is legitimate to send an enlargement in competition at an Exhibition, finished and worked up by a well-known firm who work for the trade, enlarged, of course, from a negative taken by my operator at my studio?"—Certainly not, if you exhibit it as having been done by yourself.

LANTERN LIGHT.—T. WALTON says: "I was recommended to dissolve some albo-carbon in the oil I use in my lantern, as it was said to improve the light. I did so, but then the lamp smoked to a degree, and stank the house out. Should that be the result?"—It is quite what we should expect, unless the lamp had a strong draught, so that there was a sufficient current of air to consume the extra carbon added to the oil.

METHYLATED SPIRIT.—S. B. R. says: "I have some methylated spirit that I have had by me some years—before the new Act came into force—and, although kept in glass bottles, it has become quite a straw colour. Is it any good now?"—We have several samples ourselves that have gone the same—it usually does so when kept a long time—but we have found no difference in its working, or, at least, in any work we have employed it for.

BAS-RELIEF PHOTOGRAPHS.—J. RAMSDEN says: "Should esteem it a favour if you can tell me how to produce photographic bas-reliefs mentioned in your JOURNAL; also if you will give me address of Mr. Taber, or of any one who produces these."—In reply: See this JOURNAL of August 7, where the method is fully described. Mr. Taber is, we believe, in this country, and a letter addressed to him, care of the Camera Club, Charing Cross-road, will, no doubt, find him.

STAINED PRINT.—A. COLLIER asks: "Am I right in supposing the marks on the enclosed photograph to be caused by using the blotting-paper in blotting off until it becomes saturated with hypo? Your opinion will greatly oblige."—We cannot say positively that the stains in question are so caused. But using paper for blotting off when it is already saturated with the fixing salt is sure to lead to troubles of different kinds. There is little doubt that the stain may be caused in that way.

ASPECT FOR STUDIO.—ROGO writes: "Could you kindly say if a southern or eastern aspect would do for a studio if ground or patent rolled glass was used in glazing? Of course, eastern would, I expect, be better than southern, but would the latter do at all?"—Excellent work can be done in a studio with a southern aspect, but it requires some skill to do it, more than in working one with an eastern light. In the latter the sun has only to be contended with in the early part of the day; but with the southern aspect the sun has to be dealt with for the major part of the working hours.

IVORY MINIATURE.—MINIATURE writes: "Can you tell me whether the ivory for miniature painting should be prepared in any way, also is any medium, other than a little gum water, advisable, and where is the best place to procure the ivory? If not trespassing too much, is there a book upon miniature painting?"—No special medium is necessary. It is usual to rub the ivory over with a little very fine cuttle-fish powder before commencing the work. The ivory is supplied by all the artist's colourmen. We are not sure that any work is published on painting on ivory, we think not. Apply to Rowney & Co., Oxford-street. They may have a work that may deal with the subject.

KEEPING SULPHOCYANIDE.—PRINTER asks: "Could you inform me whether one pound of sulphocyanide of ammonia, diluted as soon as purchased in a comparatively small quantity of water, say, from two to four pints, will keep for a very considerable time, and whether distilled water would be essential? I get one pound at a time, given me to use by my employer, and I weigh it out at present one drachm at a time; but I fear after a time it becomes wet, and in consequence is not correctly weighed."—It is much better to make a stock solution of the salt than to weigh out the crystals in small quantities at a time. Unless the consumption is rapid, we should say, Dissolve half a pound, and then seal up the bottle containing the rest. It keeps well for weeks in solution, but the crystals rapidly absorb moisture when exposed to the air. Ordinary water may be used if distilled is not at hand.

BREAKING SURFACE OF GLASS.—A. C. WRIGHT says: "Will you oblige by informing me what is the name of the gelatine or other substance which is used abroad to so pull away the surface of glass in drying as to cause the peculiar cracked-all-over look one sees in glass ornaments of the kind? I remember an allusion by the late Editor in THE BRITISH JOURNAL OF PHOTOGRAPHY some few years ago to this substance, and if you can just state the name of the glue or gelatine, and where procurable, in a word or two, I shall be infinitely obliged."—If ground glass, such as is used for the collotype process, be coated with gelatine, and then be dried, and the drying be carried on in a tolerably high temperature, its contraction will tear away the surface of the glass. It is to the record of this fact that our correspondent probably alludes. Any strong gelatine will do that.

PRINTING, &c.—CYMRO. Will you please help me in the following questions:—1. If I fix a print (P. O. P.) in the hypo, is it as permanent as one toned and fixed? I like the tone when only fixed. 2. Where is the fault? I developed a plate, and while printing, after drying the print, I find that as to the collar and the neck there is no distinction between them? 3. Do you think there would be a vacancy for one going out to Africa in the photographic trade? I have been advised to go out for the benefit of my health. If you know of any firm that want a man, please mention in this week's paper. 4. While toning P.O.P. I find that the edges of the print tone quicker than the middle portion, and the result is that the edges of the print tone darker than the middle.—1. Doubtful. 2. Evidently the negative is faulty. 3. We know of no one requiring assistance at present. 4. Keep the prints in constant motion while toning, as also when washing prior to toning.

SPOTTY PRINTS.—A. E. G. says: "I should feel obliged by any information as to the source of spots on prints. I have been much troubled by it of late. Sometimes it is much worse than others. If I remember rightly, about two years ago you answered a correspondent about the same, which I think you said was caused by particles of iron dust. Do you think, where the spots appear at the back only, they would have any influence in fading the front of print? My batch of prints last week was much freer from spots than on any former occasion. I had each print toned face downwards, with the result mentioned above. Do you think this the cause of improvement? How do you think they can be prevented?"—In this case it is pretty clear that the spots are due to particles of foreign matter coming in contact with the prints at same stage or other. Whether they are iron or anything else we cannot say. Their avoidance is easy with additional care. It is possible that the spots at the back may eventually show in the front.

LANTERN MATTERS.—MAGIC LANTERN says: "I should feel obliged if you would give me your advice on the following questions: I have one of ——'s enlarging apparatus, one something like the one in their advertisement in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1896. 1. Is it suitable for giving magic-lantern entertainments? it has a three-wick lamp, burners one and a half inches wide, and a four-inch condenser. The lens is the same as supplied with the apparatus. 2. What size picture should it give on the sheet? The last time I tried it, I think it must have been too big, viz., twelve feet, the slides looked awful yellow, and the light was bad indeed. 3. Could I have incandescent gas burners? would that be quite so hot? I find the outside woodwork is cracking with the heat from the lamp. 4. My next trouble is in colouring lantern slides. In the first place I can paint in oils, being a portrait painter, but I find when I have done a slide, and it is in the lantern, it looks ropy, and some of the colour does not show at all, although when out it looks fine and clear. Please tell me where I go wrong. Water colours I can't manage on the slides any way. With the Diamond dyes I get on fairly well, but do not like them, for, should you make a blunder, you cannot alter it. Do slide painters use any special medium? if so, can you please tell me the name?"—In reply: 1. Yes, on a small scale. 2. The screen was too large for the light. 3. The incandescent burners would not radiate so much heat as the oil lamp. 4. This is simply due to the work not being fine enough, the brush marks showing too strongly when magnified. We do not think that any special medium is employed.

SILVER PRINTING *versus* PHOTO-MECHANICAL PRINTING.—FUTURE says: "The following questions are troubling my brain very much, will you kindly answer them? (The questions are not meant for any particular country, competition being as great here as anywhere else.) 1. As the average conjunctures now are for the landscape firms working on a large scale in silver prints, can such a business, in expert hands, and now started, be made to prosper in the end, while patiently gathering the most valuable negatives summer after summer, and having capital enough to lay out for a reasonable number of under-balancing years? 2. Will it be only a question of time when photo-mechanical processes will kill the silver printing for such purpose as above, or spoil its business by cutting prices still more? if so, within how near a future will such be the case, and which photo-mechanical process will be the main competing one against the silver printing? 3. Will it mostly be the new silver printing landscape firms that will take up the photo-mechanical processes in question 2 for landscapes, or will it mostly be other firms that will go in for it? 4. Which precautions should already be taken by the now silver printing landscape firms with a view to the future when photographing their landscapes?"—In reply: 1. It is very doubtful; we ourselves should not care to run the risk of starting such a business in the hope of its paying. 2. Generally speaking, yes. We cannot fix a date, but probably collotype is the most formidable competitor silver printing has. 3. The chances in each case are about evenly balanced, we should say. 4. If we understand the question aright, it is, Is it worth while landscape firms adopting photo-mechanical printing methods? We should say yes in such cases as that supposed by our correspondent.

JOURNAL OF PHOTOGRAPHY.

No. 1906. Vol. XLIII.—NOVEMBER 13, 1896.

Contents.

EX CATHEDRÂ.

It will be observed, from a brief report that we give in another part of the Journal, that the General Committee having charge of the Traill Taylor Memorial Scheme has, at length, on the recommendation of the Executive Committee, come to a decision with regard to the best form which the memorial should assume. The annual income of the invested funds is to be applied to the holding of a lecture, preferably embodying the results of original research, and a commemorative medal will be bestowed upon the lecturer. A permanent committee, consisting of town and country members, has been appointed. For other details of the scheme we refer our readers to the report. In all probability the very best manner of perpetuating Mr. Taylor's memory has been chosen, and it possesses the added advantage of stimulating, to some extent, photographic progress.

* * *

The Executive Committee has met several times during the year, and their recommendations were the result of much anxious deliberation and discussion. To Mr. Alexander Mackie, who has acted as Secretary and Treasurer of the Fund, and who, in all probability, will continue to serve in the former capacity, every credit is due for the time and trouble he has devoted to the Fund. Our own thanks are, in a special manner, also tendered to him for having adopted the suggestion made to him nearly a year ago to interest himself in the matter.

* * *

The lecture recently given at the Camera Club by Mr. Arthur M. Brice, on the Jackson-Harmsworth Polar Expedition was noteworthy from a photographic point of view, as it elicited from Mr. Child, the photographer to the expedition, some details as to camera work in Arctic regions. He said the chief photographic difficulty arose from the condensation of moisture from the hands on the plates. The exposure required was very short owing to the strong light and clear atmosphere, and to the fact that the subjects photographed reflected a considerable amount of light; with a slow landscape plate, one second was sufficient with *f*-64. Development was easy, as the temperature in the house was never below 40° F., but there was some difficulty in obtaining enough water for washing the negatives. Rolled films were very useful, as they required less handling, and, if they got immersed in water, only the outside was damaged. Interesting, however, as these details are, it is highly probable that they could advantageously be amplified. Will not some enterprising secretary of a photographic society persuade Mr. Child to "fill an evening" with the subject of photography in the Polar Regions?

* * *

A lady writes us as follows, with reference to the formation of a Society for lady professionals. So far as we know, no such Society has ever been mooted, but we entirely agree that there is plenty of scope for the carrying out of our correspondent's suggestions: "Might I ask you whether any one has ever started, or thought of starting, a society for lady photographers—I mean professionals, *not amateurs*, of the same description as the Society of Musicians? It seems to me that a helping hand could be held out often to members of such a society when in sickness or out of a situation. It could be supported by a subscription from each member, and also by voluntary contributions. I myself am an orphan, and, though I have relatives to whom I can go, I feel too independent to care to be a drag on them. I may also remark that, as in all trades, photographers seem to think, as long as their employees eat and drink and look respectable, that is all

that is needed. They do not consider that clothes cost money and one does not grow younger. It also seems to me that employers in need of assistants could always apply to a society of this kind, thus facilitating matters on both sides. I am afraid I have expressed myself rather incoherently, but so many women earn a living at this kind of work as operators, mounters, spotters, and in various capacities, there seems a need of some kind of help for them, especially as they are none of them *over*-paid."

* * *

The Multum in Parvo is the title given to negatives which Mr. Singer, photographer of Chippenham, is supplying for Christmas and New-year's card purposes. The design consists of an ornamental border with a seasonable greeting, and spaces are left for printing in a view of one's house or a portrait of oneself. The idea is a good one, and may be appreciated by many at this time of the year, when novelties, however small, are welcomed.

* * *

The Actien-Gesellschaft für Anilin-Fabrikation, of Berlin, inform us that at the Berlin Industrial Exhibition, 1896, they have received the highest award, the Gold State Medal; and that their exhibits at the International Exhibition for Amateur Photography, Berlin, 1896, likewise received the highest distinction, the Gold Medal.

COLLODION SCREENS FOR ORTHOCHROMATIC PURPOSES.

Now that colour screens have come to form so important an addition to the numerous paraphernalia of the photographic *atelier*, the easiest means by which they can be improvised is a matter that must exercise many minds. Optically worked sheets or discs of suitably coloured glass are necessarily expensive luxuries, besides being liable to physical defects from which ordinary plate glass is in a great measure free; consequently, coloured films, spread upon properly polished plate glass, are more generally employed, and, if less permanent, are at least more easily renewed should any accident happen.

Of the various media employed in the formation of the coloured coating, spirit varnish, gelatine and collodion are those most generally in use; and, though the last-named has been condemned by many experimenters as useless, on account of the "structure" it shows, it will be our endeavour to show that injustice has been done to collodion, and that, in fact, if properly prepared, it is far the best of the three. With spirit varnishes we have had practically no experience, the few attempts we have made with such preparations having been so manifestly inferior to either collodion or gelatine that we have never thought it worth while to persevere. With gelatine, undoubtedly, very fine films may be obtained, so far as freedom from structure is concerned; but there is always more or less tendency to mechanical defects and a want of absolute transparency, such as can be obtained with collodion, besides which the extreme care necessary, in the preparation both of the solution and the screen, renders the manufacture one of the greatest delicacy. With collodion, however, when the proper sort is obtained, the removal of an injured screen is a matter of only a few minutes and very little care.

The first step in the preparation of the collodion is to obtain a suitable sample of pyroxyline, and this is the point on which all those who run down collodion screens have come to grief. If collodion for the wet or dry processes depends for its quality upon certain properties of the pyroxyline from which it is made, the same is equally true when it is to be used for screen work, and it may be remarked that the very qualities that go to render a sample of cotton especially fit for photographic purposes may be just those that have a reverse tendency when clearness and freedom from structure are concerned.

In examining a number of samples of pyroxyline, they will be found to vary very materially in the character of the film they give, when dissolved and spread upon glass. Some—and these are the ones that are frequently best adapted to negative purposes, especially dry plates—are at once placed out of court owing to their setting and drying with a certain amount of opalescence. These may be at once rejected. Of those that appear to be perfectly clear, some will present, when set, a fairly, if not perfectly, even surface, while others will set in lines or ridges running in the direction of the "pour off." Although the latter may dry apparently as even as the others, they also should be rejected, as, when colouring matter is added, the ridges will show more or less after drying, owing to the greater thickness of colouring they contain.

But the solvents employed in making the collodion exercise an equally important influence on the character of the film, as all old collodion workers are well aware, not only so far as their quality is concerned, but equally as much in the proportion to which they are used. Thus, the addition of water to collodion, or, what is tantamount to the same thing, the use of weak solvents, *i.e.*, those of high specific gravity, is known to render the film open and porous, but, at the same time, to make it flow unevenly, and dry with more or less structure. Then, again, a preponderance of alcohol in the mixture is found to give a film which dries slowly and without structure, though the collodion may flow rather unevenly, while an excess of ether causes the film to set quickly and evenly, but with a fine "ribbed" or "twill" surface, while moist and thin lined surfaces will, as already stated, show in the coloured screen.

Almost every sample of pyroxyline exhibits some difference in behaviour under similar conditions of treatment, some requiring an excess of alcohol over ether, and others the reverse. Some, again, absolutely require the very strongest solvents, while others will admit of the presence of a considerable proportion of water without exhibiting any marked "structure." Hence it is only by carefully selecting the pyroxyline and afterwards as carefully studying the proportions of the solvents with which it works best, that perfect success can be realised. But, as a small stock of such collodion will last a long time, the trouble will not be wasted.

The best way, however, to arrive at a structureless film with as little trouble as possible, failing a really good sample of cotton, is to operate on such as may be obtainable in such a way as to render them suitable. It is well known that by the action of water upon pyroxyline in the state of solution, that is, in the form of collodion, its character and properties are very materially altered, and in this direction lies the power of rendering almost any sample of cotton—except such as are naturally opalescent—suitable for our present object. In other words, by precipitating the gun-cotton from collodion already made, drying and redissolving it, its characteristics are so materially altered that it almost invariably gives a limpid, easily flowing, and structureless film. Added to this, it may be said that its solubility is so greatly increased, that very much

thicker films may be used without incurring the danger of unevenness, and, by the removal of any remaining traces of acid and the greater purity of the resulting collodion, there is less danger of the colouring matters subsequently added being damaged or altered.

To prepare the precipitated cotton, take any ordinarily good sample that sets and dries quite transparent, and dissolve it to form as thick a collodion as may be convenient in view of subsequent filtration or clearing. It will not do to make it so thick that insoluble particles will not subside, but just thick enough to economise solvents. Let it clear by subsidence or clear it by filtration, and then add to it, a little at a time, sufficient water to make it begin to look thick. Then pour it in a thin stream into a large volume of clean water either cold or very slightly warm, and stir it vigorously all the time. The result will be a bulky, white, flocculent mass, which, after changing the water once or twice, may be squeezed out and dried in the sun or in a gentle oven.

Pyroxyline so precipitated will be found very soluble, to the extent sometimes of thirty or forty grains to the ounce of solvents; to give a perfectly clear collodion, to flow evenly unless too thick, and to dry without structure; to be, in fact, the very perfection of pyroxyline for making screen collodion. If this be dissolved in absolute alcohol and ether, if not higher specific gravity than ·720, it will give a clear hard film that is scarcely scratched with the finger nail, and that will bear a considerable degree of magnification without showing any grain or structure.

Celloidine forms a very good basis to work upon, being pure and limpid and comparatively free from structure, but it must be remembered that it is not a precipitated preparation, and has therefore not undergone the chemical change that gives the latter its peculiar properties.

A stock of prepared collodion on the principles stated above can be kept on hand and coloured with any suitable dye as required, the process of applying it to a piece of optically worked glass, and the subsequent drying scarcely occupying the time required to pen this paragraph, while the result for working purposes will prove at least equal to the best and most expensive screens obtainable.

The New President of the Royal Academy.—Contrary to the expectations of some who were supposed to be able to form an opinion, Mr. E. J. Poynter, the Director of the National Gallery, was, at the meeting last week, elected President of the Royal Academy, as successor to the late Sir John Millais. A fortnight ago it was thought in some quarters that the honour would fall to Mr. Val Prinsep, but in the first vote at the election that gentleman received but little support, the greatest number of votes falling to Mr. Briton Rivière, Mr. Poynter, and Mr. Dicksee. In the final vote, Mr. Poynter secured 19 votes, and Mr. Rivière 16. The former artist was therefore declared duly elected to the highest honour that artists aspire to. It is to be hoped that the President will live to enjoy the distinction much longer than did his predecessors.

The Illustrations in the Royal Photographic Society's Catalogue.—A correspondent writes asking if the illustrations in the Pall Mall Exhibition catalogue were done from the identical prints there shown or from others supplied for the purpose. He says he asks the question because several of the pictures in the book show more detail, and have greater vigour, than is seen in those on the walls. As we have heard several comments to the same effect, we give prominence to the query here instead of in the usual Correspondence column. It would be interesting to a good many to know, authoritatively, if the negatives from which the blocks were produced were taken from the actual prints shown or whether they were taken from others; and, if the former, whether the greater detail and vigour seen in some of the reproductions are due to hand work on the negatives or the blocks.

Something New (?)—One of the evening papers that often "enlightens" its readers on scientific matters, one day last week said:—

"An enterprising photographer has succeeded in photographing a bullet in its flight. He has also succeeded in photographing those waves of air which are produced by the tremendous onrush of the bullet through the elastic medium of the atmosphere, and which are expressed not to our eyes but to our ears by the 'sing' or hum of the fatal missive. In front of the ball is a dark line of compressed air and behind it the hole cut in the air may be seen closing up."

After this, possibly, in the near future, our contemporary will chronicle the demise of Queen Anne. Professor Boys must feel highly flattered at being designated "an enterprising photographer," we should imagine.

Röntgen Rays at the Hospitals.—Mr. Luxmore Drew held an inquest at Hammersmith, one day last week, on the body of a child who died from ulceration of the stomach and hemorrhage, through having swallowed a halfpenny. In the evidence one of the witnesses is reported to have said that she had taken the child to the hospital, and they had offered to photograph the boy, to find where the coin was, but she could not afford the five shillings fee. If this statement be true, it would seem that, although the hospitals are taking advantage of the X rays, it is only where the patient is able to find the fee for the photographing. Five shillings is little enough for taking a photograph of a child's body, but it is a sum that many patients who are compelled to avail themselves of hospital treatment cannot afford. If they cannot, and the above statement be correct, then Röntgen's valuable discovery is as nought to them.

A New Art Reproduction.—It is stated, in a daily contemporary, that the Committee of the Burlington Fine Arts Club has obtained permission from the President and Council of the Royal Academy to reproduce by photography, and by the carbon process, the famous cartoon, by Leonardo da Vinci, in the Diploma Gallery, Burlington House. It is added that, as it is felt that many lovers of art, throughout Europe, desire to obtain copies of such a unique and extraordinary work, exceptional arrangements have been made by which students and connoisseurs may obtain copies; but these copies are only to be had through members of the Club. It will be interesting to see if the reproduction will be executed by an English or by a foreign house. We have heard that this famous work was photographed some little time back by a foreign firm, but whether for a restricted publication or not we cannot say. If this work is of such great interest, and it certainly is, to art students, it is a little surprising that the Royal Academy does not permit the work to be reproduced for unrestricted publication.

Another Judge on the Pharmaceutical Society's Prosecutions.—County Court judges are continually expressing their opinions on the vexatious actions of the Pharmaceutical Society. As was seen by our last issue, that astute Judge of the Bow County Court, Judge French, made some very strong comments on the subject in the case where a poor man had innocently procured some rat poison, to oblige a neighbour, as he thought. The Judge asked the Society's representative if he pressed for the full penalty of £5 against this poor man, whose wages were 30s. a week, on which a wife and four children had to be kept. He did, and the Judge had no option in the matter but to order the payment of the 5*l.* with costs. The Society will get their "pound of flesh," but they will have to wait for it; for Judge French marked his idea of the prosecution by ordering the payment by instalments of one shilling

a month. This will take over eight years to complete it. The Pharmaceutical Society will not profit much over this transaction, we opine.

Photographing in the Parks.—The Royal park-keepers are evidently fully alive as to the appearance of hand cameras, unless they are less conspicuous than was that of a writer to the *Standard* one day last week. He says that he was informed by two park-keepers that he could only photograph in Hyde Park with a special permit, one of the officials remarking, "You see, sir, yours is the instantaneous process." The writer adds that he has since obtained one of those precious documents, and finds that it is not available on Sundays. But what strikes him as more extraordinary is that "the photographing of persons or groups is not permitted," and asks, if armed with "the magic permit," whether a photographer is deterred from taking snap-shots at the cyclists and equestrians in the Row? We imagine that there is no impediment to taking such pictures as those alluded to. The regulations as to "persons and groups" are intended to prevent itinerant photographers of the ferrotype order from taking up their stands in the parks. It would never do to allow the parks to be studded with the itinerants' paraphernalia, such as are to be met with on Kew Green, for example, on Bank Holidays. If we remember rightly, many years ago a professional photographer was allowed a stand near the Row, where he took equestrians' portraits, but the photographs were of a much better order than those of the present itinerant class.

PHOTOGRAPHS AND CHARACTER READING.

The large extent to which some of the weekly journals devote their attention to giving written statements of the character and disposition of their readers on their sending a photographic portrait caused me to make reference to a well-known phrenologist, in whom I had confidence, to ask him certain questions with a view of satisfying myself of the value of such reports or opinions.

The first question I asked Professor W. Cross in his consulting room at Victoria-street was this: "Can a person's character be read or told from a photographic portrait?" and his answer was: "Yes, decidedly yes, and if you will read my opinions on the photographs of the well-known men and women I have placed in the window, you will be able to judge how far I am able to read characters from the phrenological aspect of the head." After making a few notes for him to consider in my absence, I went outside and looked at the photographs he had displayed for the public to see, with the character and disposition report attached thereto. I was simply astonished at the outspoken nature of these reports, and in the case of a Royal couple recently married, if each knew of the peculiarities of the other, and they were free agents in the matter, it would be quite a wonder if they ever had married.

No doubt there is a good deal to be said in favour of the White Cross League, and the elimination of hereditary taint, and, if young folks are to know if their lovers are likely to make suitable partners for life, they cannot do better than get a phrenological report. I imagine, however, that, in both sexes, there would be a strong objection to submitting to examination for the information of the other, but no objection probably to submitting a photograph for report.

As an extra means of bringing business to photographers, it may be worth while for professional men to know what is required by the phrenologist to aid him in his report. The best of all positions is profile, for then he can see the ears, the back of the head, the crown, and the brow. In the case of ladies, the hair must be dressed so as to show these portions of the head.

With a view of testing the accuracy of this system of examination, I submitted photographs of three persons well known to myself, and three well known to the Editor of this Journal, but neither of the six had ever been seen by Professor Cross, or were known to him by reputation or as public characters.

Having so far become interested in this matter, I said to myself, Would it be any advantage to a professional or business man if he had a certain amount of phrenological and physiognomical knowledge? and, propounding the question to the Professor, he said that to "take stock" of one's patrons or clients was always an advantage from a commercial point of view. He thereupon gave the following examples:—

The Vain Man or Woman would be known by the lips being of a cupid's bow shape, and they would be somewhat affected in manner generally. They would like compliments paid them, and even be pleased with flattery in some cases.

The Proud Man would be noticeable by large development in centre of the head (the crown), and he would have to be treated with respect, and not in any way flattered. He would be bigoted in his views, and must be humoured and nothing forced upon him. If anything was in question it should rather be put, "Not wishing to go against your judgment, but I suggest," &c.

The Avaricious Man will be found to be broad at the back of the temples, and head flat above, showing lack of moral and refining qualities. He is not likely to be a patron to any large extent; in fact, often these gentlemen only have their portraits taken at their country's expense (in Her Majesty's prisons).

The Nervous Man will be broad at the head in the region of the parietal bone, and often very shallow round the ears. He must be put at his ease at once by having his attention drawn to something attractive in the studio, and the actual business of portrait-taking deferred a little until his confidence is secured. Other causes of nervousness are indigestion and ill health, shown by hollows at the side of the skull in front of the ears, but on the brow level.

The Open-handed Man will be known by being flat or hollow at back of temple, but care must be taken to study the back of the brain to see if the skull is well arched (in Saxon form); if not well arched, he might, and probably would, forget to pay for his photographs, &c., if trusted at all.

Tact is shown by a well-rounded head just above the forehead. This is one of the most useful developments a commercial or professional person can have, and, if one thinks of the successful men in the medical, legal, military, and other professions, or the trading world, those who have achieved fame in nearly all cases are such as have had the common sense to secure and keep friends or retain the services of those who could render them most assistance, their own personal abilities or genius being in many cases not transcendent.

Lovers.—If a man or woman wishes to know the disposition and character of his or her lovers, it is necessary to have a profile photograph of the head, because the development of the skull at the back, or lack of it, will show whether the love would be lasting or fleeting.

Practical advantage to parents in the phrenological examination of children will accrue by their being told their capabilities, for it is no use to put a child to an engineering business if he has no mechanical tastes, or to painting and music if these developments are non-existent in his or her skull. In cases of choosing managers, secretaries, or assistants for positions of trust, a photographic examination reveals dispositions that are seldom wrong, and, in criminal cases, the character reading of submitted portraits has been wonderfully verified by acts and deeds

I append Professor Cross's reports on the photographs I submitted to him. Nos. 1, 2, 3, and 5 are those of persons known to me, and I can vouch for the accuracy of the delineations.

Nos. 1B and 2B refer to photographs handed me by the Editor.

"*No.* 1.—As far as can be seen of this child's head it is indicative of a high degree of literary ability. It is endowed with a great amount of the emotional temperament and granting vitality improves it will excel as a writer of fiction, but unfortunately the photo indicates a great lack of vitality. There is also much musical and artistic ability. Would be very kind and sympathetic in disposition and exceedingly sensitive to the world's opinion. Cautious and diplomatic, but unfortunately the head is too much covered to give a very accurate description.

"*No.* 2.—"The constitution is somewhat delicate. Very romantic temperament, ideality being so large that this lady will suffer too much from despondency, because the practical will not come up to her strong ideals of what they should be. She is quick in reading character, has a very emotional temperament, will be too fond of the mysterious, and must avoid all forms of mysticism; will be sympathetic, very lovable in disposition, and will not be truly happy unless she has a partner of the opposite sex in whom she can confide. She must never live in a malarial climate. If she had the fever, would have it very badly.

"*Nos.* 3 *and* 5 appear to be the same; but, taking No. 5 to describe, he possesses a high degree of the mental temperament. The brain is far too active for the physical conditions, and he will have to be most careful of diet, and must be most careful not to overtax the brain in any way whatever. His head is indicative of a high degree of firmness and stability of character; he will be most persevering, and yet he will not undertake anything without well considering the end, as he possesses a large development of caution and causality. This combination confers upon him a sound judgment and much originality of mind. Will decidedly be a lover of order and discipline, and will be most methodical in everything that he takes in hand to do. Pretty accurate as an observer, imitative, and possesses much dramatic ability, and, had he been stronger, he would have made a good comedian. Upon matters of theology somewhat broad in his views. Although brim full of fun and wit, yet hope is moderately developed, and therefore occasionally will suffer from feelings of despondency and heaviness, and more especially as the liver is rather inactive.

[Note.—Nos. 3 and 5. These are brothers; hence, the similarity of features.—G. B.]

"*No.* 1B (*Lady*).—This lady possesses a very decided character in many ways. The faculty combativeness is well developed, and it confers upon her a high degree of nerve and courage. She will be decidedly progressive in her thoughts, and, doubtless, will often wish she had been a man. Intellectually, she is a most keen observer, most critical, and will detect mistakes in the reasonings of others with great rapidity. She has large benevolence, and this will make her a reformer, and she would take great delight in putting forth efforts to improve humanity. She

possesses a high degree of artistic and musical ability, and upon the stage would have manifested very great talent. Very great in her likes and dislikes, yet will manifest a great amount of tact when dealing with others. Amativeness is very large. She must have fallen in love very early in life, and even then had a very exalted opinion of what her lover should be. Although she possesses great practical talent, yet she will be deeply interested in the mysterious, and, if she had the time, would take delight in reading up occult sciences. The head being covered, the back of brain cannot be described, excepting amativeness already noted.

Constitution, very wiry. Great power of recuperation, and would surprise medical men how she would pull through an exhausting disease.

"*No.* 2B (*Gentleman*).—This gentleman possesses very marked abilities of a scientific nature, he will be most methodical in his manner of reasoning, punctual in all his appointments Language, very small, not fluent as a public speaker, but would be brilliant as a writer. Very clear insight into character, and, in fact, would be very fond of the study of nature generally. Great firmness of character, and yet has been sympathetic in many cases to his own disadvantage, as caution is not large. Very courageous in the midst of danger. Social in disposition, yet never affected in any manner whatever. Most independent, and will decidedly rely on his own judgment. Would have been very successful as an historian, or in literary work. Constitution strong and vigorous; only difficulty would be that the nervous system may overtax the digestive organs, as this appears to be the weakest part of his frame. In music would be successful as an organist, and, as a teacher, would exercise very great power over young men. Possesses a great amount of true love and affection, but the intellect would decidedly predominate over the amative propensities." G. R. Baker.

[We handed Mr Baker three photographs to be submitted to Mr. Cross, who, in his reports (Nos. 1 B and 2 B) describes the characters of the originals—one of whom is now dead and the other not resident in England—with remarkable correctness. The third photograph was that of ourselves, and those who are qualified to judge declare the Professor to have given a very exact reading.—Ed.]

THE LATENT IMAGE AND THE THEORY OF DEVELOPMENT.

It may not be uninteresting at the present time to give a summary of some of the older hypotheses which have been advanced to account for the formation of the latent image and the development process.

In 1853, Schnauss published a treatise in the *Archiv der Pharmacie*, vol. cxxiv. pp. 6, 7, "On the chemical processes in the production of photographs," and stated that he considered the development of the latent image as a special kind of electrical attraction, in opposition to the generally accepted theory of the chemical decomposition of the silver iodide. He considered that it remained unchanged, and merely became endowed with electrical power to attract the silver particles in *statu nascendi*.

Notwithstanding the many experiments and papers published during the next few years, most of them dealt indirectly with the subject, by drawing comparisons between the formation of the image in printing-out processes and the invisible image; but, in 1857 (*Bulletin de la Soc. Française*), Davanne published an important paper, in which he points out that light could produce chemical decomposition, chemical combination, and molecular attraction; as a proof of the latter, he draws attention to the well-known fact that a glass or silver plate when touched with a hard substance would at that place condense the breath, and he argues that the appearance of the photographic image, whether on glass, metal, or paper, should be ascribed to molecular attraction.

He goes on to say that the question, "What is the action of light?" can only be answered by hypotheses, because no action is recognisable, either by the eye or by analysis; but the assumption that the light exercises a reducing action is supported by the fact (1), that the silver salts are almost all reduced by light; (2), with many preparations the image when the plate is removed from the camera is visible, so that a reduction must have taken place, or, in other words, a subiodide or metallic silver has been formed which could be proved by analysis.

It might also be assumed that, instead of a separation of the elements having occurred, a release of the smallest particles had taken place, since by the more or less strong light action the molecules had been slightly removed from one another, and that development completed this separation and set free the silver molecule. In such a case, pyrogallic or gallic acid ought to be able to develop the image on a thoroughly washed silver iodide film, and this Davanne had been unable to do. He finally comes to the conclusion that the silver film is reduced invisibly by light, and the silver molecule set free by the developing agent was deposited on this, and as the deposit increases the image becomes visible and will develop with ever-increasing quickness. It therefore follows that all bodies which can reduce silver nitrate or metallic salts are suitable for development of the photographic image.

In *Horn's Photographic Journal*, vol. xvi. p. 2, appears an extract from Marie-Davy's work, *Hauptinhalt der Untersuchungen über die Elektricität*, which is somewhat too lengthy to include, but which suggests the action of electricity.

Hardwich, in his *Manual of Photographic Chemistry*, 1863, p. 37, distinctly states that it is the hydrogen which reduces the silver haloid to the metallic state and not the developing agent.

Monckhoven contributes the next important paper, and he comes to the conclusion that silver iodide does not suffer chemical decomposition in light, and there is no reduction, assuming that it is not combined with any organic substance; and he says, (1) if light acts chemically on silver iodide and silver itself, or the suboxide be formed, diluted nitric acid must dissolve the silver or suboxide. A plate thus treated, and well washed to remove the nitric acid and flooded with pyro and silver nitrate, gives, however, an image which, although faint, is distinctly visible; (2) silver bromide darkens easily in light, nevertheless it is less sensitive than silver iodide if a developer is used; (3) if the action of light on silver iodide were chemical, it must be in proportion to its duration, that is to say, if one second produced a vigorous image, two or three seconds must produce an image twice or three times as intense. But this is not the case, light needs a certain time to produce a maximum; if this is overstepped, the action decreases and the image loses its intensity, which has been called solarisation.

He recalls some of Moser's experiments which have some bearing on the question; (A) if a sheet of glass be exposed to sunlight under a stencil, the breath will condense on the exposed part and make the light action visible; (B) a silver plate gives the same result, but, if, instead of breathing on it, one exposes it to the vapour of mercury, the image can be made visible after a much shorter exposure; (C) if a copper medal be gently warmed and laid on a polished silver plate, the breath or mercury vapour will condense and make the image visible even if the experiment be performed in the dark; (D) if the medal is left very long on the silver plate, the image produced by the breath or mercury is solarised and the reverse of (C) is obtained.

This is exactly analogous to the action of light on silver iodide. Monckhoven finally concludes by saying that the action of light on silver iodide is purely physical; and, if in certain processes an image is produced by chemical action, this must not be ascribed to silver iodide, but an organic silver compound.

In 1862, Poitevin published his work *Traité de l'Impression Photographique sans Sels d'Argent*, in which, in chap. x. p. 129, he says, "If light is to reduce a substance, another substance must be in contact, or mixed, with it, which substance must be capable of absorbing the element set free, and forming a more stable compound." This view was subsequently advanced by Vogel in 1865.

In the *Photographic News*, 1866, p. 380, Carey Lea advanced the theory that the latent image was merely of a physical nature, and that there was no chemical decomposition of the haloid, no iodine or bromine was set free, and finally, that, at least in the wet-collodion process, the image was formed at the cost of the developer. In order to support this theory, he made the following three tests:—

(1) If a reduction takes place during the formation of the latent image, that is to say, if iodine or bromine is set free, then the haloid must, to a certain extent, lose in volume. He developed an image in the ordinary way, and, instead of dissolving out the unaltered haloid by fixation, he allowed it to remain, and dissolved out the silver image; and, to effect this, he placed the plate in a weak solution of mercuric nitrate, in which, in three or four minutes, the image entirely appeared. The well-washed plate showed a perfectly flat surface, without the slightest trace of a positive image, and therefore, no iodine or bromine could have been used.

(2) The second experiment was still more convincing; the same developed plate which, as just described, was treated in the dark room with mercuric nitrate, and was then found to be an absolutely unchanged homogeneous film, gave after careful washing with ferrous sulphate, on treatment with silver nitrate, exactly the same negative, by which it would appear to be proved that the latent image had not been destroyed by the mercury, as, after removal of the silver precipitate, it could be again developed.

(3) In the third experiment Carey Lea used, instead of iron, the pyro developer, and obtained the same satisfactory results.

This extraordinary result that an image could be developed twice, or three or four times, and that each time the sensitive film can again be brought back to its original condition, shows also that the latent image is not altered by development, that is to say, remains

in the latent condition, from which Carey Lea concluded that it only underwent a physical change, and his theory was thus completely substantiated.

Another experiment of Carey Lea's is very striking, and was considered by him to still further substantiate his physical theory. A sheet of ground glass was coated with pure metallic silver, iodised, and carefully washed, and exposed for some hours to bright sunlight, and then for some time to diffused daylight. Finally, it was kept in a yellow covering in the dark for thirty-six hours, and, at the end of this time, was exposed under a negative for a few seconds. On development, it gave a sharp, clear image, without any trace of fog. There was obviously no organic matter present here; but, when a bromo-iodide collodion plate was treated in the same way, a much fainter and foggier image was obtained.

We now come to Nelson K. Cherrill's theory of the polarisation of the silver haloids, which was supported by a long paper from his pen in the *Photographic News*, 1866. In 1866 there appeared a paper in the *Photographische Correspondenz*, from the pen of Dr. Reissig, in which he details several experiments with silver iodide, prepared in various ways such as with excess of nilver nitrate, and also potassium iodide, and found that, although the iodide darkened, yet he could detect no sign of chemical change, and he concluded that the purest silver iodide, when exposed, underwent no chemical change, and yet was capable of attracting silver from the developer. He also states that a film of iodide of silver, expoeed to light in the presence of silver nitrate, and treated with iodine prior to development, gives no image, proving conclusively that the iodide, under these conditions, is transformed into subiodide, which latter compound again reverts to its original condition by absorbing the iodine with which it is treated.

In the *Photographic News*, August, 1867, p. 406, appears the translation of a paper, by M. Sytenko, in which occur the following passages:

"The action of light upon pure iodide of silver sets up an electric current which tends to precipitate the molecules of metallic silver; but, the intensity of this electric current being much weaker than the chemical affinity possessed by iodine for silver, the tendency of the latter to become precipitated takes place only in the presence of a third body having no affinity for iodide of silver.

"If the light has been very intense, and, consequently, the galvanic action very strong, although not sufficient to produce an image direct without development, the strengthening of the electric current by means of the developer does not produce a deposition of metallic silver in the same way as in the ordinary electrotype process, where a very strong electric current fails to reproduce a regular metallic deposit; the effect produced with an over-exposed plate is thus explained.

"If a sensitised plate, after exposure to light, is subjected to the action of a voltaic battery, a precipitaton of metallic silver is brought about on those parts of the plate which have been affected by light, and this reduction subsequently covers the whole of the plate, the galvanic action exerting the same power as that of light."

In THE BRITISH JOURNAL OF PHOTOGRAPHY, of July 31, 1868, Carey Lea describes some experiments, in which for the first time he took into account silver bromide, but comes to precisely the same conclusion, namely, that the action of light is physical, and not chemical.

W. B. Bolton's theory has already been referred to, and his article will be found on page 397 of THE BRITISH JOURNAL OF PHOTOGRAPHY for 1870. In this year Schnauss brings forward the theory that there are two kinds of silver iodide, one not actinic, the other actinic.

In 1871, in vol. iv., page 343, of the *Berichten der deutschen Chem. Gesellschaft*, appeared a paper by Schultz-Sellack, which, however, beyond including a statement as to the different spectrum sensitiveness of the various silver salts, contains little that adds to the arguments on either side.

It was my intention, when commencing these notes, to abstract the principal papers on this subject, but I now see that they will need more than one article to do thoroughly. I can, therefore, only conclude here by drawing attention to one paper, though out of chronological order, which was read by Captain Abney, before the Photographic Society, which appears in the *Photo News*, June 12, 1885, when the lecturer exhibited a eample of subchloride of silver which, by analysis, showed that the proportion of Ag to Cl was within one per cent. of the fractional amounts required for Ag_2Cl. This was prepared by Dr. Hodgkinson, Professor of Chemistry at the Royal Military Academy at Woolwich. A. D. PRETZL.

PHOTOGRAPHY AND POLYTECHNICS.

POLYTECHNICS were originally established to impart technical education pure and simple, the main object of the promoters being to instruct apprentices and journeymen in the technique and scientific principles underlying their trade. By such means it was hoped that the intelligence and general character of the workman would be greatly raised, thus improving his own condition and increasing his economic value to an employer, intelligence and sobriety having a commercial value above ignorance and irregular habits.

Had the original idea been strictly carried out, we should by this time have had little to fear from "made in Germany" scares, and German competition in general; but our present polytechnics have largely departed from the designs of the pioneers. It was soon found that instructing genuine workmen resulted in a pecuniary loss, and, to make technical education possible, it wae necessary to widen its scope, so as to include other than apprentices and journeymen. In no trade has this been done to such an extent as in photography, the smallest polytechnic having a large photographic class.

In photography the polytechnics now set before them the threefold task of: (1) giving instruction in the scientific principles to apprentices and journeymen; (2) training persons in manipulstion and technique, who have no serious intention of following the trade for a livelihood; (3) teaching the whole trade, or certain sections, in a course of lessons to take the place of the ordinary system of apprenticeship. The two latter objects have now become the main work of polytechnics, and the genuine workman has very little attention bestowed upon him. What instruction is given is mainly "cram" to pass some examination. With this enlargement of their operations, the polytechnics now claim the ability to turn out a thoroughly practical photographer after a twelvemonth's training, as proficient and able as one who has undergone three or four years' apprenticeship in the printing room or studio; and they follow this up by asserting that the apprenticeship system is out of date, too slow and unreliable to suit present-day methods of business. These claims, I consider, have no warrant in fact, and, as the methods they support have been used in manufacturing a number of ignorant photographic employers and ill-trained assistants, resulting in considerable injury to the whole profession, it will be well to show their fallacy, and, if possible, counteract the mischief already done.

Dealing first with the matter of instructing *bonâ-fide* assistants in the scientific principles of photography. Some years ago I was a polytechnic student. At that time my fellow-students, almost without exception, were photographic assistants, employed in business during the day. Our class numbered about a dozen, and we studied the whole range of photography, from the latent image to photographing the sun's corona; from astigmatism to the stannotype. Hardly a subject having a close relation to every-day matters was studied. It is needless to say that I have not been called upon to photograph the sun's corona, to make stannotypes, to correct astigmatism, nor investigate the latent image. In due time I received a beautifully lithographed certificate from the City and Guilds of London Institute, and felt that I had done something to be proud of, and that my children and children's children would also be proud of. That certificate has long been destroyed as useless lumber, because I afterwards recognised that it merely meant a certain amount of cramming, and had no practical value. Not a single employer in the trade will pay an assistant one farthing a week more in wages because he can show a City and Gnilds certificate, for the economic value of an assistant to an employer depends, not upon what he knows, but upon what he can do. Of my fellow-students I can now count six out of the dozen, who are engaged in giving instruction on similar lines at the various polytechnics in and around London, and only one who has made any commercial success due entirely to the application of theoretical knowledge. Such a result would be regarded as a complete success by those who believe in cramming scientific knowledge with a view to passing examinations; but to me it means failure, proving, as it does, that mere acquisition of knowledge has taken the place of the application of knowledge, upon which commercial success depends. A too close a study of the purely scientific is extremely likely to draw away the attention of the student from the mundane and practical; for this reason, a leading photographer will not engage a City and Guilds man, for, as he says, "such men are too fond of experimenting at my expense." Indiscriminate theoretical teaching is of little use in raising the economic value of a workman, since the value of theory to any man depends upon his ability for putting theory into practice, and this is a very rare gift. To study the theory of the latent image is a harmless occupation for an assistant, but his time would be much better employed in striving to develop the latent image into a better negative than others can develop. All the theory will not aid him to do this, for men could develop images long before they had formulated a theory. As Ruskin remarks on the same matter, "The principle of chemical equivalents, beautiful as it is, matters far less to a peasant boy, and even to most sons of gentlemen, than their knowing how to find whether the water is wholesome in the back-kitchen cistern, or whether the seven-acre field wants sand or chalk." Likewise, in photography, it must be recognised that theoretical knowledge is but supplementary, and can in no way make up for a deficiency in technique and the applications, or art, of what is to be learned.

The second action of the polytechnics—giving instruction to persons having no serious intention of following photography as an occupation—has done considerable harm to the profession, and to find a remedy is by no means an easy task. It injures both employers and assistants by making

competition more severe, flooding the market with bad and indifferent work, worthless assistants, and reducing prices, profits, and wages to a minimum. A person having no knowledge of photography, by paying a few pounds to some polytechnic, can receive instruction in all branches. He turns out a few decent negatives and prints, and, inflated with success, imagines himself a competent photographer. Photography being a most attractive profession, the chances are that, if such a person has a little money, he will forsake his own occupation and rush headlong into photography, buoyed up with the false rumours of little work and enormous profits which are prevalent. A business is started in opposition to some established photographer, but many weeks do not elapse before he discovers that something is wrong, three and four resittings become common, proofs are taken and no orders received, and things generally go to the bad. To save himself, a reduction in prices all round takes place, and a temporary success is achieved by taking the custom of others. In many neighbourhoods such tactics are successful, the outsider manages to survive until greater experience improves the quality of his work. The success is obtained by the permanent reduction of prices, and from such a fall they are not likely to recover. In other localities such men will go down, for none will buy their indifferent portraits. An instance of the kind came under my notice. A man of this class started a business, having scarcely any opposition, but failed solely through bad work. In the same place two photographers from first-class houses are now firmly established.

If the class-trained man has not the means of starting a business, he will endeavour to find an engagement as an assistant, being willing to hire his services for a wage which experienced men cannot possibly accept. In his ignorance of the trade, he cannot judge all the factors which operate in deciding what is a fair wage in the open market, and, as a consequence, he generally under or over-estimates the price of his services. The low salaries induce some to engage, thinking they may gain on the transaction; and others, looking at the high salaries demanded, decide that the men must be able, or they would not have the confidence to ask for such high wages. Both are deceived, for the assistants have no just estimate of their own commercial value to an employer, often proving worth much less than even the lowest salary demanded. Photographic assistants cannot be put outside of the law of supply and demand, and with them, as with others, a fair day's work is worth a fair day's pay.

Coming to the third point, that of supplanting the apprenticeship system by a method of technical training, this, on the surface, looks plausible, but experience is daily proving its inferiority to the older system. The employer is finding that, in engaging an assistant from the technical school, he is incurring a loss both of time and material, because, on leaving the school, the assistant's training has practically to commence again, to give him an insight into the details of commercial production. In addition, he has to be broken of a certain leisurely style of going about his work, the class system failing to educate a workman in that quickness combined with precision which is essential when work is to be done at a profit. In photography, besides the acquisition of skill, there is needed a cultivation of taste, and in training apprentices it will be found that it requires incessant attention to awaken and impress upon the mind a preference for the superior above the inferior, whether it be in the tone of a print, the pose of a limb, or the retouching of a negative. Individual attention is necessary for such cultivation, and it cannot be properly attained by any mode of class instruction, the teacher being unable to study the peculiarities of each student, and treat them accordingly.

Imitation is also a fruitful source from which to acquire skill, and it can only be utilised by an apprentice being in daily contact with a capable and experienced worker. If left to himself, a learner will use his own methods, and in general these are not the best nor the most economical from an employer's point of view.

Constant practice, close watching to prevent a clumsy or wrong method, and some means of bringing pressure to bear to avoid careless and slovenly habits, are of the first importance in training photographic apprentices, and in all these the polytechnic system is lacking. Hence, when a lad leaves the technical school and enters a business house, it means that all this must be undergone before he is of any commercial value to his employer. The lad must unlearn his previous knowledge, because it was acquired under conditions quite foreign to those which prevail in the profession, and this brings me to the chief merit of the apprenticeship system, and the glaring defect of all technical education—the matter of experience.

What do we call an experienced man, and why are employers willing to pay a man a salary according to his experience? An experienced man is one who has had ample opportunities of meeting and dealing with his work under many different conditions, and in encountering circumstances outside of the usual course of events. In printing, retouching, or operating, he can treat any case that may come up with facility, and it is precisely on the possession of this quality that his value to an employer depends. Apprenticeship is devoted to gaining a similar experience quite as much as in learning the practice of photography. To overlook this fact, and suppose that practice without experience is of much value, is to confuse photography with a photographer. A class-trained man would do very well if work in business followed the same lines as work in classes. As a matter of fact, it does not, but takes various forms, and to gain experience of these only a course of years will be found adequate. Twenty years will not exhaust them all, much less one year.

I have not touched upon what may be called "professional etiquette," that is, the treatment of sitters and studio conduct, perhaps the most important part of a photographer's training, without which success is almost impossible. The need of it was impressed upon me by a youth, brought up in a middle-class family, who, on being told to conduct a lady into the studio, shouted across the room, "Come on! Come on!!" leaving the lady in doubt as to whether this was a photographic form of salutation or a challenge to mortal combat. Now, no form of training other than the apprenticeship system would correct such deficiencies in a youth.

JOHN A. RANDALL.

TABER'S IMPROVEMENTS IN THE METHOD OF EMBOSSING PHOTOGRAPHS.

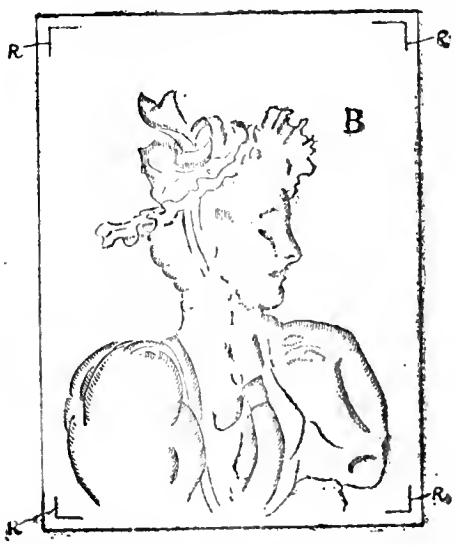
MR. F. A. TABER, of 609, Broderick-street, San Francisco, says:

"Heretofore, and before this, my invention, difficulty has been experienced in producing embossed photographs on account of the failure of the embossing mould and photograph to be embossed to register, which difficulty may be effectually overcome by the use of the process, which I will now describe by the aid of the accompanying drawings of which—

Fig. 1.

"Fig. 1 is a view of a photographic negative with guide or register marks thereon.

Fig. 2.

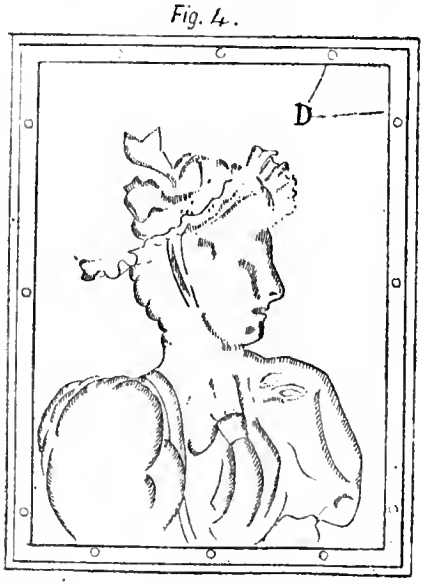


"Fig. 2 is a back view of the block with the embossing mould and register marks.

Fig. 3

"Fig. is a view of the photograph with the register marks cut out.

Fig. 4.



"Fig. 4 is a view of the mould with guide or register bars attached therete.

"The invention relates to the embossing of photographs so that the surface of the figure or figures thereof will be raised or projected from the plain surface, and consists of providing on the photograph guide or register marks removed from the figures to be raised, transferring to the surface of a block in which the embossing mould is to be made the outline of the figure or figures to be embossed, and guide or register marks corresponding with those on the photograph; forming in the block a mould in accordance with the outline of the figure or figures thus transferred to the block, and adjusting a photograph having thereon the guide or register marks to the mould, in accordance with the register marks on the block and on the photograph, and pressing the photograph to the surface of the mould, and the various modifications hereinafter specified and set forth, as will more clearly appear hereafter.

"The usual manner in which I carry on this process is to provide on the negative, shown in fig. 1, the guide or register marks, R R, which may be produced by pasting on the negative strips of paper, or painting the same on the negative with any suitable material, so that they will show upon the sensitised paper on which the prints or photographs are made. The surface of the block to be used as a mould is sensitised, and the reverse of the negative A is printed thereon, shown in fig. 2, and marked B, where the picture to be embossed is shown on its surface with the guide or register marks, R R. The embossing mould is now made in accordance with the picture on the block by hand engraving, or any appropriate means to such depth and to such degree of nicety of detail as may be desired. A photograph from the negative A is now made, and the same is trimmed so as to bring the register marks, R R, at the edge of the sheet. The photograph C, with the register marks thus trimmed, is placed on the embossing mould so that the register marks of C and the register marks of B will correspond. The photograph C is then fastened to the block D by any appropriate means so that it will retain its position on the block with the figure of the photograph directly coincident with the figure of the embossing mould. The photograph sheet, having preferably been moistened to soften it, a backing of soft and elastic material, such as rubber sponge, is applied to the back of the photograph, and the whole is subjected to pressure, whereby the rubber sponge forces the photograph into conformity with the embossing mould, giving to the surface of the photograph the contour of the mould. If desired, the face of the block B may be provided with guide bars or frame, as shown at D in fig. 4, where they are put on in accordance with the guide or register marks. When a frame of this character is used on the face of the mould block, the photographs to be moulded should be trimmed in accordance with the register marks on them, which will make the edges of the photograph prints correspond with the frame D on the mould block, causing the photograph of the figures to correspond with the mould when they are in the frame D.

"I do not wish to limit my invention to the particular manner above described of carrying the same into effect, as good results may be obtained by drawing the outlines to be moulded for a photograph, as shown in fig. 1, on a piece of transparent paper or other like material placed over the same, and transferring the outline thus made to the block B by placing on the block B a piece of carbon paper, and placing over that the tracing of the photograph face down, when, by following the outlines on the tracing paper with a pencil or like instrument, the lines will be transferred to the block through the medium of the carbon paper placed thereon, the guide marks R R, being preferably placed on the block at the same time.

"One of the advantages of this way of carrying on my invention is that it may be applied to any photograph without the necessity of having the negative, or more than one copy of the photograph to make a proper mould to emboss the photograph.

"It is manifest that, instead of placing a guide or register mark on the negative, the edge of the negative may be used as the guide or register mark, and be shown on the photograph and on the block in which the mould is made, and serve as a register mark without departing from the nature of my invention.

"I am aware that embossed photographs have been made before this my invention—a patent for a method of producing embossed photographs having been granted to me by Letters Patent, No. 21,422, A.D. 1895—but never before this my invention has a method been set forth whereby the photograph and mould may be made to readily register with accuracy, as is accomplished by the process here described.

The claims are:—

"(1) The method herein described of embossing photographs, which consists in providing on the photograph to be embossed guide or register marks removed from the figures to be embossed; transferring to the surface of a block in which the embossing mould is to be made the outlines of the figure or figures to be embossed, and the guide or register marks; forming in the block a mould in accordance with the outlines of the figure or figures thus transferred thereto; and adjusting a photograph, having thereon the guide or register marks, to the mould, in accordance with the register marks on the block and on the photograph; and pressing the photograph to the surface of the mould.

"(2) The method herein described of embossing photographs, which consists in providing on the photograph guide or register marks removed from the figures to be embossed; tracing on a transparent material placed over the photograph the outlines of the figures to be embossed, and the register marks; transferring to the surface of a block the outlines of the figures and register marks thus made, and cutting out the figures in accordance with the outline; adjusting a photograph having thereon guide or register marks to the mould, in accordance with the register marks on the block and on the photograph, and pressing the photograph to the surface of the mould."

THE ROYAL PHOTOGRAPHIC SOCIETY'S PROGRESS MEDAL.

THE Council of the Society (says the Society's *Journal*) have made the following regulations concerning the award of the progress medal:—

1. The Council of the Royal Photographic Society shall consider the award of one progress medal annually,

2. The progress medal of the Society may be awarded in recognition of any invention, research, or other publication which shall in the opinion of the Council have resulted in any important advance in the scientific or artistic development of photography.

3. The award shall be conducted in the following manner:—

(*a*) At the November Council meeting the names of nominees shall be duly proposed and seconded; the nominators handing in, in writing, a statement of the special work for consideration.

(*b*) At the December Council meeting the work of the nominees as already stated shall be discussed, and their names balloted out until only one remains.

(*c*) At their January meeting the Council shall, without discussion,

vote openly as to whether the medal shall be awarded. Votes received in writing from absent members are to be accepted. The medal shall not be awarded unless two thirds or a larger proportion of the recorded votes are in favour of its bestowal.

4. The above with the names of past recipients of the medal shall be published in the October number of the *Journal* in each year.

The medals have been awarded as follows:—1878, Captain W. de W. Abney, R.E.; 1881, W. Willis; 1882, L. Warnerke; 1883, W. B. Woodbury; 1884, Dr. J. M. Eder; 1890, Captain W. de W. Abney, C.B., R.E., F.R.S.; 1891, Colonel J. Waterhouse, R.E., I.S.C.; 1895, P. H. Emerson, B.A., M.B.; 1896, T. R. Dallmeyer, F.R.A.S.

THE TRAILL TAYLOR MEMORIAL.

A meeting of the General Committee of the Fund, to which all subscribers were invited, was held on Friday, November 6, at the Exhibition Gallery, 5A Pall Mall East. In the absence of Sir H. Trueman Wood, Mr. A. Haddon took the chair.

The Hon. Secretary announced that, up to that date, the total amount of subscriptions received had been 242*l.* 9*s.* 6*d.*, and that the expenses had been 13*l.* 8*l.* 2*d.*, the principal items being 8*l.* 5*s.* 10*d.* for postage and 3*l.* 17*s.* 6*d.* for printing. The balance in hand was 229*l.* 1*s.* 4*d.* He asked that two auditors be appointed to audit his accounts to date. Messrs. A. Clarke and H. W. Bennett were thereupon appointed.

The Hon. Secretary then said that, at the meeting of December last, at which it was resolved to raise a memorial to the late Mr. Traill Taylor, an Executive Committee was appointed to consider the form the memorial should take, and how the fund should be administered. That Executive Committee had held several meetings, and had drawn up a report; that present meeting was for the purpose of receiving and dealing with that report. He then read the Committee's report, and, after a long discussion, with certain amendments, it was adopted.

The articles of the report as amended were as follows:—

1. That the annual revenue of the fund be devoted to an award of a medal for a lecture on a subject connected with photography, and preferably embodying original research, to be known as the Traill Taylor Memorial Lecture.

2. That the fund be administered by a committee of ten London and ten country members. Two London and two country members to retire annually, and not to be eligible for re-election for twelve months. The annual retirement to be by lot until retirement by seniority of service can come into force. Any alteration in this clause to be effected only by the vote of at least four-fifths of the entire Committee.

3. The Committee to appoint a Secretary annually, not necessarily from their own body, who shall be *ex officio* a member of the Committee. The Secretary to hold office during the pleasure of the Committee.

4. That the fund be vested in two Trustees, to be chosen by the Committee. The Trustees to be *ex-officio* members of the Committee.

5. That a trust deed be executed embodying the above regulations.

It was a further recommendation that the first Committee be appointed by the General Committee.

A ballot then took place for the Committee, resulting as follows:—London members: Messrs. T. Bedding, R. C. Bayley, P. Everitt, A. Haddon, A. Mackie, E. J. Wall, H. Snowden Ward, W. D. Welford, H. Wilmer, and Sir H. Trueman Wood. Country members: Messrs. W. I. Chadwick (Manchester), W. Crooke (Edinburgh), Martin J. Harding (Shrewsbury), Geo. Mason (Glasgow), H. P. Robinson (Tunbridge Wells), A. Seaman (Chesterfield), John Stuart (Glasgow), H. Sturmey (Coventry), G. Watmough Webster (Chester), A. Werner (Dublin).

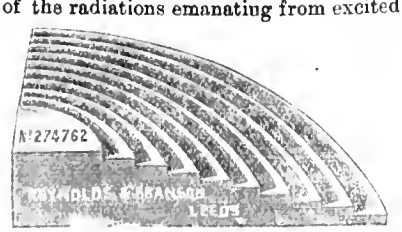
Votes of thanks to the Chairman and the Hon. Secretary closed the proceedings.

Our Editorial Table.

An X-Ray Meter.

Reynolds & Branson, Leeds.

This little instrument supplies a definite means of comparing the actinic power of the radiations emanating from excited tubes used in



X-ray work. A quadrant of aluminium is made in concentric terraces, the thickness ranging from one to ten millimetres. By placing this meter between the excited tube and a phosphorescent screen, the thickness of aluminium which the rays can pass through can be seen on the screen. The meter, therefore, gives an easy method of comparing the intensity of the rays emitted by different tubes, and the same tubes at different times.

Les Rayons Röntgen.

By Charles Henry. Paris: Société d' Editions Scientifiques.

The author, in a series of short chapters, summarises, from an entirely French point of view, what had been done in the investigation of the mysterious radiations examined by Hertz, Lenard, and others, prior to Röntgen's discovery of the X rays, and devotes the remainder of his book to a discussion on some theoretical and practical aspects of those rays.

Manuel du Microscope.

By Dr. A. Miquet. Paris: Société d'Editions Scientifiques.

This work is addressed to beginners in microscopy, a fact which explains the circumstance that so important a subject is dismissed in about fifty pages. However, much useful matter is compressed in the concisely written chapters which treat of the mechanical and optical parts of the microscope and its accessories, and other topics germane to the study of microscopy.

News and Notes.

The Watford Engineering Company, Watford, now make apparatus for portraiture fitted for acetylene gas as well as electric light.

Royal Photographic Society.—Photo-mechanical Meeting, Tuesday, November 17, at 12, Hanover-square, at eight p.m. *Successful Half-tone Illustration*, by Mr. Eddington.

The Christmas lectures at the Royal Institution will be on *Visible and Invisible Light*, by Professor S. P. Thompson, F.R.S. At the London Institution Professor J. A. Fleming will deliver a short Christmas course on *Rays of Light: New and Old.*

Photographic Club.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock on Wednesday evening, November 18. Mr. Thomas Fall will read a paper, entitled *Birds and Animal Life.* Lantern illustrations.

The Bristol Exhibition.—The Hon. Secretary writes: "We should be much obliged if you would kindly announce in your next issue, that entries must reach us for our Exhibition not later than December 1. You will, I am sure, be glad to hear that we have every prospect of a very successful Exhibition, and that entries are coming really well."

Napoleon Sarony, the well-known photographic artist, was (according to a Dalziel's telegram from New York) found dead in his bed on Monday morning from apoplexy. He had evidently died while asleep. His wife tried to awaken him, and discovered that life was extinct. Mr. Sarony was born in Quebec. He went to England and settled in Birmingham in 1866 for a time, and then came to the United States.

The Woodford Photographic Society's Exhibition of members' work will be held at the Coffee Tavern, George-lane, South Woodford, on Saturday, the 21st inst., from 4 to 9.30 p.m., when the Society will be glad to see any of their photographic friends who may like to pay them a visit. The Secretary (Mr. F. E. Emier), 1, Florence-villas, Chelmsford-road, Woodford, will be glad to send a card of invitation to any one who may like to have one.

An Art Delirium.—He uttered a cry of horror. "Take it away!" he yelled. "Take it away! I'll never touch another drop as long as I live." It was several minutes before he dared look up again, but, when he did, he seemed a little reassured. "I never thought I would come to this," he said; "but I have learned a lesson, at any rate. From this moment I am a total abstainer." And, after all, it was nothing but a Beardsley poster that he had seen.

"'Cosmos'—the esteemed mystery whose periodical 'Jottings' serve to diversify contemporary pages—hits the right nail on the head! He asks," says the *Optician*, "how it comes about that the Judges, who officiated at the Royal Photographic Society's Exhibition, passed over the Dallmeyer-Aldis stigmatic portrait lens, without due recognition of its great merit. Evidently a blunder has been committed, and those responsible are morally bound to offer some explanation and amends."

The Lumière Kinematograph.—In reply to numerous inquiries, we are able to state that Messrs. Fuerst Bros., of 17, Philpot-lane, E.C., are now in a position to take orders for the Lumière Kinematograph. The apparatus, which will be ready for delivery in the forthcoming spring, includes the camera, lens, stand, film, &c., for taking the negatives; the necessary apparatus, &c., for making the positives; and a complete optical lantern system for projecting the transparencies. Films of positive pictures, varied as regards subjects, will also be supplied. Messrs. Fuerst are the agents for Great Britain, the Colonies, and India.

ACETYLENE EXPLOSION AT GRIMSBY.—A few days ago a loud explosion was heard in the shop of Mr. Dewing, chemist, Grimsby, and a curious crowd quickly collected. The accident turned out to be an explosion of acetylene gas, which Mr. Dewing was using for photographic purposes. While the apparatus was being lighted the main became ignited and blew out the top of the cylinder, which, striking Mr. Dewing severely on the shoulder, flew upward and pierced the ceiling. Mr. Dewing was rather severely bruised and burnt, and for a moment became unconscious. An assistant standing near escaped entirely unhurt. The damage done in the shop was very slight.

SOCIETY OF ARTS.—The opening meeting of the one hundred and forty-third session will be held on Wednesday evening, November 18, at eight p.m., when an address will be delivered by Major-General Sir Owen Tudor Burne, K.C.S.I., C.I.E., Chairman of the Council. The subject of the address will be *India: its Arts, Manufactures, and Commerce.* At the subsequent meetings before Christmas, the following papers will be read:—*Recent Developments in Mechanical Road Carriages*, by W. Worby Beaumont, M.Inst.C.E.; *The Teaching of Economics*, by W. A. S. Hewins, M.A.; *Mining at Great Depths*, by Bennett H. Brough, Assoc.R.S.M.; *The Chamber Music of Purcell, Handel, and Bach* (with illustrations on the original instruments for which it was written) by Arnold Dolmetsch.

LIFE IN TRIPOLI.—Mr. G. E. Thompson, of Liverpool, gave a lantern lecture at the Pall Mall Exhibition, on the 2nd inst., upon this subject to a crowded and appreciative audience. Life under the dazzling sunshine and intense blue sky of the East is about as different as anything can be from ours in England at the present time, and Mr. G. E. Thompson's beautiful series of photographs of Tripoli, its people, animals, palms, and great desert, had a pleasing novelty about it. The pictures were largely instantaneous, showing the inhabitants at their usual avocations. There was the great crowded weekly market on the shore of the almost tideless Mediterranean. There were street scenes, shops, mosques, and orange gardens. The disdainful camel figured often, and the photographs taken on the great desert were not the least interesting of the series. Mr. Thompson described how he reached Tripoli, staying a week at a comfortable Italian hotel during the early springtime. The lecture was replete with useful and amusing information, and was much appreciated.

THE PRIZE POSTER.—Once upon a time a green cat sat under a blue rose bush, devouring a red mouse. This cat did business in the south-east corner of a poster, while at the upper left grew a vague, lavender-faced maiden against a lemon sky. Her hair and eyes were the colour of the cat; also the shirt front of the dim-featured, alizarine-faced youth beside her. The purple grass hesitated driftily about them. In the distance a vermilion sail was cutting a wide swath against a mauve moon. Something akin to intelligence azured the reflection of the far-faced boy. "The washing is on the line," he grieved. "The lavender eyelids fell. "Out of the intense comes——" She hesitated, and the rest was lost in the cream-coloured silence. The cat sped a gobelin-blue yeowl, such as thrive only in Poster Land. The tragedy was finished. The prize poster was ready for the contest. I do not know what it means. Neither does the artist. But those who have gone deeply into the heart of things, who have solved the elusive far-ness of Browning and Beardsley, they —they will understand.—*Detroit Free Press.*

CHEAP OXYGEN.—"It is reported from America," says a contemporary, "that the cheap production of oxygen on a commercial scale has been solved, and that oxygen gas is being manufactured at 3*d.* per 1000 feet, which, if true, may have very far-reaching effects. Air is blown through a mixture of caustic soda and black oxide of manganese, the bath being maintained at a temperature of between 500° and 600° Fahr., when the atmospheric oxygen is absorbed and manganate of soda formed, the nitrogen passing off unchanged. When the formation of manganate of soda is complete, the air is stopped, and a current of steam is forced through, by which means the manganate is decomposed into oxide of manganese and caustic soda again with the liberation of oxygen gas, which can be collected. This process of the alternate formation and decomposition of manganate is not by any means new; but, owing to the tendency of the alkaline manganates under the action of steam to form a viscid mass, and so prevent the intimate contact of air and steam with the chemicals used, it has never been a commercial success. The present inventor, however, claims to have completely overcome this difficulty by so regulating the constituents and the temperature to obtain a fluid manganate when the oxygen is being liberated."

VITAL (!) PHOTOGRAPHY.—Says our contemporary, the *Daily Chronicle*: "Dr. Baradue, whose experiments in what he calls mental or vital photography we noticed some weeks ago, has recently been pushing forward his researches in a fashion that would in this country attract the attention of the Society for the Prevention of Cruelty to Animals. This amiable physiologist 'crucifies' a pigeon, that is to say, he fastens it to a board, with its wings and legs firmly secured, and then places a sensitised plate on its breast. So long as it struggles for freedom, and throws off vital force, the plate, on being developed, shows a number of little round spots, much like those on a sheet of paper at which a shot-gun has been fired. When the bird gets used to its position, or is too tired to exert itself, the images recorded are cloudy or striated. The next step is to cut the pigeon's throat, the picture of its death agony taking the form of curling eddies, such as the doctor has observed when the plate is applied to suffering human limbs. As soon as death has supervened, no photographic effect can be procured, and a sheer blank is the only result. It is difficult to see what useful information can be derived from this combination of cruelty and absurdity. Admitting that the changes in the sensitised plate are really records of vital force, and not of other more obvious physical agencies, all the phenomena can be observed in the human subject without causing the slightest pain, much less wantonly sacrificing the humblest life."

PHOTOGRAPHY OF THE SOLAR CORONA.—Rev. T. E. Espin writes to the *English Mechanic*: "In accordance with my promise, I have made some experiments to try and confirm Mr. Packer's results. A wooden box was used as a camera; a pinhole was also used. The plate was placed in a cardboard box, the bottom of which was removed, and a thin plate of amalgamated zinc let in. The sensitised plate was in contact with the zinc. The sun's image was allowed to trail across. The plate was carefully developed, but nothing was found on it. In the next experiment, a piece of lead, on which was deposited a film of copper, was exposed to the image of the pinhole, the sun being again allowed to trail. This was removed to the dark room, and a sensitised plate laid on it, and left for two hours. On development nothing was found. In the third experiment a half-plate camera was used, the lens removed, and a pinhole substituted. This plate was enclosed in a sheet of tinfoil, which exactly went round it once. This was inserted in the carrier, and, being placed in the camera, the sun's image was allowed to trail over it. It was then left two hours in its sheath; on development nothing was found. These three experiments are all I have yet had the time to make. It may be well to observe in passing that if the sun's image, as formed by a pinhole, is received on a white piece of paper, it has what appears to be coronal structures, but which rotate as the pinhole is turned round. I have used amalgamated zinc, and a pure film of copper, because the X-ray work showed me that these affected a sensitised plate more decidedly than any other metals I have tried."

MADE BALD BY X RAYS.—Mr. William Levy, of Eau Clair, Wis., who recently had an X-ray examination of his skull made by Professor Fred S. Jones at the physical laboratory of the Minnesota State University, had an experience in consequence not generally supposed to accompany the process, says the St. Paul *Dispatch*. Levy was shot in the head about ten years ago. The bullet has been somewhere in his head ever since, and in July he made up his mind to have it located. Accordingly he came up, and sat from eight o'clock in the morning till ten at night for a Röntgen-ray picture of his head. The bullet had passed into his skull just above the left ear, going towards the back of the head. The doctors wrapped his head in wires, which were definitely located. A picture was taken through the skull from the front towards the back of the head, the tube from which the rays radiated being for this purpose placed inside his mouth. The picture thus secured showed the bullet very distinctly to be lying at the junction of two of the wires which crossed right under the occipital bone. A very strong current, about 100,000 volts, had been passed through the tube in making the exposure. The next day Mr. Levy began to notice a peculiar effect on his skin wherever it had been most exposed to the rays, and the hair on the right side of his head, which had been near the wire, began to fall out. In a few days the right side of his head was perfectly bald, his right ear had swollen to twice its natural size, and presented the same appearance as if very badly frozen. Sores were visible on his head, his mouth and throat were blistered so that he could not eat solid food for three weeks, and his lips were swollen, cracked, and bleeding. Mr. Levy has recovered from the effects of the rays, but still has half a bald head. He intends to have the investigations carried further, and the bullet removed, but nothing is stated on the subject of hair restoration.

LECTURE ON THE RÖNTGEN RAYS.—At the weekly meeting of the Manchester Arts Club on Tuesday, November 3, Mr. W. I. Chadwick delivered an address on the Röntgen Rays, with an abundance of illustrations, experiments, and lantern views. He pointed out that many of the scientific discoveries of the present century now in general use had ceased to be regarded by the public with any particular interest. Towards the end of last year, not only the public, but the scientific minds all over the world, were aroused to the highest pitch of enthusiasm ever known in the history of science by the discovery of Professor Röntgen of the presence of an agent which would pass through opaque bodies and affect a photographic plate behind them. As everybody knows, a photograph is produced by the agency of light, and opaque bodies are those which suppress the passage of light. To say, then, that photographs can be made through opaque bodies is as paradoxical as to say that opaque is transparent, and this appeals to our natural curiosity. Although this new agent has been examined in nearly every scientific laboratory in the world, its real nature has not yet been defined. Its action on a photographic plate and its power to excite vision under certain circumstances points to a form or condition of light, but its refusal to conform to other well-known laws of light, and its passage through opaque bodies, is against the present accepted theory of light. It is, or it was, admitted to be a radiation of some kind and, until we can discover something more definite about it, Professor Röntgen has called it X rays, X being the unknown quantity in mathematics. The practical application of the discovery as an aid to surgery was demonstrated at its birth, and too much must not be expected from an infant so young. Franklin, rejoicing at his success in bringing lightning from the clouds to the earth by means of his kite string, was asked by somebody, "Well, what good is it?" To that he replied, "What good is a baby? It will grow, and you must make it of use." Since then Franklin's baby has grown, as we know, and so Röntgen's baby will grow. Even now it gives promise of most important communications before long. That the X rays is a movement establishes either a movement of particles or a mode of motion. If the movement be in the ether as a transverse vibration of the nature of light, then light is something different or additional to that which we at present understand it to be. That is just what modern physicists suspect, and Röntgen's discovery is another link in the chain which is fast drawing together light and electricity as one. To the question as to what electricity is, the safest reply would be, that we do not exactly know. It is quite true that we make some use of it, but in most cases a very extravagant one, when we consider the purpose for which we intend it. For example, for every 100 pounds worth of energy inside a lamp, disregarding the energy expended to get it there, we have only four per cent. useful for lighting purposes—the other ninety-six is wasted in the form of heat, a thing we do not want for illuminating purposes. Mr. Chadwick made a few references to the production of light without heat—something not yet achieved by man, although a certain beetle does it. The nature of light Mr. Chadwick illustrated by a number of mechanical appliances and various experiments. Showing some views upon the screen, he remarked that the spectrum is the result of certain vibrations to which our visual organs respond. There are, however, other vibrations to which our eyes are not sensitive, and

amongst these (and beyond those producing the sensation of violet) may possibly be found the X rays. By a series of brilliant and intensely interesting experiments the lecturer illustrated phosphorescence and fluorescence. In describing the electrical appliances used to evoke the presence of the X rays, he said the battery was an arrangement for propagating electrical energy. The coil used in connexion with it increased the electro-motive force. The nature of electrical discharges in different media and in vacua was illustrated by a large number of Crookes' and other radiant-matter tubes—radiant matter being an ultra-gaseous state in which molecules were free to move, like grains of sand in a bottle. When these molecules were driven against the sides of an exhausted tube, they produced a vibration causing what is known as fluorescence. The nature of this bombardment of particles or cathode rays inside the tube was shown to be quite different to the rays outside the tube, and these outside rays are the mysterious Rontgen or X rays. After showing various objects visible to the entire audience, though placed behind thick wooden boards, a radiograph was taken and exhibited by the projection lantern. Then followed a number of radiographs taken by Mr. Chadwick for surgical purposes. His explanations were wonderfully interesting. He told of one case where a man shot himself in the hand. The surgeon who was to operate, the man himself, and Mr. Chadwick knew there were pellets imbedded in the hand, but they did not know that there were no fewer than twenty-four shots. Under ordinary circumstances, the surgeon might have removed twenty-two, and the two remaining might have caused serious trouble afterwards. On the other hand, he might have removed twenty-four, and still have been "fishing" for more. Owing to the radiograph taken of the hand, he knew the exact number of pieces of lead he had to extract. In another case, a man stepped on to a needle, but it was only by means of the radiograph that it was found that the needle had broken into three pieces on entering the foot. Early this year it would have been considered an achievement to have shown such things as the humerus or the ulnar in the arm, but, at the present time, the collar-bone and the spine were quite ordinary things to show. The X rays had recently been used for detecting stone in the kidney, and this was only another proof of the rapid advance of the discovery.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK

November.	Name of Society.	Subject.
16	Bradford	*A Tour in Italy and the Riviera.* Rev. J. Beanland.
16	Camera Club	*The Eye Considered as an Electrical Organ.* Dr. Lindsay Johnson.
16	Ealing	*Lantern Slides and their Production.* E. Dockree.
16	North Middlesex	*Chemical Symbols.* R. Child Bayley.
16	Richmond	*Making a Negative.* G. Ardaseer.
17	Birmingham Photo. Society	*The Treatment of Figures.* Rev. F. C. Lambert.
17	Gospel Oak	Improving Negatives, and Printing Dodges.
17	Hackney	Annual Exhibition.
17	Isle of Thanet	*Pictorial Photography.* A. Horsley Hinton.
17	Leeds Photo. Society	*Air Brush Demonstration.* R. Bownas.
17	Lewisham	*Practical Pictorial Photography.* A. Horsley Hinton.
17	Royal Photographic Society	*Successful Half-tone Illustration.* Mr. Eddington.
18	Borough Polytechnic	*Remarks on the Improvement of Landscapes by Retouching.* Roland C. Whiting.
18	Croydon Camera Club	*Picture Making with the Camera.* A. Horsley Hinton.
18	Leede Camera Club	*A Holiday Tour through Germany.* A. Homburg.—Demonstration with Stockwell's Patent Uno Dissolving Lantern.
18	Leytonstone	*Reminiscences of Travel.* G. E. Cox.
18	Photographic Club	*Birds and Animal Life.* Thomas Fall.
18	Southport	Annual General Meeting.
19	Ashton-under-Lyne	*Lantern-slide Making.* Walter Leigh.
19	Camera Club	*In Eastern Lands.* E. R. Ashton.
19	Leigh	Competition: Outdoor Photography.
19	London and Provincial	Lantern Night. L. Medland.
19	Putney	*Architectural Photography.* H. W. Bennett, F.R.P.S.
19	West Surrey	Demonstration: Toning. Mr. Bulbeck.
19	Woodford	*Intensification and Reduction.* J. McIntosh.
20	Aintree and District	Exhibition Matters.
20	Croydon Microscopical	Reception of Photographs, &c., for *Soirée.*
20	North Middlesex	Date for Sending in Pictures for Exhibition.
20	Wolverhampton	Demonstration of Messrs. Wellington & Ward's Specialities. J. Gale.

ROYAL PHOTOGRAPHIC SOCIETY.

NOVEMBER 10,—Ordinary Meeting,—The Right Hon. the Earl of Crawford, K.T., in the chair.

THE ALPINE CLUB'S EXHIBITION.

A letter was read from the Secretary of the Alpine Club, inviting members of the Society to contribute to an exhibition of Alpine photographs to take place in December next. Members proposing to exhibit were requested to communicate with the Club as early as possible.

THREE-COLOUR PRINTING: DR. JOLY'S PROCESS.

Mr. E. J. Wall showed and presented to the Society the first specimens which had been shown in England of the application of Dr. Joly's method of colour photography to photo-mechanical work.

Mr. T. BOLAS thought it only fair to mention that the credit for the fundamental principle of this process was due to M. Louis Ducros du Hauron, who had described and discussed the essential points in his book published in 1869.

EFFECTS OF THE X RAYS.

The Assistant Secretary (Mr. R. Child Bayley), in response to a request for "objects of interest," showed his right hand, which he had used in demonstrating the X rays to the visitors to the Exhibition, and which had thus been exposed to a fairly strong radiation for about an hour each day, and had acquired a distinctly darker colour than the other hand.

Mr. J. SPILLER had used one of his hands in a similar manner for half an hour at the opening *soirée*, and, later in the evening, experienced a burning sensation, as if the hand had been scalded.

Mr. WILSON NOBLE mentioned a case, reported in the *British Medical Journal*, in which dermatitis had been induced by an exposure of an hour and a half at a distance of one inch from the tube.

Mr. J. CADETT suggested that these and other instances referred to might have arisen from poisoning with platinum salts in handling fluorescent screens, and mentioned a case of a young lady engaged in photographic printing whose skin had been very seriously affected by the use of platinotype paper.

Mr. C. E. HEARSON thought the effects in question might be due to decomposition of the water in the tissues of the body, owing to an induced state brought about by the high tension of the currents in the coils, oxygen or hydrogen being set free according to the direction of the current.

Mr. WILSON NORLE had noticed that an enlarged heart had greatly diminished in size during the period of exposure to the rays.

MEASUREMENT OF LIGHT REFLECTED FROM PRINTS.

Mr. H. CHAPMAN JONES (Hon. Secretary) read a paper describing *A New Form of Apparatus for Measuring the Light reflected from Prints.* As in his apparatus for measuring the densities of plates (brought before the Society in December last), his aim had been to make an instrument as simple as possible and complete in itself, comparable in its completeness and unity with a microscope or a spectroscope. The measuring of the light transmitted by plates and reflected by prints was to the scientific photographer what weighing was to the chemist, and he expressed the hope that the introduction of simpler means for making such measurements would cause quantitative photography to become more general. The apparatus was described as follows: The source of light is a Welsbach burner, and two mirrors—one on each side of it—give two beams of light, which pass through two openings into a velvet-lined box and illuminate the patch of paper to be tested and a comparison patch. A shadow rod is used, as in Rumford's method of photometry, so that each beam illuminates only one of the patches. The illumination of the lighter patch is reduced by drawing the mirror back until the two are of equal brightness. Thus the apparatus did not measure the absolute proportion of light reflected, but the proportion as compared with that reflected from the white paper or whatever might be taken as the standard. Mr. Chapman Jones exhibited the instrument and very fully described it and also some experimental measurements made by its aid, and stated that, as he had many inquiries concerning his density measurer, he had made arrangements with Messrs. Baird & Tatlock, who would be prepared to supply that apparatus and also the one now described, in both of which there would be certain mirror improvements that experience had shown to be desirable.

Mr. W. E. DEBENHAM suggested that the movable mirror should be fitted with a rack and pinion, so as to make it self-centering as it travelled along, instead of readjusting it by hand for each observation.

Mr. MOTE did not think the two sides of an incandescent mantle could be depended upon to give exactly the same light, and he suggested that acetylene gas would probably be a more trustworthy illuminant.

Mr. CHAPMAN JONES said he had unsuccessfully tried two or three ways of making the mirror self-adjusting, and would be very glad if some one would tell him exactly how it could be done; he found, however, that there was really no difficulty in using the instrument as it stood. There was the possibility of variation in the incandescent light, but one would always test the zero point before starting, and it would thus be ascertained whether the burner was giving a symmetrical light. He had not tried acetylene, but would do so.

A vote of thanks was passed to the Hon. Secretary for his paper, and he then read a communication by Mr. CHARLES E. BENHAM on

A THEORY OF THE RONTGEN PHENOMENA.

In the early days of the science of magnetism, Mr. Benham wrote, it was imagined that some sort of rays of force proceeded from the magnet to the attracted iron. The conception of magnetic influence as a radiation was exploded by Coulomb's experiments, and the writer suggested that the Röntgen "field" would probably soon be spoken of rather than the Röntgen rays, and that it would be found that the influence was akin to induction and not to the emanation of waves like those from a luminous object or a reflector. There was some *à priori* evidence of, at any rate, a partial correspondence between the transparency and opacity of various substances in the Röntgen field on the one hand, and in the magnetic field on the other, for the position of a needle in the hand might be indicated not only by "the new photography," but by simply placing a card over the hand, with a powerful magnet underneath, and then strewing iron filings on the card. The filings were too unwieldy, as compared with molecules, to have their movements modified by the varied paramagnetic or diamagnetic qualities of the tissues of the body, so as to show bones or internal structure, but they, nevertheless, so to speak, "photographed" the needle. He did not suggest that the Röntgen field and

the magnetic field were the same, but that the phenomena had features in common, and that the one might serve to illustrate the other seemed to him more than probable, and, at the same time, the analogy appeared to offer some foundation for a plausible hypothesis regarding the so-called new light.

Mr. CADETT had experimented in the direction of trying the effect of magnetism on a photographic plate, but could not find the slightest trace of action. He thought the suggestion that the X rays should be called a "field," similar to the magnetic field, was not a very happy one.

Mr. TOWNSEND had made a large number of experiments with a powerful electro-magnet, and could not find any action on the photographic plate.

The CHAIRMAN mentioned an experiment performed at a recent *conversazione* of the Royal Society. An ordinary bulb was shown in which two needles had been inserted in front of the cathode, and no particular effect resulted from the turning on of the current; when a magnet was brought near the tube, however, both the needles threw shadows on the glass, and the shadows moved as the magnet was turned in either direction. A very slight change in the pressure within the tube caused the phenomenon to cease altogether.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

NOVEMBER 5,—Mr. A. Mackie in the chair.

Mr. Walter E. Woodbury, the Editor of the *Photographic Times*, of New York, who was present, was welcomed.

A considerable portion of the evening, which had been set aside for a print competition, was taken up in discussing the regulations concerning the competition for papers, prints, and slides, instituted by Mr. Henderson, who had provided a sum of five guineas for the purpose. The competition was originally intended for the 1895-96 session, but, not meeting with the support expected, the period was extended to another year, that is, the present year. The point under discussion was whether the same rules applied, or whether they dropped with the expiration of the first year, and as to the legality of the resolution passed on October 22 with reference to the grant. Eventually this resolution was rescinded, leaving the matter in the hands of the Committee.

Mr. E. J. WALL then proposed that Judges, who should be members of the Association, be appointed for this competition, their number being limited to three.

A ballot was taken, which resulted in the election of Messrs. Robert Beckett, A. Mackie, and E. J. Wall.

A fair number of prints were entered for the competition arranged for the evening, and Messrs. Beckett, Wall, and W. E. Woodbury were requested to act as Judges; but, after an examination of the pictures, they reported their inability to make any award.

PHOTOGRAPHIC CLUB.

NOVEMBER 4,—Mr. Frank Haes, one of the Trustees, was in the chair.

The balance-sheet showed a credit balance of 47*l.* odd to current account, and a sum of 160*l.* invested in India stock as a reserve fund. The Committee's report referred to a successful year's work, and was adopted—as was the balance-sheet—*nem. con.*

Mr. Horace Wilmer retired from the Committee in accordance with the rules, which only permits three consecutive years' service as a Committeeman. The new members of the Committee were Messrs. R. P. Drage, Alex. Mackie, and W. D. Welford. Mr. F. A. Bridge resumed his former post of Hon. Secretary and Treasurer, and Mr. Herbert Fry was elected Recorder. All other officers as before.

The SECRETARY announced that the Committee had decided to institute a Trade Night, in order to provide an opportunity for the display and demonstration of new and interesting manufactures to the members. The first three trade nights will take place upon the first Wednesdays in January, March, and May respectively.

Brixton and Clapham Camera Club.—November 3, Mr. J. W. Coade (President) in the chair.—Subject,

AN HOUR WITH THE LANTERN MICROSCOPE,

by Mr. R. G. MASON (Club Lanternist). There was a large attendance, ten new members being elected, and three more nominated. The Club does not always devote its meetings to strictly photographic matters, such as the action of developers and toning baths, or even to "Art with a big A," but occasionally gets out of the usual routine with a fixture like the present. Mr. Mason's demonstration was really a natural history lecture, numerous mounted microscopical specimens of the insect and vegetable world being projected on the screen, and their peculiarities described. This was followed by the projection of living specimens taken from ponds in the locality, Mr. Mason remarking that the improvements of the County Council made his subjects increasingly difficult to find. However, he had got together a good selection of water mites, water fleas, and other aquatic insects, perhaps the most interesting exhibits being the circulation of blood as shown in the leg of a frog, and the water hydra stretching out its tentacles to capture its prey, and afterwards devouring the same, an exhibit so realistic as to produce cries of "shame" from a somewhat susceptible member of the audience. In conclusion, Mr. Mason received cordial thanks for demonstrating a branch of science so inviting in its photographic possibilities. On the table were specimens of collotype encaustic tiles; also a liberal supply of a useful booklet by Jules Fuerst, F.R.P.S., on *Modern Developers*.

North Middlesex Photographic Society.—November 9, Mr. J. McIntosh in the chair.—Mr. Samuel R. Schofield, 1, Highcroft-road, Hornsey Rise, N., was nominated for membership. Mr. E. J. WALL then proceeded to give a lecture on

THE SPECTROSCOPE.

He projected a spectrum on the lantern screen, and showed the effect of placing in the path of the rays different coloured glasses, which cut off different parts of the spectrum according to their colour and purity. A chart of the spectrum of the sun and various metals was shown, and their lines pointed out. A spectroscope was set upon the table, and the sodium line was seen in an ordinary spirit lamp by the members. He also showed a direct vision spectroscope. Some negatives, showing the effect of different screens on the spectrum, were put through the lantern, taken on ordinary and different makes of orthochromatic plates. The Burchett screen was shown to be wrong in theory, as it did not give the value of the green which was wanted in landscape work. In reply to a question by Mr. Cox, he recommended a screen of collodion dyed with uranine or naphthol yellow in preference to the commercial screens, about 1 part dye to 5000 of collodion. At the close of the lecture, a hearty vote of thanks was accorded to Mr. Wall. Mr. H. Stuart was elected chairman for the next meeting, when Mr. S. H. Fry will demonstrate *Home Preparation of Rough Bromide Paper*.

Richmond Camera Club.—On the 26th ult., Mr. Cembrano presided at a meeting which was but thinly attended—an unfortunate circumstance for the members who stayed away, as the evening was of exceptional interest. Mr. ALFRED WATKINS, inventor of the exposure meter which bears his name and of the eikronometer, lectured on

SYSTEMATIC DEVELOPMENT.

Mr. Watkins holds that the development of a negative proceeds by fixed rules, and that density is built up in a definite ratio from the first application of the developing agent to the moment when development is completed, and that, by noting the time which elapses between the application of the developer and the first appearance of the image, the proper time for stopping a development can be calculated to a nicety, regard being had, of course, to the nature of the developer. Mr. Watkins is master of his subject, and demonstrated his theory by a series of highly interesting experiments and lantern illustrations.

ON the 2nd inst. (Mr. Purcell in the chair) there was a good attendance. Members' slides were shown, some excellent specimens amongst them. Mr. Gibson showed a series of views in the Trossachs; Mr. Skone James, some from Brecon; Mr. Purcell, some French and Italian snap-shots; Mr. Davis, Alpine scenes; Mr. Bickerton, some good architectural slides; and Mr. Dimsdale some pretty bits of Devonshire scenery.

South London Photographic Society.—At the last ordinary meeting, held at Hanover Hall, Hanover park, Peckham, the President (Mr. F. W. Edwards) in the chair, Mr. A. P. Wire, of the Leytonstone Camera Club, attended and described a series of slides illustrative of *A Holiday in Hereford*. He dealt with all the points of interest in the city, and afterwards with the surrounding villages, Whitecross, Weobley, Kilpeck, &c. Reference was also made to the dovecotes for which the county is famous.

Aintree Photographic Society.—November 6.—There was a good attendance of members and friends, who were entertained with an illustrated lecture on the

HIGHLANDS OF SCOTLAND,

by Mr. D. J. Neill, the Secretary. Nine new members were enrolled, bringing the total up to over seventy, and others are expected, especially now that suitable rooms have been provided in the new building. A well-equipped dark room for the exclusive use of members has been built to the plans of Mr. C. H. Adkins, the President.

Leeds Camera Club.—Mr. P. ELLIFF (a member of the Committee) gave a practical demonstration at the meeting on Wednesday week of his method of producing

PHOTO-CERAMICS,

one of the oldest and most charming, yet least-known branches of photography. An impression seems to prevail that the production of photo-ceramics is attended with considerable difficulties and expense; but Mr. Elliff clearly proved the fallacy of this, and showed that not only was the process extremely simple and inexpensive, but that it was one of the most beautiful developments of our already fascinating and multifarious art. Unlike all other printing processes, the results are absolutely permanent and indestructible, not only to the action of light, atmosphere, and acids, &c., but also to the gentle domestic's tender "dusting" and "scrubbing" attentions. Briefly, the process consists of making a print from a positive upon a glass plate coated with certain gummy substances in conjunction with a sensitive salt, developing the image by "dusting on" a finely powdered mineral pigment, transferring the same to the final support, and "firing" or burning-in in a muffle furnace. A good transparent positive of the subject to be reproduced is prepared. A glass plate is next coated with a mixture of equal parts of the following:—No. 1. *Organifier:* Le Page's fish glue, 1 ounce; glucose, 4 ounces; glycerine, 4 drops; water to 10 ounces. No. 2. *Sensitiser:* Ammonium bichromate, 1 ounce; water to 10 ounces. Allow to stand at least four days, and always filter before use. When coated, the plate can be dried over gas or spirit stove or fire. These operations must be conducted in the dark room, or in subdued light. When perfectly dry, the sensitised plate is placed in contact with the glass positive in a printing frame, and exposed to daylight for from one to thirty minutes, according to density of positive and actinicity of light. Only a very faint image is discernible when fully printed; but the same methods for calculating the necessary exposure can be adopted as are employed in carbon printing. As soon as possible after printing, the image is developed by dusting over the somewhat "tacky" surface, by means of a camel-hair mop, the ceramic colour—a finely powdered oxide of iron pigment, containing a little "flux" to give brilliance. When the image is fully developed (which may be assisted in dry weather by breathing upon the surface), coat with enamel collodion let down with equal bulk of

ether, scraps round the margins to make a free edge, and immerse in water. In two or three minutes the collodion film, to which the ceramic colour adheres, will float off the glass. The surface of the object to which the picture is to be transferred is next coated with a flux consisting of a saturated solution of fused borax, made by boiling for ten minutes; when cold, the clear liquid must be decanted from the borax thrown down. The film may now be transferred and dried, by the application of heat, if desired. It is then inserted in the muffle furnace (free from sulphur and dust) and "fired" until the colour is bright. The objects to which this beautiful process may be applied are very numerous, glass and pottery ware being principally employed at the present time; but there is a wide field for expansion, and ere long we may expect to have our homes made beautiful by photo-ceramics in every imaginable form.

Leigh Photographic Society.—November 5, Mr. T. Lee Syms presided.—The subject for the Society's competition, for which Mr. Syms kindly promised an enlargement to the winner, was the Landscape with Figures competition. This subject brought such good work, that the Judges had great difficulty in deciding the winner of the first and second prizes, and it had to be decided by the voting of all the members present, the result being Mr. William Hampson was awarded the first prize, and Mr. W. R. Moore the second prize for a view, *Near Alderley*. Messrs. H. Isherwood, T. Haddock, P. Seddon, and R. Welch showed work worthy of special mention. Mr. T. Lee Syms, by request, gave a criticism on the work, to assist members in improving their work in future competitions. The Secretary distributed samples of Cadett's lightning and lantern plates.

Sheffield Photographic Society.—The newly elected President (Mr. Tomlinson) occupied the chair. The prints sent in to the recent annual competition were on view, and the Judge's awards made known, the silver medal being secured by Mr. Joseph Smith for four well-executed whole-plate platino-bromide prints of the interior of Durham Cathedral, Bishop Ryder's statue (Lichfield Cathedral), Netley Abbey, and Haddon Hall, the print of Durham Cathedral being specially mentioned by the Judge. The bronze medal in the same class falls to Mr. J. H. Lygo for four capital half-plate matt-surface chloride prints of Haddon Hall, that of the ball-room being greatly praised by the Judge. A hearty vote of thanks was passed to the Judge, Mr. R. Keene (Derby), for making the awards, and passing criticisms on the work generally. The lantern was then brought into requisition, and the competition slides thrown on to the screen first. In this class Mr. J. H. Lyo again secured the bronze medal easily with four very fine slides, good alike both in quality and technique. A large number of members' slides were then put through the lantern for criticism, the lantern being ably manipulated and suggestions for improvements made by Mr. J. W. Charlesworth, who was accorded a hearty vote of thanks.

Edinburgh Photographic Society.—November 4, Mr. F. P. Moffat (President) in the chair.—Mr. R. H. Bow, C.E., read a paper on

THE FERROUS-OXALATE DEVELOPER,

in which he held that, as a good all-round developer for plates, this was as good as any. Mr. Bow explained that a fresh developer had a tendency to give flat results, an older one gave more contrast. A few drops of a weak solution of hypo was recommended as a powerful accelerator. After stating that plates developed with ferrous oxalate took a shorter time to fix than after treatment with most other developers, Mr. Bow called attention to a point which he considered new, viz., that any developer which contained much bromide caused plates treated with it to take a longer time to fix than those treated with a developer wanting in bromide. Mr. JAMES PATRICK then read a paper, entitled

STRAY THOUGHTS ON LANTERN-SLIDE MAKING.

Thin negatives, he said, such as were generally made for chloride of silver printing, were no good if the very best quality of slide was wanted. The negative must be vigorous and full of gradation. Good composition was an essential quality in a lantern slide, and in shaping the picture the mask should always be made to suit the subject, and not the subject to the mask. One brand of plates should be chosen and stuck to. Hydroquinone was a very good developer, and a great variety of tones could be produced by it. Mr. FRASER said that, in making slides by reduction (by artificial light), he secured equal illumination of his negative without the aid of a condenser in the following way: At each side of his negative he placed an incandescent gas light, while directly behind his negative he placed a sheet of white paper, the reflected light from which was all that could be desired. A generator for acetylene gas was shown by Messrs. Walla and Fraser, who showed, through the lantern, the light produced by this gas. Several members expressed the opinion that acetylene gas was too dangerous to be used at home.

FORTHCOMING EXHIBITIONS.

1896.	
Nov. 17-20	Hackney Photographic Society. W. F. Fenton-Jones, 12, King Edward Road, Hackney.
,, 26, 27	Romford and District Photographic Society. A. John Ormiston, 4, Laurie-square, Romford.
,, 30-Dec. 1, 2 ...	North Middlesex Photographic Society.
December 3, 4.....	Aintree Photographic Society. E. P. Heron, 2 Tilney-street, Orrell Park, Aintree, Liverpool.
,, 28-31.....	Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.
Dec. 1896-Jan. 1897	Bristol International. Hon. Secretary, 20, Berkeley-square Clifton, Bristol.
1897.	
January 14, 15	Weymouth and District Camera Club. E. C. Bennett 10, Newberry-terrace, Weymouth.

Patent News.

THE following applications for Patents were made between October 28 and Nov. 4 1896:—

PHOTOGRAPHIC APPARATUS.—No. 22,627A. "Improvements in or relating to Apparatus for use in Taking Photographic Pictures." H. J. HEINZE.

DEVELOPING.—No. 23,781. "Improvements in Photographic Developing Apparatus." J. MCINNES SKINNER.

COPYING PROCESS.—No. 23,831. "A Method of Reproducing an Autograph or Design upon Photographic Prints Direct from the Original Copy." W. TYLOR.

HAND CAMERA.—No. 23,840. "A Magazine Hand Camera." HENRY PRADEAU.

SINKS.—No. 23,842. "Improvement in Lavatories and Sinks for Hospital Surgical Photographic and Other Purposes." T. W. TWYFORD.

LANTERNS.—No. 24,112. "An Improvement in Magic Lanterns whereby Dissolving Views can be Shown with a Single Lantern and Instantly Focussed on a Perpendicular Screen." Complete specification. H. L. HASTINGS.

CAMERAS.—No. 24,269. "Improvements in Photographic Cameras." Communicated by F. A. Bownell. THE EASTMAN PHOTOGRAPHIC MATERIALS COMPANY, LIMITED.

PHOTO-MECHANICAL PROCESS.—No. 24,273. "Improved Means or Method of Producing Designs (Photographs or Drawings) by Combining Vitreous Enamel or Equivalent Substance into and with Photo-Mechanical Process Blocks and Electro-types." THOMAS SYMMONS.

CAMERAS.—No. 24,368. "Improvements in Photographic Cameras." W. H. TOMKINSON.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

COLOUR PHOTOGRAPHY.

To the EDITORS.

GENTLEMEN,—I am sorry to be compelled to make any comments on Mr. Bennetto's statements, *re* "Colour Photography." It is evidently impossible to discuss the relative merits of a secret process, and a fully published process, which produce substantially the same result; but I cannot allow a gross misstatement about my own method to go uncorrected.

There can be no good excuse for the statement that my method has inherent defects which "entirely destroy the truth of the original colours, a disagreeable monochrome running throughout the whole picture," &c., &c. My prints are as sharp as the best carbon prints. The gelatine of each print in its thickest part is considerably thinner than the film on an ordinary gelatino-bromide plate, and practically colourless after the treatment which it receives before immersing in the dye solution. The aniline dyes used for two of the prints are quite permanent in the sealed prints. The third print is coloured by prussian blue, which is usually classed as a permanent colour, and, although not really quite permanent, is probably more so than any other dye of the right colour. In short, I see no reason for thinking that Mr. Bennetto's prints can be better than my own.

All that I know about Mr. Bennetto's work is that he wrote to me some months ago, saying that he had worked out an improved method of making colour prints from three negatives, and that he wished, if possible, to obtain one of my photo-chromoscope cameras for making the three negatives on one plate.

If Mr. Bennetto's triple-colour print is in a single film, the idea is not new, but the working details may be. If the result is accurate in colour, and "as easy to produce as an ordinary silver print," the method will stand on its own merits, and he need not resort to questionable methods of crying his wares.—I am, yours, &c., F. E. IVES.

119, *Shaftesbury-avenue, London, W.C., November* 6, 1896.

[We can corroborate all that Mr. Ives says of the sharpness and the purity of colour of the results produced by his method.—EDS.]

ACETYLENE.

To the EDITORS.

GENTLEMEN,—The experience that Mr. Knowles relates is interesting, and I hope that he will let us have further details of the incident. I

have written to him, offering to arrange for the communication of a more complete account of the matter to the Royal Photographic Society, if he is willing so to favour the Society.

My remarks at the meeting he refers to were made for the purpose of taking exception to the comparison of acetylene to dynamite, as being likely to exaggerate in the minds of those present the actual danger in the use of acetylene. I referred only to the apparatus then before the meeting, and said that the danger of the copper compound of acetylene when produced in small quantities, as, for example, in the brass cocks and burners of such fittings as were shown, was not, so far as experience appears to indicate, in the explosion of the copper compound itself, but rather in the possibility (when that exists) of its firing an explosive mixture of gas and air.—I am, yours, &c., CHAPMAN JONES.

November 6, 1896.

THE CARRIAGE OF CALCIUM CARBIDE.

To the EDITORS.

GENTLEMEN,—Perhaps you will give me some information regarding the carriage of calcium carbide by the railway companies.

I had a parcel of 7 lbs. sent me the other day, the charge for which was so excessive that I had to refuse delivery of it. On calling at the railway agent's office, he informed me that the railway companies only carried calcium carbide under the following conditions:—To be packed in an air-tight tin, placed in a strong wooden box or iron drum, and not to be placed in closed van or in the companies' closed sheds, at the owner's risk, charged the highest rates, and the contents declared in a form supplied for the purpose, under a penalty of 20*l.*

The railway company to which I refer, the Great North of Scotland Railway Company, are so excessive in their charges that the traders of this town own two steamers for the purpose of carrying their goods between Leith and Aberdeen, so as to escape the railway charges.

If these restrictions are not enforced on every line, I should still be able to get calcium carbide; but, as it is, I am practically debarred from using it.

I should be obliged if you would let me know how to proceed in the circumstances.—I am, yours, &c., JAS. L. BROWN.

32, *St. Andrew-street, Peterhead, November* 6.

[This is a matter upon which we invite the remarks and experience of our readers.—ED.]

UNFAIR COMPETITION.

To the EDITORS.

GENTLEMEN,—I was very pleased to see and fully endorse the sentiments of Mr. Victor Thomas in a recent issue *re* a beautiful life-size three-quarter length portrait for 6*s.* 6*d.* as advertised by the proprietors of two halfpenny papers.

I think photographers, after this, should boycott these papers by not purchasing them in the future. I, for one, have fully made up my mind not to do so, and I think all other brother photographers should act likewise. W. G. S.

To the EDITORS.

GENTLEMEN,—The letter published on page 719, "*Re* Unfair Competition," may, I think, just as well be headed "*Parler pour ne rien dire.*" Readers of your BRITISH JOURNAL OF PHOTOGRAPHY do not read probably much of these halfpenny papers, and certainly the contrary happens with the very great majority, that is, readers of the newspapers do not read THE BRITISH JOURNAL OF PHOTOGRAPHY, and then what is the use of your fair complainant's letter? We all know that she is perfectly right, but are the *artists*, who are finishing these pictures, not as much to blame, if not more even than the editors of the newspapers? I would even bet that the idea has not originated with the editor, but with the photographer supplying the enlargements. I can very well see the editor in his office, receiving the visit of the photographer, who proposes the scheme, and offers in exchange of advertisements and goodwill, so much royalty on every order (which, by the way, reduces the result to much less than 6*s.* 6*d.*), but I cannot as well imagine the editor running about to find the photographer, or several of them, and the numerous crayon artists necessary for the work, besides the rooms necessary, &c., and the outlay of money. Mind you, I do not defend or praise the editor, but I do not think he is to blame so much, and probably less, than the brother photographer. Let every one have his due. Newspapers carry on to-day a business just as well as any other business, and what else is it than a regular business, this vast amount of advertising, taken at different rates, according to quality (read amount of subscribers) and quantity?

Are you perfectly sure that the diary scheme and photographs for nothing, of which so much was spoken about lately, was not originated somewhat similarly by a brother photographer, friendly to Mr. Editor. Of course, this does much harm to photographers, but I am afraid this controversy, and writing about it, does in the end more harm than good, calling attention to facts which may remain unknown with a great many otherwise. It advertises the scheme more extensively, and stops none of it.

Supposing your fair complainant's father had a splendid run of business, and an advertiser of some goods would ask for permission to hang a frame in his parlour, under the understanding that, on every invoice sold, he would pay him a fair allowance for his permission, I hardly think he would refuse, however it would not be at all in his line of business, yet a frame in his parlour amounts to the same as an advertisement in the newspaper, and he would not think doing any harm to other manufacturers of the same line of goods.

Is it not an English saying, "Business is business?" This has been stretched, some may think, to "Unfair business is business, anyhow," but some others don't. I am, yours, &c., A. LEVY.

4, *Avenue Pinel, Asnières, (Seine), November* 6, 1896.

A TIT-BIT.

To the EDITORS.

GENTLEMEN,—'Tis from the serious *Athenæum*, and the more enjoyable because of its origin. Their critic found out—or he thought he knew!

On page 608, col. 2, of the issue of the 31st ult. of the above-mentioned literary periodical appears a review of the *Cathedrals of England and Wales through a Camera* (Birmingham: J. L. Allday), which, of course, caught a roving photographic eye—focus unknown. In this paragraph occurs the following deliciously unique tit-bit: "Being, generally speaking, on an almost uniform scale, the prints afford something like a notion of the comparative size of each of the churches. The smallness of St. Asaph, for instance, enables the student to form an idea of the vastness of St. Paul's. The simple dignity of Carlisle offers a contrast to the leanness of Truro!"

Criticism here would be more than superfluous; but the joke is too good to enjoy alone, so through your columns I pass it on, and perhaps thus back again to the *Athenæum*. K. B. M.

THE PHOTOGRAPHIC SALON.

To the EDITORS.

GENTLEMEN,—I went to see the Salon on the second day that it was opened, and the impression that was left on my mind was that the charwoman, who had been deputed to stick on the label numbers, after having affixed most of them on the right-hand side, had changed her mind and reaffixed them on the left, but, unfortunately, had forgotten to wash off the paste or gum, and, in one case, had left the remains of a portion of the ticket on the mount.

I did not think the Exhibition worth visiting again, but this morning, as I was passing, I thought I would look in to see if my former impression was confirmed. I found the same gummy marks on the glasses of the frames, the same remains of a ticket. Surely, if it is worth while having the Exhibition, it is worth the while of taking a little trouble to see that the pictures are properly exhibited. Fortunately, it closed on Saturday; but the Exhibition in Pall Mall, which is still open, is much more worth a visit, in my humble opinion, than the Salon.

I enclose my card.—I am, yours, &c., M.

November 5, 1896.

To the EDITORS.

GENTLEMEN,—Mr. Henry W. Bennett goes to a great deal of trouble in his letter to you last week to prove what is at the outset very evident. The Committee of the Photographic Salon being composed of men who are admittedly the leading pictorial photographers of the day, work from their hands must necessarily be the principal feature of an Exhibition of the best examples of the year.

Mr. Bennett says that, out of 339 frames, 189 are contributed by members of the "Ring," and then asks if it is reasonable or fair to invite photographers to send in their best work when it has so little chance of being accepted? Is not the very difficulty of getting work accepted an inducement to outsiders to try? or does Mr. Bennett think it is more satisfactory or more satisfying to send in one's work to an Exhibition where the competition is not so keen, and consequently the chances of being hung are greater? It is, I think, generally held that that is most worth winning which is most difficult to win. Mr. Bennett would have us believe that the reverse is the case, and refers to the Exhibition of the Royal Photographic Society as being more representative than that at the Dudley Gallery. There is certainly more variety, and the Exhibition is distinctly a better one than any the Society has held for some time past; but, as many of the leading pictorial workers are absent, I fail to see how the Exhibition can represent the best work of the year. There is more opportunity at the Royal for the lesser lights in the photographic world to get their works hung, but whether it is better to be

amongst the brightest of the lesser, or the least of the brighter lights, is a question which every photographer must answer for himself.—I am, yours, &c., CHARLES MOSS.

Coombe-road, Croydon, November 7, 1896.

To the EDITORS.

GENTLEMEN,—In your columns of last week I notice another complainant, one signing himself Henry W. Bennett, who protests against the alleged unfairness of the Salon Committee in sending invitations to contribute and then not accepting what is sent in. Now, if these indignant persons would point to any single word or sentence in the Salon prospectus which even implies an "invitation to contribute," it might make things clearer. Beyond the "Conditions of Entry," the list of the Committee, and the Entry Form itself, the only other printed matter on the prospectus is as follows:—

"The Photographic Salon, 1896 (fourth year), will be held at the Dudley Gallery, Egyptian Hall, Piccadilly, London, W., from September 24 to November 7, 1896.

"The aim of the Committee, whose names are given above, is to exhibit only that class of work in pictorial photography in which there is distinct evidence of personal artistic feeling and execution.

"Careful consideration will be given to all pictures entered for exhibition, and a selection of works of pictorial merit made by the Committee. Pictures which have already been publicly exhibited in London will not be accepted. Pictures sent for exhibition to any other Exhibition open in London at the same period are liable also to be disqualified.

"No awards are offered, and no charge made to exhibitors.

"Exhibitors will be entitled to a season ticket.

"Arrangements will be made for the sale of pictures, if desired, and a commission of fifteen per cent. will be charged on sales effected."

If, therefore, Mr. Bennett, or any one else, says an "invitation to contribute" was sent, that statement is untrue.

Mr. Bennett also states: "Merit alone does not secure admission to this Exhibition, and that the absence of merit does not of necessity involve rejection, as a glance at the walls each year will show."

This, as an expression of personal opinion, no one need begrudge the writer, but, expressed thus publicly, it should be remembered that it charges the Committee with one of two things—either they are guilty of scandalous breach of faith amounting to rascality, or else they are incompetent to judge or select.

In the first case, Mr. Bennett should remember that a great proportion of those forming the Salon Committee are also respected members of that Society which, by calling himself "ardent Royalist," I presume he wishes to support; they are also men of position and good repute. Does Mr. Bennett understand what this means?

Secondly, the Committee is composed largely of those photographers whom the public, the general Press, the photographic Press, and photographers generally have awarded positions in the very first rank—men who are asked to judge, to lecture, to write, to exhibit, all over the world—thus showing the confidence usually reposed in them. They select the best from the whole of the works sent in, and these are hung according as space permits. Mr. Bennett does not agree with the judgment of these gentlemen, which, after all, is not in the least surprising, nor of much importance.

Like many others, Mr. Bennett appears to regard the Salon Committee and The Linked Ring as synonymous, for which he has no authority whatever, and further he would seem to affect some knowledge as to "articles of faith" among the "Links," all of which is pure fabrication and a not very reputable performance either.

Your discontented correspondent complains that forty-three "members" have contributed 189 works, which I should have thought was not a very large average for well-known workers, and one might fairly well assume that in whatsoever "selected" Exhibition those forty-three "members" showed they would hardly have had less accepted; as one who had five frames rejected, I have the impertinence to think they might have accepted more!

The Pall Mall and the Salon are both equally "open" Exhibitions, but perhaps, as things are at present, the chance of being accepted and hung at the former is greater, because of the fact that quite a number of exhibitors do not send at all, while at the Salon there is nothing like the same abstention.

Suppose, for instance, there had been no Salon this year, and those same forty-three exhibitors had sent twelve pictures each to Pall Mall, my own impression is that more than 189 works from them would have been accepted—not perhaps the identical works which the Salon would have taken, because probably the respective Committees judge from a different standpoint.

It would be a happy thing, Sir, if you and those of us who have the control of contemporary columns could agree together to suppress all letters from private persons attacking either the Pall Mall Exhibition or the Salon; they seem to invariably emanate from persons whom some imaginary grievance has rendered spiteful, and their sentiments are not, I believe, re-echoed by responsible persons of either Exhibition; and in conclusion I would like to say that, whilst Mr. Bennett has done me the honour to refer to me as a member of the Salon Committee and as Editor of the *Amateur Photographer*, I write this only as a private individual, and without any wish to involve others who may or may not agree with me.—I am, yours, &c., A. HORSLEY HINTON.

November 9, 1896.

To the EDITORS.

GENTLEMEN,—I do not think the subject of Mr. Evans's letter in your issue of the 6th inst. is of sufficient public interest to warrant a detailed explanation of the circumstances of the case.

I must, however, correct two statements of fact.

It is not the fact that the pictures referred to were sent to Mr. Evans's address by me or by my instructions, and I am sure he holds no receipt from us of the sum of 2*s.* paid by his housekeeper.

It is not the fact that Mr. Evans has been invited to show at the Salon from the very first, as he says he has, or that he has ever been invited to exhibit at all.

My connexion with the Salon brings me a large correspondence, and into relation with a considerable number of persons. Doubtless, Mr. Evans's correspondence is also very large. I hope I may be permitted to flatter myself that those who best know us both will be easily able to form a correct judgment upon the probable merits of the case.

That Mr. Evans has transferred the favour of his correspondence from myself to you, Sir, is a matter of which I should be the last to complain; but I must beg to be excused from any further replies.—I am, yours, &c.,

ALFRED MASKELL.

63, *St. James's-street, Pall Mall, S.W., November* 10, 1896.

THE AINTREE EXHIBITION.

To the EDITORS.

GENTLEMEN,—Will you kindly remind readers in the next issue of the *Journal* that all entry forms from intending competitors in the five open classes should be received by me not later than November 21, and oblige, yours faithfully, E. P. HERON.

2, *Tilney-street, Aintree, near Liverpool, November* 7, 1896.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post. Questions are not answered unless the names and addresses of the writers are given.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2, *York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

Robert William Howes, East Dereham.—*Two photographs of Clare Sewell Read, Esq.*

Weber & Coggins, Cleveland Studio, London-road, Bracknell, Berkshire.—*Photograph of their Royal Highnesses the Duke and Duchess of Teck.*

PRINCESS PEACE.—See under Ex Cathedrâ.

TONES.—TONING. Please say definitely the paper you mean, and not by letters, as more than one paper is known under those initials. We shall then be able to help you.

GELATINE PAPERS.—A. C. ROSEN. Gelatino-chloride papers will not stand the same treatment as regards washing in hot water as albumen. Hot water must not be used with these papers. The "hypo salts" can be washed out with cold water, without the use of hot.

HAND-CAMERA LENS.—C. COX. What is generally known as a "wide-angle lens" is not suitable for a hand camera at this time of year. Lenses of that class have a small angular aperture, and are therefore slow in action. The largest aperture of this type of lens is usually about *f*·16.

W. J. BARKER.—Sorry we can give you no further information than that contained in the paragraph you quote. Were we ourselves trying the method, we should apply the ammonium tartrate after the acid bath. We do not think any chemical danger would arise; but as to whether all traces of the iron salt would be removed we can hazard no opinion.

LANTERN SLIDES.—CHARING CROSS. The slide sent in is far too dense even for the Camera Club lantern. Why not make two or three slides from the same negative, of varying density, and try them at the Club one evening before printing the lot? If the slides are too dense for the electric light, they will be much too dense for any other light.

CRACKED ALBUMEN PRINTS.—W. ASTON. Much of the very highly glazed albumen paper is prone to crack if allowed to curl up as it dries, when it is unrolled. This may be prevented in two ways. First by mounting the prints while they are wet; second, by drying them between blotting-paper, so that they are kept flat the while.

LENS FOR GROUPS.—T. BURROWS. The orthographic lens is an excellent lens for some purposes. You will find it admirably suited for groups out of doors or in the studio. For such purposes, for large sizes, it is preferable to the portrait combination, and, being longer in focus, will answer your purpose best of the two.

CHARGES FOR PHOTO-MICROGRAPHIC WORK.—There are no fixed charges for this class of work any more than for any other; but, being of a highly technical nature, it is always charged pretty high. For the work specified, if it be skilfully done, we should suggest from five to ten guineas; mediocre work proportionately less.

SOUTH AMERICA.—PRINTER. We are not aware what are the salaries paid to assistants in the Argentine; but, judging from the work we have seen from there, we should not advise any one to go out with the idea of obtaining an engagement unless he is up to the highest possible work.

LIGHTING.—BEGINNER. The portraits Nos. 1 and 2 are better than the others, but they want more shadows. There is too much top and front light. In lighting the subjects there are no definite rules for arranging the blinds. That must depend upon the type of subject to be illuminated and the light at the time. A bright cloud here or there will often necessitate a rearrangement of the blinds.

DISCOUNTS.—H. B. If one house allows you a discount off their list prices, it is no reason why other houses should do the same. As an amateur, we see no reason why you should expect a discount at all. We hope you have not represented yourself as a professional to the house from which you succeed in obtaining a discount. That would not be honourable.

AGREEMENT FOR SERVICES.—OPERATOR. If there is a duly executed agreement for your services to the end of March next, you cannot be discharged now under the plea that there is not work enough for you during the winter months. An agreement is an agreement, and it is binding on both parties to it. You can certainly claim your salary, and get it, up to the end of the term. The County Court will settle that.

PHOTOGRAVURE.—D. DENMAN. If the negative image, when developed on the copper plate, shows blisters, it will be of no use to etch it, as the blisters will show on the copper when the image is bitten in. The blisters are due to faults in the manipulations, but in what way it is impossible to indicate, as there are many causes from which they may arise. With fuller details we might aid you.

ACETYLENE.—W. BORER. Acetylene, under the best conditions we have seen it used, will not compare with the oxycalcium light in the lantern, nor is it claimed for it that it will. With regard to its safety in inexperienced hands, we can add nothing more than has already appeared in the JOURNAL. In experienced hands—those who understand its properties, &c.—it is doubtless as safe as any other light.

INSOLUBLE GELATINE.—T. DILLON writes: "I have tried to make gelatine insoluble by the addition of chrome alum, but cannot. If I add a large quantity of the alum to a solution of gelatine, it coagulates into a stringy mass. If I add less, it gives a film which, when dry, absorbs water, though it does not dissolve in hot water."—Although chrome alum renders gelatine insoluble, it does not prevent its absorbing it with long soaking.

REPAIRS.—B. J. A. As the lease you hold stipulates that the tenant is to keep the premises in thorough repair, and the lease was transferred to you by the landlord from the one from whom you purchased the business, you are, of course, liable for all delapidations, notwithstanding that the place was out of repair when you took it over from the previous tenant. Had the landlord not accepted you as a tenant, he would have had to look to the one to whom he granted the lease for the repairs.

COPYING A PICTURE.—A. H. CADE says: "I am asked to copy two of the original-proof engravings of Doré — *Christ Leaving the Prætorium*. May I ask if you know whether the copyright has expired, or shall I be rendering myself liable to damages if I make a copy?"—In reply: We are under the impression that the copyright of the picture referred to has not run out. Our correspondent had, therefore, better ascertain for himself before running any risks, which he certainly would do in copying the picture.

PHARMACEUTICAL PERSECUTIONS.—DEALER. On the whole, you were wise to pay the penalty and the solicitor's charges, so far as your pocket was concerned, for it would probably have cost you more had the case gone into court. Possibly not, however, as the County Court Judges are getting to be very much against the Society's vexatious proceedings. You have our sympathy, as you evidently sinned unwittingly. No good would result from the insertion of your letter, particularly as some time has elapsed since you settled with the Society.

PHOTOGRAPHIC SOCIETIES.—F. E. F. says: "You would greatly oblige me if you let me know the addresses of a few London photographic clubs or societies which take amateurs as members, also kindly let me know what the subscriptions would be to become a member—a beginner who wishes to perfect himself."—In reply: Better consult the list of societies in our ALMANAC. The subscriptions range from 5*s.* to 5*l.* 5*s.* per annum. If you care to call upon us any morning between ten and one, we would advise you in the matter.

LENS.—W. W. WILLIAMS: "I am writing to ask you kind advice in choosing a lens for a quarter-plate stand camera, capable of doing all-round work, such as landscapes, near and distant objects, interiors, architecture, &c. I am going abroad for some months, and must needs make my luggage as portable as possible. Would the new anastigmats answer the purpose, or would it be necessary to carry several lenses?"—In reply: The Convertible Anastigmat is probably the lens which more nearly fulfils our correspondent's requirements.

REPAIRING CAMERA BELLOWS.—T. COLEBROOK. If the bellows of the enlarging camera is of mackintosh cloth, there is nothing better than a similar material for repairing it. Get some black indiarubber sheeting, and then smear over such strips as will cover the defective parts with rubber solution as well as the parts to be covered. Allow to dry, then apply the strips as plasters, and rub well in contact. The rubber solution can be obtained where the sheeting is purchased, and the finger is a good medium for distributing the solution.

EXHIBITING WORK OF EMPLOYÉS.—BOURNE writes: "I thank you for your reply to my inquiry in last week's JOURNAL. I still venture to ask you one more on the same subject. I am sending a frame with six cabinet portraits to an exhibition for competition. My operator took the negatives and printed them in platinum. Can I enter them in my name, or must it be in that of my operator?"—Photographers do occasionally exhibit pictures in competition in which they have had no hand in the production; but how far this is legitimate is much a matter of individual opinion. It is very doubtful, if the jury is made aware of the fact that the whole of the work is that of an *employé*, that they will award you a prize at all.

BACKGROUND.—W. RICHARDS says: "I have several times tried to repaint my background in distemper, but have signally failed every time, as I cannot avoid the brush marks. I mix the distemper in the usual way with whiting, lamp-black, and double size and water. I think my trouble arises from my not being able to get all over the background before the stuff gets cold and like a jelly."—Our correspondent's trouble is due to his using the distemper warm. It should be made the day before use and allowed to become a jelly; then it should be applied in that state, the jelly being broken up and evenly distributed with the brush. If the background has been distempered before, it should be sized before the distemper is applied.

KINEMATOGRAPHY; HALF-TONE WORK.—A PROFESSIONAL says: "1. Is the Kinematograph and slides for moving effects to be had, and where, and what would the probable cost be? 2. I am anxious to have some lessons in process work, line and half-tone, and am well up in photography (wet plate); is there any one who would give lessons in it—one who is first class?"—In reply: 1. Address Messrs. Watson & Sons, High Holborn; Mr. Birt Acres, Barnet, N.; Mr. Paul, 44, Hatton-garden; The Kinetograph Company, 62, Romola-road, Herne Hill. The cost ranges between 30*l.* and 100*l.*, but this is only a rough guess. 2. We know of nobody in your town; but such lessons are to be had at the Polytechnic Institution, 309, Regent-street, W.

LENS; PRINTSELLERS' ASSOCIATION.—E. F. C. asks: "1. Can you, in your Answers column, give me the benefit of your advice on the focal length of lens desirable for copying purposes? Taking a plate 18×16 as maximum, is nineteen to twenty inches too short a focus to use with an anastigmat such as the Goerz? In reproducing oil paintings, would not reflections cause trouble, the lens being somewhat near the picture? I am told that this focal length is sufficient with the size of plate mentioned when such a lens as the Goerz is used. 2. Can you inform me if the Printsellers' Association concerns itself with photographic prints (as distinguished from photogravures)? and could you give me any information as to its purpose and membership, if any, or direct me to a source whence I could obtain particulars?"—In reply: 1. A lens of the type and focus named will, when used with a stop, cover the size of plate mentioned; but, in practice, it will be preferable to have one of somewhat longer focus, so that the camera has not to be brought so near to the subject to be reproduced. 2. The Printsellers' Association have nothing to do with photographs pure and simple. The Secretary of the Association will give you all particulars as to the objects of the Association. Sorry we do not happen to know the address.

*** *We have in type several articles, answers to correspondents, &c., which pressure on our space obliges us to hold over.*

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1907. Vol. XLIII.—NOVEMBER 20, 1896.

Contents.

EX CATHEDRÂ.

The President of the Society of Patent Agents devoted his annual address last week to the subject of the value of Patent property. The address was full of interesting facts and statistics regarding the successful working of the patent laws as amended by Mr. Chamberlain thirteen years ago, and other subjects cognate to the author's main theme. A suggestion has recently been made that Patent litigation should be conducted in a Patent Court, presided over by a High-court Judge, but Mr. Fairfax discounts that suggestion by pointing out that the Judge in most, if not all, technical disputes would be entirely at the mercy of the highly trained counsel engaged, so that injustice would be difficult to avoid. He does not, either, appear to favour the suggestion that professional witnesses—composed of men of high theoretical training, of great intellectual ability and experience in the Courts—should be relied on by either side or both, inasmuch as they must, sooner or later, become advocates, and therefore expert witnesses in a double sense.

* * *

Mr. Fairfax, however, advocates the extension of the power of the Court "we now have at the Patent Office, under the Comptroller-General, so as to apply to cases of infringement and revocation, in addition to the opposition cases which it now hears. All the expert evidence could then be given in the form of statutory declarations, and the points of law and evidence, after submission to each party under the direction of the Patent Office, referred to the Judge for his decision. This would bring the evidence of opposing experts directly in conflict instead of through the intervention of Counsel, thus bringing out all the points; the procedure would be very much hastened and the cost of an action greatly reduced as compared with the present system."

* * *

The suggestion made by Mr. Fairfax is an eminently common-sense and practical one, and, if adopted, would partly, at any rate, put an end to the very hap-hazard system under which patent actions are at present fought; but, in reading through Mr. Fairfax's address, we were sorry, although, of course, we were neither surprised nor disappointed, not to see a portion of it devoted to the inequitable method at present adopted by the Patent Office for granting Letters Patent. As we and others have repeatedly pointed out, it virtually amounts to taking a patentee's money under false pretences, for no protection whatever is guaranteed him. In the course of a year, very many Patent specifications pass through our hands, by far the greater number of which should not, and would not, have been granted under some such methods as those adopted in the United States and Germany, where, we believe, the Patent Offices have an examining or searching system which prevents repatenting or the utilisation of old ideas. In both these respects the English Patent Office is almost entirely impotent; and the consequence is, especially as very many patentees do not employ agents, that the number of patents annually granted conveys an altogether erroneous idea of the sum of the really original inventive ability which the cheapening of patents is supposed to have called into existence.

* * *

A transformation has been effected at the Dudley Gallery, Piccadilly, within the last few days. The Exhibition of Modern Pictures, held by the New English Art Club, has taken the place of the pictorial photographs got together by the Photographic Salon. The familiar little room is now ablaze with colour. There are about ninety pictures hung, among the exhibitors being Legros, Pennell, Wilson Steer, F. Bate, Baxton

Knight, D. S. MacColl, W. Rothenstein, the Sickerts, Moffat Lindner, Fred Brown, &c. A criticism of the Exhibition would be slightly out of place in a photographic journal. We feel called upon, however, to make one remark, viz., that, having attended many Exhibitions of the Club, we discern year by year fewer evidences that its members deliberately produce work for the purpose of defeating comprehension. It is worth noting that a like remark holds good with regard to the Photographic Salon.

* * *

We have received the syllabus of the Bolt Court Guild and Technical School, 6, Bolt-court, Fleet-street, E.C. The school is under the joint control of the Technical Education Board of the London County Council and the National Society of Litho Artists. In the technical department of the school evening classes are held in collotype, half-tone, and line etching; photo-lithography, three-colour work, and other subjects. The teaching staff includes Mr. C. W. Gamble, Mr. E. J. Wall, and other qualified gentlemen. The fees, both for non-members and members, are exceedingly moderate, while non-members who are in receipt of less than 30s. per week are admitted to any or all of the classes on payment of 1s. per month. This opportunity of cheaply acquiring a practical knowledge of some branch of process work is one that should commend itself to and be taken advantage of by many young photographers. The Secretary, Mr. Donagan, at the address given, will forward to those who send for it a pamphlet giving detailed particulars of the various classes.

* * *

The winter session of the London and Provincial Photographic Association has started unusually well. The meetings of late have been very numerously attended, and a reference to the reports and papers emanating from the Association which we have recently printed will show that the discussions that have taken place have been of extreme practical and scientific interest. We are asked to state that efforts are being made to draw up an attractive programme of subjects for next year. Furthermore, the officers desire it to be known that visitors are always welcome to the meetings, which are held on Thursday evenings at eight o'clock at the White Swan Hotel, Tudor-street, Blackfriars, E.C.

A SUGGESTION FOR A TECHNICAL EXHIBITION.

These remarks are designed to supplement our article of a fortnight ago, in which we expressed the ideas of many photographers that at its Exhibition just closed the Royal Photographic Society permitted the purely artistic side of photography to predominate, almost to the exclusion of the technical or scientific branches. In a paper read before one of the societies three months ago the present writer threw out the suggestion that an Exhibition devoted entirely to photographic technique would probably be welcomed, and since that time a like suggestion has emanated from other quarters. Evidently, a strong feeling in its favour exists, and we therefore hope that the attention of the Royal Photographic Society will be directed to the matter.

It will not, of course, be gainsaid that the Society is the most suitable body to consider the suggestion and to endeavour to carry it into effect. That its annual Exhibitions have always paid some regard to technical and scientific photography is unquestionably the case, but it will probably be admitted that this has only been done to an inadequate extent. The consequence has been that the pictorial or artistic features of those Exhibitions, appealing, as they have done, to popular and general tastes, have overshadowed the technical and scientific, the result being that the latter have admittedly dwindled down to insignificance. This seems to indicate that the two sides of photography are not called for in the autumn Exhibition of the Society; that it is undesirable to unite the two sections in one display, and that a distinct Exhibition, held at a different time of the year, and devoted exclusively to photographic technique and science, is required.

We do not count ourselves among those persons who, while recognising photography as a progressive science, are yet unable to discern that it is constantly producing fresh developments and improvements. Consider what the last five years have brought forth! Interference photography; radiography; acetylene; animated photography; new lenses having properties of which our optical friends of the last generation did not dream; highly sensitive plates; improved or modified printing processes; and new developing reagents. In three-colour work and in the various photo-mechanical processes persistent improvements and experiments are being made; orthochromatism is absorbing undiminished attention; while scarcely a day passes but what reveals some new application of photography to industrial, commercial, or scientific purposes! Surely, aside of the fact that even the technique of every-day photography requires opportunities for demonstrating its advances, here is scope enough for some such Exhibition, the holding of which we are advocating.

"Pictorial" or "artistic" photography has no firmer friends than ourselves, but we are inclined to think that this branch of photography stands at present less in need of encouragement and advocacy than the more prosaic technical and scientific branches. It is upon the latter that photography as an industry and as a profession chiefly depends. Our processes want perfecting; there are still many problems awaiting solution at the hands of the chemist and the physicist; above all, there is a widespread demand for a dissemination of technical photographic knowledge, towards which a properly organized and regularly held technical Exhibition is capable of rendering great assistance. By a frank recognition of this fact the Royal Photographic Society will earn the approval of photographers all over the country.

It appears to us that the spring of the year and in London would be the best time and place for holding such an exhibition as is here suggested. We are not blind to the fact that the financial side is not the least of the difficulties the Society would have to face in dealing with the matter, but the support which it would be entitled to receive from the trade, the manufacturers, and others interested in the technical progress of photography should be sufficient to guarantee it against loss. A feature might well be made of foreign exhibits, so that by this and similar means an Exhibition entirely typical of the technical position of photography could be organized.

But, as it is scarcely within our province to enter into matters of detail which could better be settled by the Society itself, we here take leave of the suggestion in the sincere hope that it may in some form or other secure adoption.

Royal Society Medals.—The Queen has graciously approved of the bestowal of Royal Society Rumford medals to X-ray workers—to Professor Philipp Lenard, and also to Professor Wilhelm Conrad Röntgen, for their investigation of the phenomena

produced outside a highly exhausted vacuum tube, through which electric discharge is taking place.

Vesuvius.—The eruption of Vesuvius continues, and the stream of lava is still flowing down the side of the mountain to the danger of the observatory. According to a *Daily News* correspondent it is now proposed to erect a second and smaller observatory at the foot of the central cone, as there slight shocks are distinctly felt, but which pass unnoticed at the large observatory. An observatory on any mountain cannot be a very pleasant dwelling, but what shall be said of one on a volcano, which is always in a more or less active state?

Motor-car Day.—The weather in London on Saturday last brought disappointment to many who had made up their minds to perpetuate by photography the epoch of a new departure in locomotion. The weather was "November" in every sense of the word. A thick, damp fog of the real November type enveloped the neighbourhood all the morning, rendering successful photography quite out of the question. Good photographs of the event would have been interesting, as well as valuable, a few decades hence, as showing the early state of the motor car in England. These photographs would then be as interesting as would photographs now of the first railway train in this country. By the bye, what a contrast such pictures, if there were any, would be to the snap-shots of our present 'Flying Scotsman,' 'Flying Dutchman,' &c., taken going at full speed.

Rapid Printing.—Mr. Friese Green's rapid-printing machine, which was exhibited at the Royal Society's Conversazione in May last, has been adopted by Herr Arthur Schwartz, at Berlin, who uses it for the printing of illustrations for magazines. The bromide paper generally used is 100 centimetres (about 4 inches) wide and a kilometre long. When several negatives can be printed from at once, a wider paper, 450 centimetres (about half a yard), is used, and under these conditions some forty thousand cabinet pictures have been printed in ten hours' time. The Russian *Photographic Review* recently gave a description of the process, illustrated by twelve hundred prints obtained by their machine, every print being stated to be exactly alike as regards colour and detail.

Turning the Tables.—The police of England, and most other countries, have a goodly collection of photographs of evil-doers, by which they can at any time be recognised. Now it is reported from Copenhagen that the police there have arrested an anarchist at whose house they found a very complete collection of photographs of the principal members of the secret police of Denmark, as well as those of other countries. It is said that the photographs, mostly, had some remarks upon them, such as "very dangerous," "used for secret missions," &c. The portraits were evidently intended for anarchists' clubs, to show the members the men to be avoided. This, if correct, would indicate quite a new departure in the use of photography for identification purposes. If the police have photographs of evil-doers, why not the latter portraits of the "tecs," if they can obtain them?

Acetylene Lamps.—Notwithstanding the accidents which with acetylene, as with most new discoveries in illuminating agents, have occurred, and the difficulties raised by railway companies, about which we may have further to say when our inquiries are completed, the industrial uses of this agent are spreading and are being catered for by the manufacturers. M. Trouvé, whose name is so familiar with regard to electric-light appliances, has designed a lamp which is described in a recent number of the *Comptes Rendus*, for burning acetylene under certain conditions which he deems essential. He attaches great importance to the gas being both cool and dry before being burnt, and to this end employs two gas-holders, the gas in one being cooled and dried while the other is being filled.

An Innovation.—The Committee of the Photographic Club have decided to have what is termed a trade night occasionally, when inventors and dealers will be invited to bring forward any novelties they may have. These evenings should be very interesting, and will, no doubt, secure good attendances as well as giving those who have novelties to bring forward the opportunity of doing so. The trade nights will be the first Wednesdays in January, March, and May next year. By the way, at the annual meeting of the Club it was proposed to have a vacation during the summer months—one of the features of the Club is that it meets weekly all the year round—but it was decided that the meetings should be be held as usual; for a short period, they should be quite informal. Informal meetings are generally very interesting to those who attend, and often much information is gained. The holding of informal meetings is a subject that may profitably commend itself to other photographic societies.

The November Meteors.—The following suggestion by *Nature*, though too late for use for the principal showers of this month, may, with advantage, be placed on record for the guidance of future photographic observers. The great value of observations of these meteors is to ascertain as exactly as possible their radiant points, as the journal named states: "One can quite understand that, by placing a small camera on a telescope equatorially mounted, and employing a wide-angle lens oriented towards the radiant point, a large space in the sky can be included on the plate sufficient to catch many of the streaks if they are at all numerous. . . . The use of a wide-angle lens necessitates that, if an equatorial be used, the camera must be placed at the extreme end (object-glass end) of the telescope, otherwise the opening in the shutters will cut off some of the field, and in consequence neutralise to some extent the value of the wide-angle. . . . *The Observatory* contains an interesting article by Dr. Johnstone Stoney on the Leonids, in which he quotes an extract from a letter received from General Tennant, who advises practically the same method advised above."

Ceramic Photography.—Although ceramic photography must be numbered amongst the earliest of photographic processes, it has never taken any great hold on the British public. In times past it has been once or twice somewhat vigorously exploited, but it did not meet with commercial success. During the last year or two it has again been brought forward with some prominence, but few professional photographers appear to have taken it up, in some instances, no doubt, through the mistaken idea that the process is difficult to work, and that costly appliances are necessary. This is a fallacy, as will be seen on reading the report of a demonstration of the process at the last meeting of the Leeds Camera Club, and those of previous demonstrations before other societies. Although photographers do not avail themselves of the ceramic process, others are doing so, and in a direction scarcely anticipated by many, namely, for advertising purposes. At one of the London railway termini are some photographs, burnt in on the ordinary enamelled iron, as used for advertisements of houses and properties for disposal. The pictures are good, though the colour is not quite all that might be desired, and the size is by no means insignificant, about twelve inches by ten. There is little fear that these pictures will share the fate of the silver prints used for similar purposes that may be seen at most railway stations.

Storing Apparatus for the Winter.—The period of the year has now arrived when the larger proportion of amateur photographers have abandoned the idea of further photography, at least out of doors, till the spring. It is somewhat surprising the little heed many amateurs pay to the storage of their apparatus during the winter months. More often than not it is put away, in some out-of-the-way place, just as it was last used, without any thought as to the state it will be found in when next required for use. "Safe bind, safe find," is an old adage, and it should be kept in mind when storing photographic apparatus for the winter season. A damp place for storage should always be avoided, as, in it, the wooden portions

would be liable to swell and the glue soften and ooze from the joints, while the leather bellows will probably become mildewed. If the apparatus is made of ill-seasoned wood, an abnormally dry place will often prove injurious by shrinking the wood and causing it to crack. The best conditions are a place of tolerably equable temperature, neither too hot nor too cold, not damp or abnormally dry.

Before the apparatus is put away, it should be thoroughly dusted and cleaned, and a little pure olive oil may then be put on the metal hinges. In the case of metal instantaneous shutters, if they have been oiled in the working parts, the old oil should be cleaned away and fresh applied. If there is any tendency in the folds of the bellows to stick together—and there is that tendency with most when tightly pressed together for a long time—the gussets should be well rubbed over with French chalk. This all done, the next thing is to protect the apparatus from dust during its long storage. Even if it be contained in a leather or canvas case, it is a good plan to enclose that in brown paper; then, when next required for use, when the paper is removed, everything is ready. With regard to the lenses, they should be dusted, wrapped in paper to protect them from the atmosphere, and stored in a perfectly dry place. Exposure to the atmosphere and moisture have a tendency to impair the polish on the surface of lenses, particularly if they are of some of the new glasses.

Röntgen-ray Notes.—*Nature* "has much pleasure in noting that a 'Yorkshire lad,' Mr. G. W. Watson, of Keighley, has obtained some wonderfully good Röntgen photographs by using an old home-made Wimshurst machine to illuminate a Crookes' tube. The machine gave a spark about one and three-quarter inches in length, and was without condensers. With this primitive instrument good radiographs of the bones of the hand were obtained in about twenty minutes. One of these pictures, and also a radiograph of an abnormally developed elbow, have been submitted to us, and both are very creditable productions. The definition is unusually clear, and the hollow structure of the bones is distinctly visible. Mr. Watson's success may induce others to see what they can do with simple means."

Theory of the Production of Röntgen Rays.—M. P. D. Heen, in the Bulletin of the Royal Belgian Academy, propounds a new theory as to the genesis of the rays, which are generally considered as being brought about when the cathode rays strike a solid object. M. Heen supposes them to be caused by the molecules projected from the anode and cathode encountering each other. He had a tube constructed with the anode composed of two thin sheets of aluminium placed parallel. When the current passed from either of these plates to the cathode, the X rays were produced; but when the connexions were changed, and the two sheets were made respectively anode and cathode, no X rays were to be discovered. The explanation given was that in the small space between the two plates there would be only such a limited number of molecules that no effect of X-rays character would be produced.

A New Use for the Rays.—The chief of the Medical School of Paris has utilised the Röntgen rays to obtain photographs of the network of blood vessels in an injected subject. Taking advantage of the opacity of certain mineral substances to the rays, he injects the tissues with an alcoholic solution of sealing-wax, to which has been added a quantity of bronze powder as ordinarily found in commerce. Upon exposing a subject so prepared to the Crookes' tube a perfect network of the vessels is shown. M. Marey exhibited three of the results so obtained; they were of excellent quality, and he stated that they were better than any hitherto obtained under more ordinary processes.

Röngten Rays.—Application to Paleontology. Dr. Lemoine, well known for his Paleontographical work, his discoveries regarding the oldest mammals known to science, those in the lower Eocene strata, has just described to the Paris Academy of Sciences a new use for the Röntgen Rays in connexion with his special investigations. Dr. Rémy, with the assistance of M. Contremoulins, presented in Dr. Lemoine's name a series of prints of a most admirable kind, alike for their sharpness and the detail shown of the various superposed planes of the objects represented, and the ease with which an examination could be made of all the interior details, bone structure, organs of nutrition, crowns and roots of teeth. It was stated that for the future it will be possible to study, without making sections, the formation of the skull and the cerebral markings, and without removing the surface, both sets of teeth as they lie close together. At once could be seen all the characteristic points of various bony parts, birds with spongy, reptiles with compact, tissue; fishes' vertebræ, and so on. Even the egg shells hidden in their covering of stone showed out marvellously. Altogether the results appeared a great success.

The Rays by the Aid of a Wimshurst Machine.—A very long, valuable, and most interesting letter appears in last week's *Nature* over the signature of T. C. Porter, Eton College, on this topic. It is difficult to give it in abstract, and those interested we would direct to the original.* We may, however, say that Mr. Porter finds he obtains, with even a comparatively old-fashioned Wimshurst machine, and a four-and-a-half-inch spark coil, a brilliancy of effect which was surprising, and a steadiness of image most grateful to the eye, with a tendency, however, to reverse after a rest, and to an alteration after a lapse of time for the character of the discharge to alter. Light patches and streaks appear on the tube, which diminish the powers of the X rays, and, after the spots enlarge and coalesce, possibly destroy them altogether. Blowing on the patches has a tendency to cause them to move to a position less injurious to the rays. Mr. Porter is now enabled to produce three different classes of rays, which he terms X_1, X_2, and X_3 rays, each having entirely different properties from the others. His X_3 rays are most brilliant, strong enough to show on the screen so as to be seen (if ordinary shadow pictures) by a whole roomful at once; while the back-bone and ribs of a man may be seen by three or four at a time. The X_2 rays, when the hand is placed before the screen, show a very dark shadow from flesh, and the bones scarcely visible. Arranging his apparatus again differently, he got the X_1 rays, which gave most bright and exquisitely clear images on the screen. The full details of how these effects were brought about will be seen in the letter we quote from.

BY THE WAY.

After all, it seems that the Pall Mall awards were generally accepted without much complaint, in spite of the somewhat hazardous experiment, as it appears to have been regarded, of trying painter Judges. Why it should have been looked upon in the light of an experiment I am at a loss to decide, for surely, in years past, there have been artists or painters on the Pall Mall jury, notably Mr. Staeey Marks and Mr. Henry Moore. True, there have been complaints, both loud and deep, in former years, in all sorts of directions, with regard to the awards, but I never heard that the "artist" element was blamed for them. Rather, I fancy, the growls were directed against what was regarded by a certain class of members and non-members as a piece of favouritism which gave the medals, year after year, or turn and turn about, to a few old exhibitors, whose names had become historical in connexion with the parent society's exhibitions. There was also, no doubt, a spice of discontent amongst another section of more or less disappointed exhibitors, who eventually wisely took themselves off, and started "a show of their own," which appears to give them, now, unlimited satisfaction, for they get "hung" without the danger of having to take second place to any one else.

The *pros* and *cons* of the system of appointing painter Judges at photographic exhibitions have been talked and written about to such an extent that it seems impossible to put forward any fresh arguments on either side. My own opinion is that, if a medal is

* Vol. lv., No. 1411, pp. 31 *et seq.*

offered for a fine photograph, the best Judge is a technical photographer; if for an artistic picture, a trained artist is the better judge: while, for a picture combining technical excellence with pictorial merit, I think no Judge can be selected who will better fulfil the part than one who has himself "gone through the mill,' who has, in fact, been himself a successful producer of artistic photographic work.

I have had some little experience myself in judging, side by side with recognised "artists," or, in other words, painters of more or less renown, and, from the photographic point of view, I do not hesitate to say that there are no half measures with them—they are either mere dummies at the job or else autocratic nuisances. I was on one occasion one of a jury of five—four photographers and one painter—and in one of the classes we had a most difficult task. I forget whether the subject was portraiture, or *genre*, or what it was; but we had placed side by side the highly finished studio work of two of the leading "art" professionals of the day. These in style and everything else differed from one another sufficiently to constitute entirely distinct classes; but, when mixed up with them we had also a lot of nearly life-size studies of heads by a well-known amateur, whose distinguishing characteristic was the grim truth to nature he put into his work, the difficulty of comparison may be imagined—it was about tantamount to attempting to compare a cauliflower with an orchid at a flower show.

When the pictures constituting the "class" were brought out for comparison, I think we looked at one another and smiled. The artist was the first to show a gleam of sense, for he expressed his intention of "standing out" of the decision, as he did not, he thought, sufficiently understand the technicalities of photography; and the rest of us cut the Gordian knot by declining to make an award at all. It was, perhaps, a mean sort of way of getting out of the difficulty; but I think we were justified, especially when the artist, a portrait painter, by the way, declared afterwards that, if left to himself, he should have unhesitatingly given the award to the large heads, because they showed "more realism than he thought photography could render." Certainly, they were wonderful examples of what a photographer with good eyesight and assisted by the best of optical means can do in the way of rendering, or, rather, exaggerating the "texture" of a rugged countenance, and they were ghastly, if I may say so, in their truth to nature. These were just the points that struck the non-technical man, for they suggested possibilities far beyond the reach of his brush; but, seeing in close juxtaposition to them such entirely different qualities placed for comparison, he had the common sense to confess himself beaten in a game he did not understand.

This is the common-sense man; but the "dummy" is one who, while not insisting on his own opinion against those of others, takes the liberty of differing from his fellow Judges in every instance, and of giving a little advice. "Now, if I were judging a painting or a drawing," he will say, &c., &c., for five minutes or so; "but in the case of a photograph it is different"—and then he will end by voting with the majority.

But the self-willed and pugnacious artist is the worst to deal with, and, unless he has as strong a mind as his own pitted against him, is likely to do damage. I met such a one some years ago, and I admit that, had I been single-handed against him, he would have been *the* Judge. There were three of us, and I the only photographer: the painter, a very good fellow, and now an A.R.A.; while the third was an art critic, and otherwise intimately connected with art, though, at the same time, full of sound common sense. In every class we had to judge, Mr. Painter invariably selected almost the very worst specimens, from a photographer's point of view, that he could find. The "sloppier" the execution, and the more absurd the conception, the better he seemed to like it; and his stock arguments were: "It's really very good for a photograph;" or, "Well, see how the poor fellow's hands were tied." It was fortunate that the other one of the trio was an old friend of the artist's, and could afford, or dared, to "chaff" him, and "talk like a father" to him with the result that we decided every case by the odds of two to one; and, after it was all over, the "minority" Judge remarked, in his most dignified manner, "Thank God, my reputation isn't at the mercy of you two fellows!"

But, painters as Judges or not, more or less difficulty will always remain in the classification of pictures; for even in any particular class, whether it be portraiture, "*genre*," "still life," landscape, or what-not, difference in style or treatment may go far to place two pictures beyond comparison. Again, although there is nowadays small excuse for slipshod manipulation, there is the difficulty of judging how far mere technique should operate against superior artistic treatment. For which reason, especially as medals have now become so common, I, for one, would willingly see them altogether done away with. DOGBERRY.

A MICROSCOPIC EXAMINATION OF THE VISIBLE CHANGES IN CHLORIDE, BROMIDE, AND IODIDE OF SILVER, UPON EXPOSURE TO LIGHT.*

[Photographisches Wochenblatt.]

If we undertake the task of studying the influence of light upon the above-named three haloid compounds of silver, with the intention of fully investigating the process in all its bearings, this cannot be accomplished in a partial manner, with, perhaps, the aid of chemical reagents only. We may, on the contrary, advantageously avail ourselves of other means to secure greater insight and to extend our knowledge.

For the following investigations we use a reagent that cannot be surpassed for delicacy, viz., Light.

We first examine the sensitive preparations by inactive light; then allow active light to work until a visible change takes place; and lastly examine the visible change.

It is evident that such slight changes can only affect the unaided eye in the smallest degree. Consequently we can only carry out these investigations, with the help of the microscope, almost exclusively.

In opposition to *chemical* reactions, investigations of this kind might be called optical reactions.

These optical reactions have a quite unique superiority over chemical reactions, and this lies in the fact that chemical reactions are always of a material nature, and therefore followed by material changes. Optical reactions, on the contrary, cause no perceptible material change whatever during the short period of observation. Against this advantage, of most sublime delicacy, must be set the disadvantage of the limited number of reactions. As experiments with polarised light have not hitherto given any results, the optical reactions are reduced to six methods of illuminating the object. These six methods are:—

A. Illumination from below:—
   1. Perpendicularly from below.
   2. Obliquely from below.
   3. Dark-field illumination.

B. Illumination from above:—
   1. Perpendicularly from above.
   2. Obliquely from above.
   3. Very obliquely from above.

As mentioned in the title, our investigations are concerning chloride, bromide, and iodide of silver. It is therefore our next task to prepare these substances in a condition of *highest purity*. We thus prepare:—

1. *Purest chloride of silver*, which is in particular *absolutely* free from bromide and iodide of silver.

2. *Purest bromide of silver*, which is *absolutely* free from chloride and bromide of silver.

* My friend Kogelmann, who died on May 14 last year, requested me a few days before his death to send this uncompleted investigation to the Editor of this paper should he be unable to conclude it. In consequence of other affairs, I have only just been able to comply with the request of the deceased. May the work receive from professional colleagues the recognition which, in my opinion, was due to all publications by the genial investigator—alas! so soon departed.
Graz, August 18, 1895. Professor FRANCIS EXNER.

3. Purest iodide of silver, *absolutely* free from chloride and bromide of silver.

These three substances are powdery precipitates.

Of *quite equal purity* we also prepare:*—

1. Crystallised chloride of silver.
2. Crystallised bromide of silver.
3. Crystallised iodide of silver.

All these substances must, of course, be prepared by red light, and, moreover, afterwards kept in absolute darkness.

Before we proceed with the proposed investigations, it is necessary to inform ourselves briefly from the purely chemical standpoint of the changes the above-mentioned three haloid compounds of silver undergo through exposure to light. We know for certain that chlorine, bromine, and iodine (?) are liberated and given off by the action of light. (This is very easily demonstratable with chloride and bromide of silver, but much more difficult with iodide of silver.)

Substances rich in silver are therefore necessarily produced from the normally constituted haloid compounds. But it will be readily understood that this excess of silver may exist in very diverse forms in the normal silver haloid.

Consequently it is of great value for our investigations that we can prepare *artificially* (without the action of light) silver haloids with an excess of silver. We can obtain these substances by fusing the corresponding haloid compounds of silver upon a support of purest silver (according to Stas).

This method, for simplicity and scientific value, can scarcely be surpassed, since it is purely physical, chemical means being completely excluded.

A. We first fuse the three haloid compounds of silver—the above-mentioned powdery precipitates—upon a glass support, or better, upon a plate of rock crystal. Of course, the three are heated separately, and guarded from strong active light. We endeavoured to obtain thin layers, and, after they had slowly set, we found the surface of each crystalline, and all three *quite clear* by transmitted and incident light. Iodide of silver, however, only sets quite clear in small patches. Chloride of silver is colourless, bromide of silver yellow, and iodide of silver darker yellow.

B. We now fuse the three haloid compounds of silver, taken from the same stock of powdery material, upon a support of purest silver, each, of course, being kept separate. We transfer the fluid masses to heated glass and allow them to set slowly as before. We again obtain layers with indications of crystalline structure on the surface, and all three are quite clear by transmitted and incident light. The chloride of silver is colourless, the bromide of silver rather browner than before, and the iodide of silver is more greenish.

C. Lastly, we again fuse our three silver haloids—each separately—upon a support of purest silver, drive up the temperature to the melting point of silver, and *then suddenly cool them with as much rapidity as possible by plunging them into cold water.*

We thus obtain broken-up fused products, pieces and grains of the most irregular form, but of most importance for us, we find the three different fused products are more or less intensely coloured by transmitted light.

Although it is possible to identify the colour of the fragments under an eyeglass, a microscope is indispensable for thorough examination. We therefore use the microscope, and examine one by one samples of our three fused products.

We illuminate first obliquely from above, using ordinary daylight. We notice, first, that the fused products we have obtained of the haloid compounds of silver *reflect light*, and that they are *dull*. Second, as shown by direct light, the colouration of all three compounds is very slight, partaking of grey and rather pale, resembling in a high degree the colour of certain kinds of calcedony. According to the degree of magnification, chloride of silver closely resembles flint, or a purer grey calcedony. Bromide of silver is decidedly more reddish-grey. It also resembles flint in colour—likewise grey, pale calcedony. Iodide of silver is more like dark-bluish grey calcedony. Under the microscope these three substances have quite different, distinctive colours by incident light; but the intensity of the colours is of very low degree.

We now illuminate our three silver haloids from below, consequently by transmitted light. All three show more or less intense colouration, therefore colours of a high degree of saturation. Chloride of silver appears violet, tending to grey. Bromide of silver is variously coloured, and particles lying near each other are blue-violet to grey-blue violet, green-blue, also pale red tending to grey, and yellow to yellowish-grey. Iodide of silver is dull carmine red (often bordering on greyish olive green); but, if we illuminate very obliquely (dark-field illumination), we see in the same sample fiery carmine red and intense, pure yellow.

After this description of the optical properties of our fused products, we will inquire into their chemical composition. The three fused products marked A are the perfectly pure haloid combinations of silver; the three marked B and the three marked C are also perfectly pure haloid compounds of silver, but *each of these compounds contains an excess of silver.* We may satisfy ourselves of this in a very simple yet certain way. We place the fused products one after the other under the microscope, and treat them with a solution of thiosulphate of soda of suitable strength.

Whilst we look through the microscope, the fused products marked A slowly but completely disappear, *and there is no trace of residue.*

The fused products, B and C, are also slowly dissolved, but there is a *residue* to each. We have not yet examined these residues for composition or quantity. It is, however, clear from the method of preparation that they must be substances very rich in silver—if not silver itself. We should estimate the quantity at three to five per cent. Resuming and collating the facts, we arrive at the following conclusion: *Chloride, bromide, and iodide of silver in the fused state have the property of taking up silver. The silver taken up and held by the normal silver haloids is in different conditions, according to the slowness or suddenness of the cooling of the fused products.*

The fused products, B, are clear. In thin layers, chloride of silver is colourless, and bromide and iodide of silver are slightly coloured. We are impelled to the idea, by the direct impression upon the eye, as well as the fact that only a small percentage of silver in excess has been taken up, that the liberated substance is transparent.

Whether the excess of silver is liberated as metal, or as sub-salt, we hope may be decided by examining its electric conductibility. But it is very remarkable that chloride of silver is quite colourless, and bromide and iodide of silver only slightly coloured, if either liberated metal or liberated sub-salt be present. Silver sub-chloride, for instance, is generally described as a dark, more or less deep violet-coloured substance. It would be extraordinary if the liberation of this substance in normal chloride were devoid of colour.

The fused products, C, appear *dull* by direct light. This fact demonstrates strikingly that we are not dealing with excess of silver in a *free state.* If we may be permitted to make a comparison by similarity of aspect, failing complete investigation, we are reminded of the appearance of a glass plate silvered in Bothe's manner, especially in the case of the fused products of bromide and chloride of silver. At the very first, the extremely thin film of silver deposited upon the plate appears brown by transmitted light. This extremely thin film, notwithstanding its slightness, can easily be recognised by its power of reflection, its glitter, when examined by incident light. As the film of deposited silver becomes thicker, the colour by transmitted light very soon turns to a very intense *blue.* By incident light the glass side exhibits the deposit of silver in its argentic whiteness, as a powerful mirror, but the back of the film is dull and grey. We see, on the one hand, by incident light, the high capacity for reflection possessed by thin silver films which likewise appear colourless (either glittering white or dull grey). On the other hand, we see the intense colour of these silver films by transmitted light. We must repeat that we only indicate, in this comparison, a certain similarity between two phenomena, and *nothing more.*

We now turn to our particular task: the study of the visible microscopic changes brought about in chloride, bromids, and iodide of silver by the action of light. First of all, it is palpable that our three powdery haloid silver preparations cannot, as such, be used for the intended investigations. For example, it is impossible to study with certainty slight changes in these *small, irregular* grains. Even a magnification of 2250 times linear is too weak, quite apart from other disturbing peculiarities.

As in a special degree suitable for our purpose we have found:—

1. Fused compounds in thin layers upon glass plates, or, better still, ground and polished rock-crystal plates.

2. The distilled compounds (distilled from a platinum support to a plate of rock crystal).

3. The crystals of these compounds, as they are to be obtained from aqueous solutions.

4. The *ripened particles*, especially of gelatino-bromide of silver emulsions. As material for preparation of the fused and distilled compounds, we use our three separate haloid silver compounds in the powdery state.

1. The fused compounds. For examination under the microscope—

* An exact description of the entire methods of preparation—and only such would be of value—would fill several pages, and be inappropriate here. We must therefore omit it.

and in particular if the most powerful immersion systems are to be used—it is our first task to spread the compounds, rendered fluid at high temperature, *in very thin* layers upon the slides, or upon the cover glasses (The appearance of such preparations, however, is seldom all that we might wish; but under the microscope we usually find a large number of places that are quite suitable.) Before we expose these preparations to light, it is, of course, our second duty to observe their *appearance before exposure*. We therefore endeavour to ascertain what can be seen by the naked eye, through an eye-piece, and through a microscope. These observations we make as thoroughly as possible by both methods of illumination, *i.e.*, *illumination by transmitted light*, and *illumination by incident light*.

With reference to the light itself by which we make these observations, that of petroleum, protected by a deep yellow chimney, has proved quite safe. Red light is very seldom necessary, and one may, in most cases, work by ordinary petroleum light. For certain purposes—as the precise determination of the colour of our preparations—the use of daylight is *indispensable*.

After we have informed ourselves sufficiently of the appearance o our preparations, we proceed to expose them. We expose to direct sunlight, allowing the rays to fall perpendicularly, and do not decide upon too short exposures, because at starting we wish to obtain very marked phenomena.

After exposure we proceed with the second examination of our preparations, to ascertain the changes brought about by the action of light.

We shall, of course, use for each preparation illumination by transmitted, and illumination by incident, light.

A. *Fused chloride of silver.* (*a*) Appearance before exposure. By transmitted and incident light fused chloride of silver appears quite *colourless* and quite *transparent*. (*b*) Appearance of a layer of chloride of silver after exposure to direct sunlight for the space of one minute (to a maximum of two hours). By transmitted light there is intense colouration—ultra-marine blue; by incident light the layer is dull, *i.e.*, it reflects light, and is yellowish to reddish-pale brown grey. After longer exposure, thicker layers are almost opaque, and by incident light they appear pale-reddish grey. FRANZ KOGELMANN.

THE THEORY OF DEVELOPMENT.

A CRITICISM ON A PAPER BY MR. EDWIN BANKS.

I HOPE that the remarks I am about to make will in no way be regarded as personal. It is only by making experiments, and thus gradually increasing our knowledge, that we can expect some day to elucidate such a subject as the reason why a developer, as we call certain reducing agents, can reduce to the metallic state those portions of bromide of silver in a gelatine film that have been exposed to the light.

My only object in criticising Mr. Banks's paper on this subject is to show where I think he has erred, and where I consider a simpler theory on modern views will explain what takes place.

I have taken as the basis of my remarks the paper as published in the *Photographic News*, and for convenience of reference have numbered the different paragraphs as they stand (1 to 15). and where necessary shall quote in full the text as there given.

The first six paragraphs require no comment, as they are merely introductory, but in paragraph 7 we come across the statement that, "when a solution of pyro was applied to an exposed plate, metallic silver was reduced on the film and bromine was liberated. It was this liberated bromine that tanned the gelatine, and that this was so was proved by the fact that it was only when the silver had been reduced and the bromine liberated that tanning occurred." *Bromine was liberated.* This statement would naturally lead any one to infer that the element itself was set free, and was capable of attacking or combining with that substance present for which it has the greatest affinity. It must be remembered that in all cases of development, when using gelatino-bromide plates, an alkali or a carbonate of an alkali is present, and, according to Mr. Banks, the bromine thus liberated has a greater affinity for the gelatine than it has for the metal of an alkali, and that the compound formed by the action of bromine on gelatine is the cause of the tanning of those parts of the film where light has fallen. I venture to think that bromine, as such, is never set free during the development, happen what may to the bromide of silver during exposure. Any one can easily prove for himself who possesses a test tube and a thermometer that oxidised pyro renders gelatine insoluble, by soaking a small piece in a solution of ammonia-pyro, as usually employed for development, for half an hour or an hour, and then placing a portion of it in the test tube partly filled with cold water; the thermometer should then be inserted into the test tube and test applied. The temperature at which the dark-coloured portions of the gelatine go into solution will give what is required. Soak another portion of the original gelatine in tap water for the same time, and find in the same way the temperature at which this dissolves. A marked difference will be observed. In some experiments I have made the temperature at which the original gelatine went into solution was 35° C, and the gelatine treated with ammonia-pyro solution for 30 minutes 85° C. At the end of two hours' soaking in the gradually oxidising ammonia pyro solution, the gelatine refused to go into solution at the boiling point of water. When a plate has been exposed to light there the developer, when applied, will be most rapidly oxidised, and that portion of the gelatine surrounding the reduced silver will be in contact with oxidised pyro; this will be taken up by that gelatine and become tanned. Condensing into a few words what I have already said, the matter stands thus:—Oxidised pyro renders gelatine insoluble; during development pyro is oxidised in reducing bromide of silver to the metallic state, and this oxidised pyro tans the gelatine when the reduction takes place. This is very well illustrated by taking the development of a plate exposed on a line subject. During the development the silver is reduced on those portions of the plate corresponding to the white paper; then pyro will be oxidised, and will attack the gelatine; the silver bromide corresponding to the black lines of the original will not be reduced, and tanning will not take place. Let us now consider what is happening to the bulk of the solution. The dish is rocked, oxygen is absorbed, and the pyro in this portion of the developer is also being oxidised; but this is a comparatively slow process, but, nevertheless, it will exert a certain influence on the whole of the gelatine; it will tan slightly the gelatine corresponding to the shadows, and increase the insolubility of the tanned gelatine in contact with the reduced silver, thus still further raising the melting point of the image gelatine.

Mr. Bolton, in a letter to THE BRITISH JOURNAL OF PHOTOGRAPHY of the 23rd ult., details some experiments he recently made, and ascribes the result to the action of light. He took two tubes, into which he poured a mixture of gelatino-bromide, pyro, and carbonate of soda. The gelatine was allowed to set. One tube was kept in the dark, and the other was exposed to light. On testing these it was found that the contents of the tube exposed to light went into solution at a higher temperature than the other. This is explained by what precedes, and is just what I should have predicted had I been asked. Light undoubtedly is the prime cause, but it has no action in causing the insolubility of the gelatine, but by its action it has rendered the salt of silver susceptible of reduction, and in being reduced the pyro has become oxidised. I thank Mr. Bolton for the slight modification of conditions, and am sure that his experiment will have some weight in convincing others of the truth of what I have said, though at the time he made the experiment he did not think the result agreed with our explanation.

In order to test what I have here advanced, the following experiment was made:—A plate was cut into two unequal portions. The smaller we will call A. The larger portion was then wrapped in black needle paper, so as to cover and protect from light about half of it. The uncovered portion was then exposed to a gas flame at a distance of three feet for five seconds. A developer was made up, consisting of

Pyro	3 grains.
Bromide	2 ,,
Ammonia	3 minims per ounce.

At the moment the exposed plate was flooded with the developer, portion A was soaked in cold water. Development was allowed to continue till the exposed portion was fairly dense. It was then washed, and at the end of ten minutes strips were cut from A, the exposed and developed part, and from that portion that had been soaked in the developer, but which had been protected from light, and which, therefore, had no silver reduced in it. A test tube was then partly filled with cold water, one of the strips introduced, a thermometer inserted, and the melting point of the gelatine determined. This was done for each of the strips, and the temperature obtained I have given below. In order to avoid complication, especially as sulphite was not mentioned in connexion with "the theory of development," no sulphite was added to the developer.

	Melting Point.
Portion A	65° C.
,, soaked in developer, but not exposed to light	70° C.
,, exposed and silver reduced (not dissolved)	100° C.

The melting point of the gelatine in case A is very high, but this is undoubtedly due to the use of chrome alum in the emulsion, as these results were obtained when using commercial plates.

Not having time to prepare any emulsion myself, I asked Mr. Bullen, of the Gem Dry Plate Co., if he would kindly favour me with a Gem plate coated with emulsion, free from chrome alum. I received the plate yesterday morning, and the results I obtained are as follows:—

	Melting Point.
Portion A	40° C.
,, soaked in developer, but not exposed	40 to 45° C.
,, exposed and silver reduced (not dissolved)	100° C.

When the contents of the tube had reached about 45° C., a thin skin left the surface of the emulsion, and only went into solution at 87° C.

This thin layer of gelatine was tanned by the oxidised pyro in the bulk of the solution.

The explanation given by Mr. Grundy and myself, that the tanning action is due to oxidised pyro, does not in any way fail to explain what takes place in Mr. Warnerke's process, and the results of the experiments just cited give the reasons; but I venture to think that, if, in the case of an under-exposed plate and prolonged development, in order to bring out all that the developer can, we were to attempt to develop with warm water, we should not be able to remove the whole of the gelatine from those parts corresponding to the shadows, as then the oxidised pyro of the solution will have so tanned the gelatine that it would require a very much higher temperature in order to cause it to go into solution, and, if the bulk of the pyro had been oxidised, that water near the boiling point would fail to dissolve it. This is only my impression, as I have not worked this process, and it would be very interesting to all, as it is now worked for a certain photo-mechanical process, if we could obtain some information on this point; it would tend still further to clear doubts that may still exist in the minds of some.

Paragraphs 8, 9, and 10.—I find it most convenient to take these three paragraphs together. Here Mr. Banks deals with the effect of light on bromide of silver, and at once dismisses the sub-salt theory and advances his own, which is that bromide of silver, previous to exposure, has the atom of silver covered as it were by the atom of bromine, but during exposure the one is shifted with regard to the other; and the silver is now partly exposed and capable of being separated from the bromine when a developer is applied. This is a very pretty mental picture, and, if it were true, the sensitiveness of bromide of silver would be identically the same whatever the medium in which it was supported on the plate; but we know, as a fact, that bromide of silver prepared in identically the same manner, surrounded in one case by collodion and in another by gelatine, has very different speeds in these two media. In any case, it seems necessary, in order to obtain the maximum sensitiveness, to associate the salt of silver with some halogen absorber, or a body which is ready and eager to take up oxygen. Chloride of silver, prepared by suspending silver leaf in moist chlorine gas, will not change colour however long it may be exposed to the light. Iodide of silver, such as was used for the Talbotype process previous to the application of the gallo-nitrate of silver, was absolutely unchanged when exposed to light; in fact, according to some authorities, it was improved in quality by such treatment. If silver leaf were iodised, as in the case of the Daguerreotype process, till the whole of the silver was converted into silver iodide, it would be imposaible to obtain an image on it. In each of these cases, before any reduction can be effected, it is necessary during exposure to dispose of the liberated halogen; if this is not done, the silver salt is in exactly the same condition as it was before exposure. In the case of the wet-plate process, the free nitrate of silver is the iodine absorber. When printing on albumenised paper, it is necessary to have a considerable excess of nitrate of silver or its equivalent, if not, the image is weak and mealy. The sliding of the atoms of bromine and silver over each other during exposure to light is not a sufficient explanstion, as it will not explain many facts that we are acquainted with.

I am, at present, more inclined to believe in the sub-salt theory, as, according to it, the medium would account for the same compound being more sensitive in one case than in another. When bromide of silver is exposed to light for some time, a change in colour takes place. If a change of colour takes place by the prolonged action of light, why should it not, only to a very much smaller extent, take place when light acts for a short time? The change may be invisible, in consequence of the dulness of the light in which the examination must of necessity be made. According to Mr. Banks we are compelled to have one theory to explain what takes place when light acts for a short time, and another when light is allowed to act for a much longer time, since he will not admit that decomposition takes place. What is true for a short exposure ought to be true for a longer one also. If I understand Mr. Banks correctly, he led us to believe that by prolonged action of light the bromine is slipped so far off the silver that the latter is no longer protected by the bromine or iodine, and, in the case of the Daguerreotype process, the vapour of mercury is able to condense on the metallic silver and form an amalgam. If the silver be thus practically set free, what becomes of the bromine? The answer will be most probably that the bromine, in the case of gelatino-bromide plates, acts on the gelatine and renders it insoluble. The medium is, therefore, inactive with small exposures, where we most require a bromine absorber, or a body capable of disposing of it, but active when a flood of light falls on the plate and is but little needed.

Mr. Banks says in paragraph 8: "They had to consider first the constitution of the undeveloped image. It has been supposed to consist of sub-bromide of silver, but this was a mere assumption, and it had not been proved. The German chemist, Guntz, was the only individual who had been recorded to have produced silver sub-bromide." In 1885, Captain Abney read a paper before the Photographic Society of Great Britain, and in it he tells us that his friend, Dr. Hodgkinson, of Woolwich, had managed to isolate both silver sub-chloride and silver sub-bromide, and that on analysis some of the constituents came to within one per cent. of the theoretical amount. One per cent. is not a very large error, and, when a substance during analysis comes as close as that to the theoretical value, we ought, I think, to be satisfied that the body is what it is represented to be. The existence of sub-salts does not rest on such a bare statement as Mr. Banks mentions, but this paper may have escaped his notice.

Edmond Becquerel, in *La Lumière, ses Causes et ses Effets*, published in 1868, vol. ii., page 62, gives the results of two analysss of sub-chloride of silver. He prepared his sub-chloride by acting on recently precipitated silver by chloride of copper, and obtained by analysis:—

Silver	85·3
Chlorine	14·7
	100·0

The sub-chloride was converted into chloride by means of aqua regia. In the second case 1 gramme of the body was acted on by ammonia, which decomposed the sub-chlorids, giving a residue of metallic silver, and chloride of silver was dissolved by the ammonia. The metallic silver weighed ·42 gramme, and the chloride of silver weighed ·56 gramme; the chloride of silver consisted of silver ·423 gramme, chlorine ·137 gramme, so that his sub-chloride consisted of—

Metallic silver	·843
Chlorine	·137
	·980

So that during the analysis he lost two centigrammes.

Theoretically he should have obtained—

			Mean of I. & II.
Silver	·859	...	·848
Chlorine	·141	...	·142

Wetzlar, in 1847, produced in a similar manner violet-coloured flakes, using silver leaf.

According to Watts, bromine and iodine do not render gelatine insoluble. This, as Mr. Grundy and myself have already, in another paper, pointed out, is not strictly true. Gelatine is made insoluble by the action of bromine water, and not by a plain aqueous solution of iodine, or by a solution of iodine in iodide of potassium. We are pleased to see that Mr. Banks confirms this statement; but I fear he has carried the idea a little too far in ascribing the tanning action that takes place during development entirely to the action of bromine.

In vol. ii., p. 828, *Watts's Dictionary of Chemistry*, under the heading of "Gelatine," you will find the following: "When a current of gaseous *chlorine* is passed through a solution of gelatine, a white pellicle forms round each bubble of gas, and the whole of the gelatin is finally precipitated in flexible, elastic, nacreous, gelatinous, transparent flakes or filaments (Thénard, Bouillon-Legrange). The precipitate is tasteless, slightly acid, inputrescible, insoluble in water and in alcohol, and soluble in alkalies. On exposure to the air it exhales an odour of chlorine." "No similar products are obtained by substituting bromine or iodine for chlorine." From this I was led to believe that the chlorine entered into combination with the gelatine, and was decomposed by exposure to air, and that, since bromine also produced a similar insoluble compound, the bromide combined with the gelatine to form an analogous body. At the meeting of this Association, on October 22, there was present a chemist, Mr. Townsend, F.I.C., who threw out a hint that most probably the insolubility of the gelatine was due to oxidation, and not due to a definite compound formed by the action of the halogen on the gelatin:; but, when I told him that the body was said to smell of chlorine, he was in doubt as to whether oxidation was the true cause. As this seemed to me to be a point worth clearing up, I have made a few experiments in order to arrive at some definite conclusion as to what is the cause of the insolubility of the gelatine. I made some bromine water and then soaked in it some Nelson's No. 1 photographic gelatine. The gelatine was then washed by repeated soakings in tap water so as to get rid of all free bromine and hydrobromic acid, if formed; the insoluble gelatine was then placed in a large beaker, with about 400 c. c. of water. The gelatine, to start, weighed about four grammes. The beaker was then placed in a vessel in which water could be boiled, and was kept boiling for about an hour. The contents of the beaker must, therefore, have been raised to near the boiling point during the greater part of this time. At the end of the time the contents of the beaker were poured on to a filter paper and allowed to drain, the gelatine was then washed with two changes of cold water and allowed to drain for two days. After the boiling the gelatine was much less horny than it was at first, and, if the boiling had been continued for another hour, most probably the bulk of it would have gone into solution. In order to test for the presence of bromine in combination, the gelatine was mixed with binoxide of manganese and sulphuric acid in a flask, and the gas that came off from the mixture was passed into water. After the bubbles had been passed through the water for about ten minutes, some chloroform was added and the two shaken together. If any bromine had been present in the water, it would have been taken from it by the chloroform, and the latter would have been tinged more or less yellow by its solution; but not the slightest tinge was visible, so that I conclude from this that bromine does not, under the above conditions, combine with gelatine, and that the tanning of the gelatine is due simply to oxidation, as in the case of carbon printing. Most probably negative results would also have been obtained if chlorine had been substituted for the bromine water, but I may have,

by the prolonged washing and boiling, decomposed the compound formed during the soaking of the gelatine in the bromine water.

Seeing that gelatine is rendered insoluble by oxidation, I tried again other oxidising agents.

Peroxide of hydrogen seems to have but little effect on gelatine.

Permanganate of potassium tans it and produces a deep yellowish-red stain. Gelatine tanned with this salt refuses to go into solution at 100° C. Thirty volumes of hydrochloric acid and seventy volumes of water reduces the melting point to about 80° C.

A dilute solution of chromic acid also has the power of rendering gelatine insoluble in boiling water, and this is, I presume, the reason why, in the carbon process, it is always recommended to add sufficient ammonia to change the colour of the bichromate to yellow, that is, to neutralise any chromic acid that may be present.

In paragraph 11, Mr. Banks refers to the original form of cell devised by Volta, the zinc-copper sulphuric-acid cell, and says: "The action of the battery was to decompose some of the atoms of water, and the liberated hydrogen adhered to the copper or negative element, and, covering it, prevented further access of the fluid, and the action ceased." The electro-motive force of such a cell is 1·03 volts before it has been used to send a strong current through the external circuit; after it has been used to send a current of about from one to two ampères for some minutes, it falls to about ·63 volt, but on breaking circuit it very rapidly regains its original electro-motive force. I am perfectly well aware that text-books as a rule very much depreciate the value of this simple cell, but, if any one who has the necessary instruments and time will take the trouble, he will find that such a cell, immediately after short circuit, and long before it can recover itself, has an electro-motive force of about $\frac{1}{3}$ volt. Its action, therefore, does not cease due to polarisation.

Paragraph 12.—I thoroughly endorse Mr. Banks's explanation of the action of pyro on water, and water on bromide of silver, if we leave out the electric current. We have practically two unstable bodies—light-struck bromide of silver (whatever its composition) and pyro. The one is willing to part with its bromine and the other is eager to absorb oxygen. By the kind intervention of water and its decomposition, both can be satisfied. Hydrobromic acid is formed on the one hand, and pyro is oxidised on the other, metallic silver (probably) being set free. This theory is not new, for we find in *Brande and Taylor's Chemistry*, published in 1863, p. 605, the following sentence explaining the development of a wet-collodion plate: "The iodine is removed from the iodide, and it must be removed either as iodide of silver (AgI), or, on the assumption that water is decomposed, as hydriodic acid (HI), the oxygen of an atom of water being taken by another portion of the pyrogallic acid." From this quotation it will be gathered that thirty-three years ago water was looked upon as the developer in the case of wet-collodion plates developed with pyro; whether we should now explain the action in the same way is outside the question I have to deal with to-night. What I want most particularly to call your attention to is, that thirty-three years ago water was regarded as the developer, and not the pyro.

In paragraph 7, as I have already explained, Mr. Banks ascribes the tanning action to liberated bromine. In paragraph 12 the bromine is disposed of by combining it with the hydrogen of the self-sacrificing water, and forms hydrobromic acid. If it does the one it cannot do the other; in fact, the one statement is dead against the other. I am entirely in agreement, as I have already said, with the explanation in paragraph 12, but I cannot accept the other. The gelatine is not, therefore, tanned by bromine; we both now agree on this point; and, since it is tanned, it must be tanned by oxidised pyro, as this body has, among others, this property. The only other body present that could tan the gelatine is hydrobromic acid; that, judging by analogy, is out of the question, as, of all reagents I have employed in order to endeavour to soften tanned gelatine, hydrochloric acid is one of the few that will lower the melting of gelatine in this peculiar condition.

In the early part of paragraph 12 Mr. Banks says, "The atoms of the silver bromide on the one side, and the hydrogen atoms of the pyro on the other, constitute the elements; a weak electric current was established, which decomposed some of the water of the developer, the liberated oxygen of the water combined with the hydrogen of the pyro, the liberated hydrogen of the water—not of the pyro—combined with the bromine of the bromide of silver to form hydrobromic acid." I have always understood that, in order that a current may flow, it is necessary to have a complete circuit. In the cell, as imagined by Mr. Banks, we have a current passing from the hydrogen of the pyro, through the water to the bromide of silver, the hydrogen of the pyro corresponding to the zinc plate in an ordinary cell, and the bromide of silver to the copper plate; the question I have to ask here is, How does the current return? The mere immersion of two plates, however different, in the same solution, or in two different solutions separated by a porous diaphragm, is not sufficient to generate a useful current of electricity. Major Waterhouse some years back showed that a current of electricity flowed from the bromide of silver, which formed the shadows of an exposed plate, through the liquid towards the light-struck bromide, also through a galvanometer and connexions back, but this is a very different case. We must have contact; some have to form the complete circuit, but in the case of Mr. Banks's cell there is no complete circuit.

M. Becquerel, in the work I have already mentioned, tells us how to make an electro-chemical actinometer. It consists of two plates of pure silver, covered with iodide, bromide, or chloride of silver, prepared by immersing the plates in a dilute solution of chloride of copper, or by placing the plates in a dilute solution of hydrochloric acid, and passing a current, the silver plates being connected to the positive pole of the battery. The plates are then short-circuited, till they yield no deflection when connected to the terminals of a sensitive galvanometer. The plates must be prepared in a dark room, and during their use all light, excepting that useful for the experiment, must be excluded. The plates and containing cell were enclosed in a metal box, having a slit at one side, which slit could be closed or opened as required. The plates during the experiments were immersed in two per cent. of sulphuric acid. When everything was ready and light was allowed to fall on one of the plates, a current was produced which deflected the needle of the galvanometer, the deflection varying with the intensity and the colour of the light that fell upon the plate. When the plates were properly prepared, and a sensitive galvanometer used, the deflection obtained by exposure to sunlight amounted in some cases to seventy-five per cent. What this deflection means we cannot say, as these experiments were made before the present electrical units were introduced. We see from this that, when two plates identical in every respect are connected together, a current passes one to the other when exposed to light.

If it is necessary that there should be a current of electricity for development to take place, then, since each particle of bromide of silver is isolated by a film of gelatine, and bromide of silver is not perfectly transparent, the front portions of each particle of bromide up to certain depth will be light struck and the back will scarcely be modified. When this particle of silver bromide comes into contact with the developer, the whole will form a microscopic cell, and then the action which Mr. Banks points out might take place. On the formation of metallic silver in contact with the bromide of silver, sub-bromide would be formed, and this would in its turn be reduced till the whole of the particle was converted into metallic silver, more or less completely.

Paragraph 14. Here Mr. Banks gives us something new, but at the same time it is easy to account for the results. Nascent hydrogen, the same as all other nascent elements, is far more energetic than it is after it has gone into the molecular condition; now, it should not matter how the hydrogen is obtained, provided it is set free in that peculiar energetic form, the nascent state. Hydrogen is formed by electrolysis, attacks the bromine, and so the silver is set free in the metallic state. When plain water is used, in consequence of its high resistance, the strength of the current would be very small, and, in addition, would most probably very soon cease in consequence of the film of oxide of zinc (insoluble in water) formed on the surface of the positive plate.

Paragraph 15. It is indeed unfortunate for us that development should have received the scant attention it has from our best chemists. It is a very difficult problem to attack, and this may be the reason why it has been neglected. The separation of the products of oxidation at different stages seems insuperable, but nothing is impossible in the hands of a man who knows his work and is willing to attack the subject. Pyro in combining with oxygen forms, undoubtedly, a number of different compounds, depending on the extent to which the oxidation is carried; but I doubt whether purpuregallin is formed in the early stages. In order to produce purpurogallin, it is necessary to act on *plain* pyrogallic acid with a powerful oxidising agent, such as permanganic acid, chromic acid, nitrate of silver, &c. The body obtained is but feebly soluble in water, but is dissolved by ether, benzole, &c. If, therefore, a solution of pyro be oxidised gradually and we shake portions of it, at intervals, with ether, we ought to be able to extract the purpurogallin. The only case in which I have been able to obtain a colouration of the ether by purpurogallin was when the pyro was oxidised by means of bromine. By repeated treatment of a bulk of pyro thus oxidised with ether, I was able to prepare a small quantity of this substance, and, on soaking gelatine in an aqueous solution for fifteen hours, found that the gelatine went into solution at 85° C., whilst gelatine treated with pyro oxidised in the presence of alkali rendered it insoluble in boiling water. The same solution of oxidised pyro, alkali being present, gave no colouration to ether, proving, to my mind, that purpurogallin is not formed, at least, in the bulk of the solution. A very small quantity may be formed where the development takes place; but even this remains to be proved. Purpurogallin is a body capable of being crystallised, and sublimes at 200° C., when it gives, so it is said, beautiful *red* needles.

When ammonia is used as the alkali with pyro, it is far more likely that *pyrogallin* should be formed in the bulk of the solution than purpurogallin, as such a solution, when oxidised at no stage, as far as I can ascertain, yields colouring matter to ether; and, in addition, as I have already said, such a solution renders gelatine far more insoluble than does purpurogallin. The only mention I can find of pyrogallin is in Watts's *Dictionary of Chemistry*, and none of its properties are mentioned, but the conditions laid down for its formation are just those that obtain in the case of ammonia-pyro development—that is, slow oxidation by air. When air is bubbled through pyro-ammonia for days, it yields no colouration to ether.

I cannot understand how pyro by oxidation at any stage can yield carbon, and to this element Mr. Banks ascribes the yellow stain in

gelatine negatives. If carbon were the colouring matter, it would not render gelatine less soluble than it is when unheated, as the carbon cannot be there otherwise than as a mechanical mixture, and a mechanical mixture of this kind could not so entirely alter the properties of the gelatine. When plates are developed with pyro-soda, no sulphite being present, the gelatine is very much stained. Now, the bulk of this stain can be temporarily altered by means of hydrochloric acid, but on soaking in water, or by the application of an alkali, it returns with full vigour. Again, if a solution of ferrous sulphate be applied to a recently developed plate, the colour of the image is changed. The change in colour may be due to a combination between the iron salt and the oxidised pyro or a reduction of the oxidised pyro, and then a combination between it and the ferrous or ferric sulphate. If the colour were due to carbon, it could not be modified, as we are all well aware that carbon is one of the most stable bodies we can deal with.

Before concluding. I should like to give Mr. Bolton the explanation of the insolubility of the gelatine in a piece of solarised gelatino-chloride paper.

Scheele discovered, many years before we were born, that if chloride of silver be exposed to light chlorine is set free; similarly, when gelatino-chloride paper is exposed to light, chlorine is set free, and, as I have already quoted, chlorine renders gelatine insoluble, probably by oxidation; therefore it is not astonishing that the gelatine, in contact with the chloride of silver exposed to light, should go into solution at a higher temperature than the unaltered gelatine on the rest of the paper.

Mr. Grundy, I may say, is in perfect accord with me in all that I have advanced in this paper. A. Haddon.

ACETYLENE.

[Newcastle and Northern Counties Photographic Association.]

There can be no doubt that in the very near future acetylene gas will be largely used for the purpose of lantern illumination; in fact, at the present time it is very largely used. The fact that the light is of such intense whiteness that when burning it has no smell, that it is, using the proper apparatus, simply and safely produced, and, I should like to say that, after a great deal of inquiry and experiment, I think it is absolutely safe, and that once lit up it requires no attention, will go far to recommend it to those who have a natural abhorrence to the foul smell of the paraffin lamp, which gives intense heat, and smoke making everything and everybody black in the room.

Lanternists in the past have had the choice practically of (1) the oil lamp; (2) the limelight, using ordinary coal gas, and oxygen, using a blow-through jet; (3) coal gas and oxygen combined, using a mixed jet; and (4), during the past few years, the incandescent mantle.

To those who live in the country, where no coal gas is obtainable, they have practically had to choose between the oil lamp and the mixed jet.

Now, there is a common belief, which is altogether an erroneous one, that the mixed or high-pressure jet is more dangerous than the blow-through. This is really not so; but it is surprising how difficult it is to remove an impression once made. It appears to me that a great many accept statements which are too often made, I am sorry to say, without due examination and experiment, and will not think for themselves. I am perfectly aware we are not here to-night to discuss the merits of the mixed jet; but, as I have pointed out, many of our friends had to choose between oil and the mixed jet; the former they disliked, the latter they were afraid of. It is perhaps particularly to them that acetylene comes as a boon and a blessing; they are now able, a few minutes before their lecture commences, to generate their own gas (I mean the gas for the lantern, not the other sort which they often inflict on the people). Now, while we must admit that we have got a wonderful light in acetylene, while we welcome it as an additional power to the lantern, do not let us lose our heads over it, as I am afraid many did over the incandescent mantle. You will remember that, when the incandescent mantle was brought forward as a possible lantern illuminant, people wrote to the photographic Press saying all sorts of extravagant things about the light. Some of the more discreet limited the light to photographic enlarging, for which purpose I will admit it is excellent. Others, more bold, said that a brilliantly illuminated disc of six feet could be obtained, which was so suitable for using the lantern in the house. A six-foot disc can be obtained, but I have never seen one anything like brilliantly illuminated. But the bolder ones still declared that it was suitable for public exhibition, that it would give a clear disc of eight to twelve feet in diameter, and was in every way equal to the lime light.

Now, I have had a fair experience with all the lights used in the optical lantern, and I challenge any man to produce a twelve, aye, or an eight-foot, disc brilliantly illuminated with the incandescent mantle. This is precisely the reason why I wish to guard you against any excessive praise of acetylene gas. As I said before, while we welcome it as a new power, we must also admit that, although it is superior to any oil lamp on the market, it is slightly inferior to the light produced from a blow-through jet. It is said that, using two optical burners made by Bray, placed at right angles to each other, a light of 200 candle power is obtained. As perhaps many of you are aware, the best oil lamp only gives 125 candle power.

But, even if it is slightly inferior to lime light, its advantages are many. In the first place you are not troubled with the carriage by the railway companies. The railway companies in their wisdom adopted a very stringent rule with regard to compressed gases. They will not allow a passenger to take his cylinder in the same train (mark me, not the same carriage) as passengers' luggage. This he could do without payment, and it is dangerous; but he may book his cylinder as a parcel, send it by the *same* train, pay the carriage, and it is not dangerous, at least, I suppose so, otherwise the company would not carry at all.

This question of carriage has always acted as a deterrent to many, and I do not wonder at it, so that acetylene comes as a welcome friend to all who move about from place to place and carry their apparatus with them. No one can prevent you taking your gasometer in the carriage with you, as it is portable and empty, the calcium carbide with which you make the gas can be carried in an old coffee tin, and all you require at the other end is water, and you are ready to begin; so that, even if our light is not quite so strong, it has many other advantages. Do not forget also that at present we are only beginning to find out the value of acetylene; in the near future, no doubt, the light will be vastly improved. To me it appears that the most serious objection is that the area of incandescence is too large. So soon as the light can be centered more to a point, so soon will we have a more perfect light.

For the purpose of making my paper to-night very plain, and, I hope, very instructive, to all, I will divide it into—

1. The production of acetylene gas from calcium carbide.
2. The apparatus necessary to produce the light.
3. Its advantages and disadvantages.

And 4, and perhaps the most important of all, the safety of the gas.

First, then, let us consider how acetylene gas is produced. Calcium carbide is made by heating together in an electric furnace for eight hours, at a temperature of from 4000° to 5000°, common lime and coal dust. The compound produced is calcium carbide, and bears the formula of CaC_2. Calcium carbide as it is sold commercially is very hard—so hard that one gentleman has suggested a steam roller to crush it—of a greyish colour, and a peculiar though not very strong smell. It is necessary to keep it in air and damp-tight tins, as it is very unstable; is easily decomposed by water, acetylene being given off and lime left as a residue. It has been stated that Thomas Leopold Wilson, a Canadian chemist, accidentally discovered acetylene by throwing a piece of calcium carbide into water, and, struck by the violent action set up, pursued his investigations with the result which we all know.

Acetylene has a chemical formula of C_2H_2, and the chemical action is as follows: The oxygen of the water combines with the calcium, forming lime; the carbon combines with the hydrogen, forming acetylene.

The characteristics of acetylene are that it has a most pungent, to many disagreeable, odour resembling garlic: it is colourless, and burns when free from air with a steady and intensely brilliant white light. Many people have raised as an objection to the use of acetylene its disagreeable smell. In my opinion this is one of its greatest points. Recollect that acetylene when burning has no smell, so that, if there is a smell, you know that some of the gas is leaking, and can take precautions accordingly.

When mixed with air it is highly explosive, the proportions varying, but the most explosive mixture is about one to twelve. Mixed with coal gas it greatly increases its brilliancy. As to its poisonous properties, opinions appear to be divided, some scientists giving it as their opinion that the gas is not poisonous, others that it is. This is a matter for further experiment.

One point where acetylene distinctly scores is that it gives off practically no heat; we all know the inconvenience of standing over an oil lamp for two hours.

Passing on, we will now consider the apparatus necessary to produce the light. I have already told you that the gas is produced by the action of water on calcium carbide. There are at the present time many forms of generators in the market, all, of course, claiming to be the best, but to-night I will speak only of one, that is the Incanto generator, made by Thorn & Hoddle. I do not say it is the best generator. Why I recommend it is because I think it is the best and safest, because the makers are thoroughly practical men, who before placing it on the market practically tried and positively proved that no accident could occur if the generator was used according to the very simple instructions sent out with it, and lastly because I have worked with it myself, have unbounded confidence in it, and therefore can recommend it to your notice. I have here to-night, on the table, one of those lantern generators, and also one of the special fittings for the lantern. You will notice the generator consists of a cylinder about eighteen inches high and eight inches in diameter. This generator is made to hold sufficient carbide to give a light, with the two special burners supplied, for two hours or more. I will now describe the apparatus.

When the action first commences the gas is mixed with air, or rather the air in the generator is forced out by the gas formed. It is therefore advisable to wait a few minutes until the air has been driven out of the apparatus. You can easily tell when the air has been expelled, by the unpleasant smell of the acetylene. Now apply a light, but you will not

obtain the maximum of light for quite five minutes. Now place it in your lantern, focus and centre it, and it can be left alone. Do not expect too much; do not forget, what I told you at the commencement, that the light is not so good as the lime light, though very nearly so, and this leads one to the advantages of acetylene.

First of all, the intense whiteness of the light, then the wonderfully easy method of production, then the extreme portability of the apparatus, no railway or other restrictions, the saving of carriage, the doing away with all regulators and cylinders; and, lastly, the very low price at which the gas can be produced. One pound of calcium carbide will produce five cubic feet of gas, and this is sufficient for two hours' entertainment, costing, at the present time, from 7*d.* to 10*d.* per pound. No doubt, in the near future, the cost will be considerably reduced. With the exception of electric, acetylene consumes far less oxygen than any other illuminant.

It gives off no carbonic oxide, consequently picture frames, wall papers, decorated ceilings, &c., are not affected, as is the case with coal gas. The light is steady, noiseless, nearly smokeless, and well diffused, practically the same as sunlight.

Surely these are very great advantages to claim for the new gas.

Disadvantages, I think, it has none.

I have now arrived at that very important part of my paper when we must take into consideration the safety of acetylene, for of what use are all its advantages if it endangers human life? I think you will agree with me, gentlemen, that it is best to speak with very great caution respecting a gas which is occupying so much of the time and energy of our great scientists; but I do wish to state that, in the present state of our knowledge, and using the particular generator which I have to-night, there is absolutely no danger that I know of. I would not speak so positively had I not studied the matter thoroughly, but I can strongly recommend all of you to use this gas, and feel sure you will be quite safe in doing so.

Let me try and make myself more plain. I have already told you that the gas is highly explosive when mixed with certain proportions of air. This is so. But consider, after you have expelled the air from this generator, there is no air, what is then coming off is pure acetylene. How, then, can you have an explosion? The makers say, and I quite agree with them, that it is impossible to have an explosion with this form of generator.

No doubt, many of you have read of the regrettable and fatal accident which occurred quite recently at the works of M. Rouil Pictet in France. I think I am correct in saying that this took place while endeavouring to compress acetylene into cylinders, the same as we compress oxygen and hydrogen. MM. Berthelot and Vielle have proved that at ordinary pressure acetylene does not detonate, but that, as the pressure increases, so does the chance of explosion. But why have compressed acetylene? It is so easy to produce that it is not necessary to carry it about in a compressed state. In every case that I know where an accident has occurred it has been whilst experimenting with the gas, and not whilst using it in such a generator as I show you to-night.

Gentlemen, you have the advantage of those experiments. Do not experiment yourselves; follow out the simple instructions given for your benefit, which have been arrived at very often at the cost of the brave men who have risked and sacrificed their lives for the benefit of science.

JOHN WATSON.

PHOTOGRAPHIC EXHIBITION AT ST. PETER'S INSTITUTE.

THE flourishing Institute in connexion with St. Peter's Church, Eaton-square, S.W., held on November 9, and the four following days, a public exhibition of photographs, which was very successful, and which, considering it was a first attempt, was distinctly creditable to its organisers. The Exhibition was held in the concert hall of the Institute building in Buckingham Palace-road, which is well suited for the purpose.

In addition to the competitive exhibits, which were confined to members of the Institute and friends introduced by them, there was an admirable loan collection, to which, amongst others, Messrs. Edgar G. Lee, Wilson Noble, W. Thomas, B. Gay Wilkinson, the Rev. F. Basil Wood, Count von Gloeden, and the Hon. Secretary (Mr. A. J. Daniels) contributed.

The Judges of the competitive classes were Messrs. Johnson and A. Mackie, F.R.P.S. These awards were: Class I. (Landscape, with or without figures).—Silver medal, W. J. Hensler; bronze, E. W. Burch. Class II. (Architecture).—Silver, R. Horton; bronze, withheld. Class III. (Portraiture and Figure studies).—Silver, R. H. Cust; bronze, J. A. Rooth. Class IV. (Hand-camera work and moving objects).—Silver, Ernest Smith; bronze, J. G. Nicholson. Special silver medal to members only: C. A. Phillips.

On each evening there was a lecture, illustrated by lantern slides, the lecturers being Rev. A. Fairbanks, M.A., Mr. J. Harris, of Cardiff, the Rev. J. Stores, vicar of the parish, Mr. E. Dockree and Mr. A. Anderson.

Our Editorial Table.

DIE CHROMO-LITHOGRAPHIE.

By Dr. FRIEDRICH HESSE. Wilhelm Knapp, Halle a/s.

WE have received the complete volume of this work, the first part of which we reviewed in our columns on April 17 last. It amply fulfils the high expectations we had formed, and we have no doubt it will be valued as a guide and reference book by those interested in this branch of work. The book is divided into two parts, the first dealing with chromo-lithography, and the second to photographic processes combined with chromo-lithography. The book contains fifteen specimens of work and a large number of illustrations in the text.

PHOTOGRAPHISCHER ALMANACH FÜR DAS JAHR 1897.

ED. LIESEGANG, Düsseldorf.

THIS excellent little volume will, doubtless, be welcomed by German photographers. It has a pathetic interest this year, in that it contains as frontispiece a photogravure portrait of the late Dr. Paul Ed. Liesegang, whose memory will remain green in the minds of all persons interested in the scientific aspect of photography. The book contains an interesting historical photographic calendar, a large number of original articles on various subjects connected with photography, a collection of formulæ, and a list of all the German and Austrian photographic societies. We trust the book will have the large circulation it merits.

A GUIDE TO MODERN PHOTOGRAPHY.

By HAROLD BAKER. London: Iliffe & Son.

MR. HAROLD BAKER is one of the ablest photographers that we have, and therefore possesses the best qualification for undertaking the task of imparting photographic knowledge to others. The most ambitious and least satisfactory feature of the little volume before us is its title, which, we think, is not new, and, even if it were, is too comprehensive. Mr. Baker addresses beginners, in the course of about 100 pages, and has compiled a really excellent elementary handbook, with scarcely a superfluous word. Theory has been eschewed, and the result is a useful, practical guide, by which the neophyte can hardly fail to profit.

INDUCTION COILS AND COIL-MAKING.

By F. C. ALLSOP. E. & F. N. Spon, 125, Strand.

MR. ALLSOP is an old contributor to our excellent contemporary, *The English Mechanic*, from the pages of which much of the matter in the present volume has been, admittedly, taken by the author. The result is an excellent work—clear, practical, and complete. The principal chapters deal with the construction of coils generally; shock and medical coils; accessory appliances for and the application of medical coils; spark coils; batteries, &c. A brief chapter is devoted to X-ray photography. The work, which appears at a time when, by reason of Röntgen's discovery, added zest has been given to experiments with spark coils, has over 120 illustrations, and has our best recommendation.

News and Notes.

WE regret to announce that Mr. T. C. Turner, photographer, of Barnsbury-park, died on the 13th inst., aged fifty-seven.

ROYAL PHOTOGRAPHIC SOCIETY.—Technical Meeting, Tuesday, November 24 at 12, Hanover-square, at eight p.m. *A Photographic Museum*, by R. Child Bayley.

THE AUSTIN-EDWARDS' MONTHLY FILM-NEGATIVE COMPETITION.—The prize camera for the current month has been awarded to Miss Mabel Metcalfe, Beccles, Suffolk, for her negative, *A Norfolk Lane*.

THE European Blair Camera Company, of 9, Southampton-street, Holborn, inform us that they have purchased the business of the Premier Dry Plate Company, of Notting-hill, and will in future manufacture the lantern plates and other specialities of that Company.

HACKNEY PHOTOGRAPHIC SOCIETY'S EXHIBITION.—The Seventh Annual Exhibition of the Hackney Photographic Society was opened on Tuesday evening, November 17, by the Rector of Hackney, the Rev. F. Evelyn Gardiner, M.A. A full report of the Exhibition will appear in our next.

A HAMBURG young man has just had his sanity proved by the Röntgen rays. He declared ten years ago that he had a bullet in his head, which he had fired into it in trying to commit suicide. He complained of the pain, and, as he attacked his keepers, and the doctors could find no trace of a wound, was locked up as a dangerous lunatic. The Röntgen rays have now shown the exact place of the bullet.

PHOTOGRAPHIC CLUB.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock, on Wednesday evening, November 25, Third Travellers' Night. Mr. H. I. N. Noel-Cox will lecture upon *Pompeii*, with lantern illustrations. Visitors are welcome.

MESSRS. SAMPSON LOW & CO. are bringing out a new book by Captain Abney, C.B., D.C.L., F.R.S., entitled, *Evening Talks at the Camera Club on the Action of Light in Photography*, which is included in the series of "Handbooks for Photographers," published by them. The work has upwards of sixty illustrations and diagrams.

UP to the end of October of the present year, the applications for Letters Patent numbered 24,380, an increase of 3762 over the corresponding period of last year. At this rate the total for 1896 will be about 29,250, the highest number yet attained. In 1895, however, there was a decrease of 321 as compared with the 25,386 of 1894; consequently the present rate of increase should not be considered as normal. As about fifty per cent. only of the applications are sealed, we may expect that 14,625 Letters Patent will be granted this year.

THE CENTENNIAL OF GAS LIGHTING.—The one hundredth anniversary of lighting by gas occurred in July. The first practical trial was made by Murdoch, in Birmingham, England, in July, 1796. It failed, however, to attract attention, and the next attempt was not made until 1802, when several buildings in Birmingham were illuminated with gas upon the receipt of the news of the Peace of Amiens. Gas was introduced in London as late as 1807. Murdoch, although not the inventor of illuminating gas, did much to secure its introduction.—*Elektrotechnische Rundschau.*

THE Second Annual Exhibition of the Borough Polytechnic Photographic Society will be held at the Borough Polytechnic Institute, on Tuesday, Wednesday, Thursday, Friday, and Saturday, December 29, 30, 31, and January 1 and 2 next. There will be competitions with open classes for both prints and slides, and one silver and two bronze medals will be given in each class. Entries will close on December 12. Judges: Lieut.-Colonel J. Gale, Mr. John A. Hodges, F.R.P.S., and Mr. E. J. Wall, F.R.P.S. The apparatus section will be under the management of the Prosser-Roberts Company, who will also give demonstrations of radiography during the evenings. In addition to lantern entertainments, &c., there will also be three distinct exhibitions of the animated photographs each evening. Entry forms are now ready. Hon. Secretary, P. C. Cornford, 103, Borough-road, London, S.E.

DULWICH PHOTOGRAPHIC SOCIETY.—The First Annual Exhibition of this Society was inaugurated by Mr. J. Albert Canston, at the Constitutional Hall, East Dulwich Grove, S.E., on Thursday, November 12. The Society is yet small in numbers, but the enthusiasm displayed by them, both in the quality and quantity of their exhibits, augurs well for its future. There were five classes restricted to members, and one open class. Altogether there were over two hundred pictures on the walls, principally in gelatino-chloride, carbon, and platinotype, and eight sets of lantern slides were shown. Mr. F. W. Edwards, F.R.P.S., was the Judge, and medals were awarded to the Hon. Secretary, Mr. H. J. Ellis (2), Mr. H. C. Jackson, and Mr. T. Mitchell; and, in the Open Class, Mr. E. Spencer. Certificates were also awarded to Mr. C. H. Hauff, Mr. H. A. Blake, and Mr. F. F. Thomas (2). The Exhibition was enlivened by music at intervals.

PROFESSORS H. B. DIXON and H. Brereton Baker have investigated the influence of Röntgen rays on some chemical actions, but from their note, published in the *Transactions of the Chemical Society*, it appears that the results have hitherto been negative. The effect was tried on mixtures of carbon monoxide and oxygen (dried and moist), hydrogen and oxygen, carbon monoxide and chlorine, hydrogen and chlorine and, lastly, hydrogen sulphide and sulphur dioxide (dried). No combination, either explosive or gradual, occurred between the gases exposed. The combination of chlorine with carbon monoxide and with hydrogen is effected by light, but the addition of Röntgen rays did not alter the rate of combination. Although the rays cause electric discharge from metallic bodies, they appear to have no effect on electrolysis. The action on a photographic plate is probably caused either directly or by the fluorescence of the film. It is not due to fluorescence of the glass, because the deposit of silver takes place entirely on the side of the film exposed to the rays.

HEAT-RESISTING QUALITIES OF WIRED GLASS.—A recent issue of the *Journal of the Franklin Institute* gives particulars of some tests recently made to determine the fire-resisting qualities of wired glass, *i.e.*, glass containing in its texture woven wire netting as manufactured by the Mississippi Glass Company, of St. Louis. The information is given in a report to the Philadelphia Fire Underwriters' Association, and the results of the trials showed that glass of this kind is capable of withstanding a high temperature, very much higher than ordinary glass, without melting or losing its continuity, even when suddenly drenched in a heated state in cold water. The conclusions drawn from the tests, and given in the report, are as follows:—1. Wired glass can safely be used in skylights, and in such situations will stand a severe fire, and not give way when water is thrown on it. A wooden framing for skylight, covered with tin, all seams lock-jointed and concealed-nailed, is superior in fire-resisting quality to iron framing. 2. Wired glass in wooden sash, covered with tin, all seams lock-jointed and concealed-nailed, can safely be used for windows toward an external exposure. 3. Wired glass can safely be used in fire doors to elevator shafts and stairway towers, where it is necessary to light said shafts. 4. In office buildings, hotels, &c., where it is undesirable to have elevator shafts entirely enclosed and dark, wired glass permanently built into a brick or terra-cotta shaft, or arranged in a wood metal-covered frame, can safely be used. 5. Wired glass plates, securely fastened in standard fire shutters, can safely be used towards an external exposure. In this case, the fact that a possible fire in a building, all windows of which are protected by fire shutters, can much more readily be detected from the outside through the wired glass, is of importance. The capability of the wired glass to withstand a temperature beyond the melting point of glass appears to be attributable to the fact that the network of wire in the glass acts as a good conductor of heat, and thereby prevents the accumulation of sufficient heat to melt the glass; and, although it may thereby be softened and rendered pliable, the network of wire prevents the glass from giving way by reason of its own weight when softened by the heat.

IMPROVING NEGATIVES.—Non-chemical methods of improving negatives are strongly advocated by some, and there is much to be said in their favour, the chief point being perhaps that the film is not tampered with; this, indeed, is desirable, especially if the negative be a valuable one. The simplest and most effective method is by means of tissue paper and ordinary household blacklead. These tools, I believe, may be found in every household. Cut a piece of fine tissue paper (the coarse quality does not serve so well, as the grain prints through) the size of the negative, and damp it and stick it lightly by the edges to the glass side of the negative; the previous damping causes it to dry as tight as the proverbial drum. When dry, it may be worked upon with blacklead by a stump or the finger tip. The sky may perhaps print too dark; if so, rub the blacklead over the sky portion where it is intended to print lighter. At frequent intervals in the sky, extra dabs may be put in the form of clouds; these, if skilfully done, show up very effectively in the finished print. In fact, any part of the negative that prints too dark may be held back by working over the desired part with the blacklead or a blue pencil. The latter is exceedingly handy, especially if in a group the faces print too dark; the same can be regulated to a nicety if the tissue paper is carefully marked with the pencil. A simple method of blocking out a thin sky is to hold the negative glass-side down over the smoke from a burning piece of camphor. A piece, the size of a small nut, will send forth volumes of black, soot-forming smoke. The glass will soon become black, when the surplus upon the landscape portion may be wiped away with a soft rag. Great care in afterwards handling the negative is necessary, as the blocking is very fragile and easily damaged. If a permanent blocking out is desired, black varnish or an opaque (red or yellow) water or oil colour may be used. Negatives that contain a large expanse of sky can be quickly done by going round the fine parts on the film side to a depth of, say, a quarter of an inch, with a fine camel's-hair brush charged with thick vermilion water colour, and then pasting on the glass side a piece of non-actinic paper which will cover the paint on the film; this, of course, can be ascertained by looking through the negative.—RICHARD PENLAKE in *Photographic Scraps.*

ROYAL PHOTOGRAPHIC SOCIETY.

NOVEMBER 17,—Photo-mechanical Meeting,—Mr. W. Gamble in the chair.

COLLOTYPE TILES.

Mr. SNOWDEN WARD exhibited specimens of collotype printing on tiles, the work of Mr. G. H. Grundy, of Derby, produced by making four or five printings in immediate succession from a collotype plate. He said there had been

in the past some difficulty in getting a really satisfactory and economical method of working vitrified enamels by photo-mechanical means, and, in order to achieve good results, Mr. Grundy carefully selected a "biscuit" sufficiently porous to take up the grease of the ink, and leave it immediately in a condition to receive another printing, the ink being composed of ceramic colour in a vehicle.

Successful Half-tone Illustration.

Mr. Eddington read a paper with the above title, prefacing it with some remarks upon a statement in a photographic contemporary to the effect that in the photographic, and also in the drawn, illustrations of the popular magazines "the pictorial quality of the pictures seems to be a matter of small importance; so long as the cuts are there, the demand is satisfied." He said this was a sentiment to which he—and, he thought, his audience also—strongly objected, because the state of things indicated was the very opposite of what they would wish to be the case. It was an extremely low level on which to place the pictorial work of the present day, and if it could not be raised above that level it had better be thrown over altogether. Proceeding with his paper, he said that the prevailing second-rate quality of English half-tone work was due to failure in three important points: first, the total lack of cohesion or mutual co-operation between the allied trades; second, the fact that process workers had not a clear idea of what they were aiming at, each having his little ideal without realising that substantial success could only be secured by striving to attain a common end; and, finally, a lack of enthusiasm—ambition was generally a negative quality, and men were content so long as the week's work produced a week's pay. All this must be changed before successful half-tone illustration could become the rule rather than the exception. The first step towards improvement must be to awaken slumbering ambition, and then the standard must be set up of a high ideal; process workers must be artists, and must aim at reproductions which should have all the qualities of works of art. It was by no means sufficient to suppose that a good photograph must be a good picture. For illustrative work, either much of the photograph must be taken out of focus, or the negative must be treated in some way to destroy offending detail, and he noticed with pleasure that this principle was practised by some photographers. A picture was an attempt to represent an impression, and, unless it made clear what that impression was, it failed as a work of art. Many instances of failure in the production of good blocks might be directly attributed to the lack of understanding between engraver and printer, and it would be easy to effect improvement by mutual co-operation.

Mr. Snowden Ward thought that, for artistic work, it was necessary to set one's face against art papers, and to endeavour to perfect the super-calendered paper.

Mr. T. Bolas drew attention to a very good print from a Pretsch block, issued as a supplement to the Society's *Journal* for November 15, 1860.

Mr. F. W. Jackson thought that, as leading photographers produced their best results on matt-surfaced paper, an effort should be made to get blocks which would print on a similar paper.

The Chairman said it would probably be impossible to print on rough paper so long as screens were use in making the blocks.

Mr. Bolas pointed out that smooth paper was not necessary for Pretsch blocks.

The Assistant-Secretary (Mr. R. Child Bayley) thought the Society was much indebted to Mr. Eddington and others, who called attention to rash statements made in various publications, and pointed out their inaccuracies. With reference to the passage quoted by the author of the paper from a photographic periodical, he suggested that it would have been strikingly accurate if, instead of referring to quality of illustrations, it had referred to the quality of the letterpress in some photographic publications.

The Chairman suggested that advantage might accrue from working experimentally at some of the old processes, such as that of Pretsch, and that it might be possible, by their aid, to produce results in advance of the work of the present day. The printer had to contend with a very grave difficulty, owing to the variation of inks and papers supposed to be identical; as to paper, a white glazed paper was an absolute necessity. Striving after an ideal was an excellent thing, but did not always pay, though if the public could be brought to believe that the best-work was the cheapest, and to pay for it accordingly, it would be all the better for the process worker and the printer. He thought it was distinctly outside the province of the process worker to tamper with originals for the purpose of eliminating excessive sharpness or aggressive detail, and, indeed, artists and photographers would probably strongly object to the adoption of such a course.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

November 12,—Mr. E. J. Wall in the chair.

Mr. A. Haddon read a paper entitled,

A Criticism on the Theory of Development as Advanced by Mr. Banks.

Considerable interest was evinced in the various arguments introduced by Mr. Haddon, and a lengthy discussion followed, in which

Mr. T. E. H. Bullen, referring to a print by Warnerke's wash-out process, produced and shown by Mr. Haddon, said he he had been unsuccessful in his attempts to get a print on the occasion of his recent paper. Warnerke distinctly said in his instructions that, with over-exposure, your image would be insoluble, while, with under-exposure, it would wash away, and this was his experience. According to Warnerke, the amount of exposure to light was decidedly a factor in the degree of solubility of the gelatine.

Mr. C. H. Bothamley dealt at some length with Mr. Haddon's paper, in which he thought there was more than one loop-hole by which he could be attacked. He agreed with Mr. Haddon as to what probably went on during the reduction of the exposed silver bromide. Regarding the formation of the sub-salts of silver, Mr. Banks, he understood, had said the sub-bromide had only been prepared by Guntz, but that was not in accordance with the facts, amongst others concerned in the production of these sub-salts being Otto Wiener, by the Guntz method, and several others. As to the action of bromine on gelatine, this could be easily seen for oneself by taking a solution of gelatine and dropping in bromine, when an insoluble precipitate would be formed. There was good reason to suppose that the gelatine of the present time was of a different composition or nature to that with which experimenters of years ago had to deal, and this might account for differences in the observations to be found. At any rate, we know it was prepared differently then to now. With reference to the electrical theory of development, and the many other effects similarly explained, he thought it was generally the case that, when an experimenter came to a problem which he could not understand, he ascribed it to electrical action. But so doing did not solve the problem, and only styled the action by a new name.

Mr. R. Child Bayley said that, in speaking of the effect of exposure on the sensitive plate, Mr. Haddon had stated that what holds good for a short exposure should also hold good for a long exposure. But we know this is not the case. We know that the effect of a long exposure, if it be long enough, is diametrically opposite to that of a short exposure. The final result is totally different. He mentioned, in connexion with the action of bromine on gelatine, that it was well known to be impossible to recover the gelatine itself after such a chemical combination, a compound being obtained which was more or less soluble than pure gelatine. A point which bore out Mr. Banks's theory was that, so far as he was aware, it was absolutely impossible to so expose a dry plate that the whole of the bromide shall be in a developable condition, some portion of the bromide invariably remaining in an undevelopable state. To him an electrical theory had a great fascination.

Mr. Haddon, replying, said he was glad Mr. Bothamley supported his theory as to the sub-salts of silver. He thoroughly believed that bromine combined with gelatine, and for this reason, that bromide of silver was much more sensitive in gelatine than in collodion, where there was nothing to combine with the bromine. In reply to Mr. Bayley he said, if he knew how to treat plates before exposure, he could avoid reversal, and he hoped to show how to so treat plates with this view.

PHOTOGRAPHIC CLUB.

November 11.—Mr. Crofton in the chair.

Mr. Donald F. Burrage was elected a member of the Club.

Attention was drawn to the statements in The British Journal of Photography regarding the attitude of the insurance companies towards acetylene gas.

Mr. Crofton pointed out that, in case of an infringement of the conditions of a policy, the insurance became void. The only safe way to renew the insurance was to give up the old policy of insurance and take out a fresh one. In law a policy once voided was always voided.

The Secretary having pointed out that the last meeting had inadvertently omitted to thank the Auditors for their services, Mr. Fry proposed that the thanks of the Club be accorded to Messrs. Bedding and Carter, and this was carried unanimously.

A selection of slides, comprising views of Continental and English scenery, was passed through the lantern by Mr. Welford.

Croydon Camera Club.—November 11.—A public lantern show, held at the Braithwaite Hall, drew a densely crowded audience. The first part consisted of some refined "gleanings" from the collection of Mr. Edwin Dockree, who explained his very varied slides with many curious and "informative" remarks, following which were a number of snap-shots representing incidents connected with the royal visit to Croydon on May 19, when H.R.H. the Prince of Wales opened our stately Town Hall. The slides, picturing the above memorable series of ceremonies—which were entirely the work of members of the Club—numbered about one hundred, and were most of them commendable examples of photography applied to recording fleeting incidents. First were shown the decorated streets, being mostly views taken in early morning, before the crowds were about. When naming the above, Mr. Hector Maclean evoked quite a little storm of applause by exclaiming, *apropos* the Whitgift Hospital, "May it never be removed to fill the greedy coffers of the Trustees." Following the above were a series picturing the procession, many of these "bringing down the house," special favour being bestowed on "the brightest carriage-load of all," depicting the Misses Edridge. Chief enthusiasm was, however, reserved for the portrait of Mr. Alderman F. T. Edridge, who could not but feel gratified by the unmistakable esteem and regard in which he was held by the audience. Some street-scene incidents concluded the snap-shots, which were followed by a truly admirable collection of slides, picturing the interior of the new municipal buildings. To particularise is hardly possible, but we may remark upon the well-photographed reproductions of Mr. Roscoe Mullin's sculptured panels, the interior views of the Braithwaite Reading Hall, the grand staircase, the council chamber (all by Mr. G. W. Jenkins), and the interesting record of "the machinery which orders our moments," viz., the clockwork which drives the hands of the great clock (by Mr. A. E. Isaac). The foregoing series of slides were by the following members:—Messrs. Victor Bender (Bender & Co.), Maclean, Whiteman, H. E. Holland, A. Jenkins, J. Noaks, A. J. Noaks, Watson, Rogers, G. Corden, Kough, Costar, Underhill, and G. W. Jenkins, of whom the last two were the largest contributors, Mr. Underhill's snap-shots being very well received, and Mr. G. W. Jenkins's interiors and snap-shots being both greatly admired. Another whose work stood well out for both quantity and quality was Mr. H. E. Holland, the ever-energetic Hon. Secretary.

Leytonstone Camera Club.—November 11, Dr. Turner in the chair.—Mr. F. W. Watts gave a demonstration on

Lantern-slide Making.

After showing the methods of obtaining various tones by means of exposure and development, a most interesting method of putting in skies by means of the

ferricyanide reducer was shown. Having exposed a variety of foregr und, and likewise sky negatives, he next proceeded to, by taking the slides out of the washing water, and, obtaining suitably lit clouds for his various foregrounds, placed the back to back films outward, and with various strengths of the reducer gradually painted away that which was not required, and blending them together while still wet, and, when dry and film to film, a most satisfactory result had been obtained. After answering a volley of questions upon the subject, a most interesting and instructive evening was brought to a close.

North Middlesex Photographic Society.—November 16, Mr. H. Smith in the chair.—Mr. CHILD BAYLEY gave a lecture entitled

CHEMICAL SYMBOLS.

He described what constituted the molecular weight and the atomic weight, and the value of the elements, illustrating his remarks by diagrams and formulæ on a blackboard. He showed that chemical symbols meant a great deal more than was apparent at first sight, namely, that H_2O meant that hydrogen was combined with oxygen in the proportion of one to eight, as the atomic weight of hydrogen was one, and that of oxygen sixteen; also that oxygen was divalent and required two atoms of hydrogen to satisfy it. He also explained the difference between ferrous and ferric salts. In the first, iron was divalent, and in the latter quadrivalent, producing salts totally different in their effects. Mr. Child Bayley, at the conclusion of the lecture, presented to the library a volume of *The New Chemistry*, one of the "International Scientific Series." A hearty vote of thanks to the lecturer concluded the meeting.

Hastings and St. Leonards Photographic Society.—November 13.—The members and friends spent an enjoyable evening in seeing and criticising some prize slides. There were over one hundred, and some of them, particularly amongst the Architecture and Figure classes, showed considerable merit. Dr. Gray, the President, announced the titles, the lantern being worked by Mr. A. Brooker, the Secretary. At the next meeting (December 7) the late President, and former M.P. for Hastings, Mr. Wilson Noble, will give a lecture and demonstration *On the Röntgen-ray Photography*, for specimens of which he has just been awarded the medal of the Royal Photographic Society. The general public will be admitted, and the proceeds given to local charities.

Newcastle-on-Tyne and Northern Counties' Photographic Association.—At the Ordinary Monthly Meeting of this Association, held on November 10 in the meeting room in the Art Gallery, Mr. JOHN WATSON read a paper on

ACETYLENE—THE NEW GAS [see page 746].

illustrated by a demonstration of the use of acetylene in the lantern. There was a good attendance of members and friends. In his very practical and interesting remarks, the lecturer considered this light very suitable for professional men who, using a portrait lens, got a fully exposed plate at any time, no matter what the atmospheric conditions might be, with an exposure of about four seconds. He contended that in the very near future acetylene gas will be largely used for the purpose of lantern illumination. The light, which at the present time is largely used, is intensely white, in burning it has no smell, is absolutely safe, and, if not as good as the lime light, is very nearly so, and when once lit up it requires no attention. He claimed for the light great advantages. It gives no carbonic oxide, and frames and decorations in a room are not affected by it. It is steady, nearly smokeless, and well diffused—practically the same as sunlight. Mr. Watson gave many interesting and scientific facts in connexion with the new gas, and stated that, if accidents had occurred with it, it had been whilst experimenting with the gas, and not whilst using it in such a generator as he had used that night, viz., a Thorn & Hoddle's Incanto. During the discussion which followed, several members expressed a desire to see the brass fittings of the generator replaced by steel.

Oxford Camera Club.—The Third Annual Exhibition of members' work was held in the Holywell Music-room on Thursday, November 12, from two till ten p.m. There were 189 entries for competition, certificates being given for the first, second, and commended pictures in the several classes. Mr. Bedding, Editor of THE BRITISH JOURNAL OF PHOTOGRAPHY, kindly acted as Judge. Besides the competition prints were others of special interest lent by members. There were also two stalls of apparatus, one dealing mainly with the purely photographic side, the other being largely devoted to novelties in lanterns and their accessories. The acetylene light was shown in operation, and from time to time the X rays were exhibited, the members attending showing that these have not yet lost their interest. At eight p.m. there was an exhibition of the lantern slides sent in, and the report of the Judge and his awards were read. The meeting closed with a hearty vote of thanks to Mr. Bedding for acting as Judge, and to the ladies who had devoted their time to the decoration of the room.

Wakefield Photographic Society.—November 13.—The Hon. Secretary showed a series of negatives on the Wellington negative paper, together with prints and lantern slides from same. The absence of grain and freedom from halation especially shown in the church interior, with the east window of clear glass, were much commented upon. The HON. SECRETARY then gave a lecture on

ENLARGING,

first dealing with making enlarged negatives for carbon or other printing methods; he then proceeded to describe direct enlarging upon bromide paper, winding up by making two 15×12 enlargements upon Wellington paper, developing with amidol.

FORTHCOMING EXHIBITIONS.

1896.	
Nov. 20	Hackney Photographic Society. W. F. Fenton-Jones, 12, King Edward Road, Hackney.
,, 26, 27	Romford and District Photographic Society. A. John Ormiston, 4, Laurie-square, Romford.
,, 30-Dec. 1, 2 ...	North Middlesex Photographic Society.
December 3, 4.....	Aintree Photographic Society. E. P. Heron, 2 Tilney-street, Orrell Park, Aintree, Liverpool.
,, 29-Jan. 2.	Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.
Dec. 1896-Jan. 1897	Bristol International. Hon. Secretary, 20, Berkeley-square Clifton, Bristol.
1897.	
January 14, 15	Weymouth and District Camera Club. E. C. Bennett, 10, Newberry-terrace, Weymouth.

Patent News.

THE following applications for Patents were made between November 4 and November 11, 1896:—

HAND CAMERAS.—No. 24,394. "Improvements relating to Photographic Hand Cameras." C. E. PECZENIK.

LENSES.—No. 24,449. "Improvements in the Construction of Great Lenses." J. SAWARD.

IMPROVEMENTS IN PHOTOGRAPHY.—No. 24,555. "Improvements in and connected with Photography." J. EWING and T. R. WATSON.

TRIPODS.—No. 24,684. "Improvements in or connected with Stands or Tripods for Photographic and Measuring Instruments and the like." A. HESEKIEL.

ARC LAMP.—No. 24,685. "An Electric Arc Lamp or Regulator for Magic Lanterns, Search Lights, or Theatrical Purposes." J. BONN.

FILM SEPARATING.—No. 24,722. "Improvements in or connected with Film Separating Devices for Use in Magazine Cameras." A. C. EDWARDS.

CENTERING TRAY.—No. 24,749. "Improved Centering Tray for Optical Lanterns." A. G. SMITH.

CHROMO-PHOTOGRAPHY.—No. 24,817. "Chromo-photography." C. C. BALSTON.

KINETOSCOPY.—No. 24,842. "Improvements in Apparatus for Rapidly Exposing Sensitised Films or Projecting Views." R. J. APPLETON.

PAINTING PHOTOGRAPHS.—No. 24,982. "Method of Preparing Photographs for Painting in Colours." Complete specification. A. E. DUNN.

Correspondence.

☛ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

AMMONIA IN EMULSION.

To the EDITORS.

GENTLEMEN,—In the JOURNAL of the 6th, there is a paragraph seeking information of the date when ammonia was first used in the manufacture of bromide emulsion. I presume that some one is writing up the history of the matter and is anxious to fix the date.

From the fact of there being no response in the succeeding number, I am induced to mention an incident bearing on the case. When I was associated with Maudsley in 1880, a great number of the plates sent out were returned giving red fog. I mentioned the circumstance to Mr. Henderson, and he informed me that he was experimenting with ammonia, and he felt sanguine that it would prove a remedy. Whether the idea was original I am unable to say.—I am, yours, &c. F. YORK.

67, *Lancaster-road North Kensington W. November* 16, 1896,

TONING GELATINO-CHLORIDE PRINTS.

To the EDITORS.

GENTLEMEN,—A few week ago the audacious operator boasted that he knew a formula to tone gelatino-chloride paper quicker than the old albumen paper, but he did not give the method. I know plenty of printers would like to know a reliable way of toning. As a rule, the combined bath is looked upon suspiciously, and the sulpho bath is not much better and too expensive. The following toning formula I have used for upwards of three years with success:—

Wash the prints in one or two changes of water, then tone ten minutes in solution:

Formalin	1 drachm.
Water...	8 ounces.

Wash again in one or two changes of water.

The formalin does not interfere in the least with the toning.

Tone in the following bath:—

B.	2 ounces.
U.	½ ounce.
St.	½ ,,
G.	1 ,,

This solution is to be made up one quarter of an hour before using it in the named rotation, shaking well after each addition.

St. can be omitted in the winter time, or if the paper is fresh, as it does not interfere with the tone.

Make the bath up for the whole amount of sheets to be toned.

The prints will turn in this bath orange-red, and even appear stronger, then return to the original strength, and, if the high lights look clean, and the colour is about like a finished albumen print, the toning is finished. Time required, about two or three minutes; even quicker if your paper is in good condition. Don't attempt to tone bluish, or your print will be over-toned, and appear dirty yellowish. Move the prints well in the toning bath, and rinse well after, or stained prints will result. Judge the tone from the surface, and not by transparency, as the uranium gives you ample range of colour. If that change to red does not take place with your paper, don't use your bath or change your paper. One grain of gold to the sheet is required, not more.

Stock Solutions.

B.

Borax	4 ounces.
Water (ordinary)	80 „

Dissolve hot, but use cold.

U.

Nitrate of uranium (in sealed tube)	1 ounce.
Water (distilled)	35 ounces.
Nitric Acid	½ ounce.

Keep in the dark, and don't expose to the light.

St.

Nitrate of strontium	1 ounce.
Water (ordinary)	30 ounces.

G.

Chloride of gold	15 grains.
Water	15 ounces.

If this way of toning is of value to my fellow-workers, I shall be pleased.—I am, yours, &c., OTTO PFENNINGER.

MORE SALON-IC ETHICS.

To the EDITORS.

GENTLEMEN,—Mr. Maskell's reply is as disingenuous as I expected. He says I have transferred my correspondence from himself to you, but he does not say why, viz., because it was impossible to extract a reasonable reply from him, and, after the letter quoted last week, impossible to get one of any sort from him, though I gave him due notice that I should write to yourselves if he refused to reply.

Mr. Maskell says it is not a fact that I have ever been invited to exhibit at the Salon. May I ask you, sir, what interpretation you would put on the unasked receipt of an entry form from the Salon?

I have never asked the Salon for an entry form or for an invitation to exhibit. For the last two Exhibitions I have received, unsolicited, the ordinary entry form, and this, I take it, any ordinary person would accept as an invitation to exhibit. Will Mr. Maskell publicly state what the Salon's invitation really consists of, if not in their voluntary sending out entry forms to workers of their own selecting? (Mr. George Davison personally had the form for the first year sent me.)

Mr. Maskell says the pictures referred to were not sent by him or by his instructions: a quibble, as doubtless they were sent by Messrs. Dicksee, acting on general instructions from the Salon. If not, why are they allowed to do as they like with pictures intrusted to them? What is a Secretary for but to control this? I, of course, have no receipt from Mr. Maskell for the 2*s.* paid, but does Mr. Maskell thereby mean to imply that I am stating that which is not true when I say that sum was paid on delivery of the pictures? I shall be extremely glad for him to be quite explicit on this point. He knows that 1*s.* per picture is the fee for the return by Messrs. Dicksee of uncalled-for-pictures; then, why this further quibble?

Since writing to you I have heard from Boston, and my friend Day is puzzled and vexed. He knew he had sent two pictures, yet he has received a rejection notice for three. This shows more mistakes by Mr. Maskell or his clerk; two were rejected, not three. It also shows how much better Messrs. Dicksee read the entry forms. *He* sends the rejection forms to America, *they* send the pictures to me, both from reading the same entry form, and *I* have to pay two shillings for the mistakes, besides putting up with the Hon. Secretary's discourteous and unreasonable behaviour.

Another mistake of Mr. Maskell's. No entry form was sent to Mr. Day, though he is a member of the Linked Ring at their own invitation; he tells me he is puzzled at not receiving it, as he had some new work he wanted to send—out-door studies of the nude—but, as he knew nothing as to dates, &c., he could not send. He has since given me the two studies he intended sending, and I can assure Mr. Maskell the Salon's walls lost two charming exhibits through his carelessness in not giving his foreign members due notice and entry forms.

It is a matter of indifference to me whether Mr. Maskell replies to this or no, now I have made public his peculiar ideas as to the behaviour due from him as an Honorary Secretary, to say nothing as to that looked for from the ingenuous gentleman.

I still, however, grudge the Salon my unrighteously exacted two shillings, and shall not be satisfied until I receive it and am able to pass it over to what local poor-box they may prefer.—I am, yours, &c.,

19, *Buckingham-street, Adelphi, W.C.*, FREDERICK H. EVANS.
November 14, 1896.

PHOTOGRAPHY AND POLYTECHNICS.

To the EDITORS.

GENTLEMEN,—I have read with interest an article by Mr. John A. Randall in your issue of November 13 on the above subject, and, whilst I consider that the question of photography as taught at polytechnic institutions needs ventilating, I think some of the statements made by this particular writer are incorrect, and the deductions he draws therefrom correspondingly false. In his opinion polytechnic institutions have left their proper position by not confining the classes to actual apprentices and journeymen wishing to learn the technique and scientific principles underlying their trade. As far as I can ascertain, this is still to a great extent the case; but, if other persons, for reasons of their own, desire to enter a course of study, the polytechnic would certainly gain nothing by refusing to accept them as pupils, nor can I see that the genuine apprentice suffers in consequence. As to the question of twelve months' polytechnic instruction, or cramming, as he terms it, taking the place of several years' apprenticeship, it is hardly likely that it would be expected to do so, excepting in the case of a naturally gifted man; but that it should shorten the term of apprenticeship, and oil the wheels of practical manipulation, is both right and desirable.

He goes on to complain of his own course of instruction, and holds it up to ridicule as not being sufficiently practical. "Hardly a subject having a close relation to every-day matters was studied," he says; but is not this an erroneous view of the matter, brought about by the pupil failing to sufficiently apply the theoretical knowledge he acquired to practical use? There are some men who cannot see the application of principles; and, if, for example, an astigmatic lens should be put into their hands, and they were asked to do some copying with it, they would most likely blunder on without being able to assign the cause of failure to produce sharp results, although the faults of astigmatism had formed a part of their early instruction.

Finally, he alludes to the etiquette of the studio being impossible of acquirement at the technical school. It should hardly be necessary to teach ordinary manners at a polytechnic institution, and the particular etiquette of any one establishment ought to be acquired by any sensible youth in a day. The example Mr. Randall gives of the boy who shouted "Come on" to the lady at the door of the studio is ludicrous enough; but it gives rise to the questions, "Had the youth a mother? and, if so, why did she not teach him elementary manners before he left his home?" Neither the professional photographer nor the polytechnic institutions ought to be called upon to teach our young men common sense and common politeness.—I am, yours, &c., MATTHEW SURFACE.

Bradford, November 16, 1896.

A TECHNICAL EXHIBITION.

To the EDITORS.

GENTLEMEN,—Thanks for your article re *The Future of Photography*. It appears to me that one Exhibition with two sections, as suggested, would be better than having two Exhibitions. Those travelling from a distance would find it more convenient. Other branches of allied work should be represented; the workers would be interested and helped by the exhibits, and will pay their shillings freely to get a notch or two in their own way.

Pleasant pictures pay best; and, if photographers can be assisted by the exhibition of technically good ones to produce satisfactory ones themselves, they, too, will go and pay to see.

All praise to those who help us on in any one direction, and, if by broadening the base more co-operators could be secured, of course more funds would accrue to the Society, and the greater would be its influence and usefulness.—I am, yours, &c., W. GIRLING.

Strathbroke, November 10, 1896.

UNFAIR COMPETITION.

To the EDITORS.

GENTLEMEN,—Some great upholders of Trade Unionists, short hours, and living wage, in the London Press, have, after denouncing various firms and trades for cutting and under-selling their smaller brethren, themselves entered into competition with the photographers of London and district by advertising to supply for 6*s.* 6*d.* what they term a three-quarter life-size crayon and India-ink portrait, packed and sent, carriage paid, to any reader, and also state that they are equal to those supplied by artists at from two to four guineas. Now, all photographers know perfectly well that a photograph cannot be copied and the negative retouched, and an enlargement made and worked up in crayon

and India ink, at the price mentioned, unless one or two things happen, either the workmen are over-worked or under-paid, *possibly both*. As a slight retaliation, I would suggest that all photographers and their assistants, especially those dealing with the working classes, endeavour to persuade their friends, &c., who at present do so, to discontinue taking in the papers, and any photographer who is a member of a club or institution should endeavour to get the papers removed from the reading rooms, &c., of such places, not that the loss of a few subscribers would materially hurt them, but it would at least show up the character of these great organs of *fair play* and denouncers of "black legs" and those who adopt cutting tactics in business.—Apologising for the length of this letter, I am, yours, &c., A LATE "STAR" READER.

To the EDITORS.

GENTLEMEN,—As your readers may be proud of having discovered the cheapest offer for *artistic* enlargements, I beg to send you herewith an advertisement as published in Paris in a halfpenny newspaper, which offers an enlargement, same as your English newspaper, for the reasonable sum of 4*s.*, instead of 6*s.* 6*d.*, as in London.

As a matter of curiosity I went to see the firm, which appeared to have opened shop for this special occasion. I was shown some pretty poor samples of enlargements, *all* framed, and having less size than that advertised, being only half life size. The price of 4*s.* was not mentioned, but I was at once shown the cheapest framed portrait, which was 12*s.*, with a beautiful 2*s.* frame around it. Upon my insisting upon the 4*s.* portrait, I was very reluctantly told that it would be made, but could only be delivered after two or three months, while the framed ones only took two or three weeks; "but we would rather furnish them framed," was added.

Now, I have not seen the advertisement as published in the English newspaper, but I would not be astonished if it were worked similar to the enclosed one, and you will see that, at first sight, it appears to be an enterprise of the newspaper, which it is not, if you read it all. The money is to be sent to the photographer at his own address, so that the newspaper has nothing to do with it, and that advertisement is exactly the same as any other one from another firm selling goods at reduced prices. It offers *to the readers of* ———, for the small amount received with the photograph to be reproduced, an enlargement, &c. So that the offer is made by the firm mentioned to the readers, and not by the editor to his subscribers, which is quite different.

But how about the photographer that offers and does the work!—I am, yours, &c., TREDLA.

November 14, 1896.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2, *York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

Frank Reynolds, 29, High-street, Bognor.—*Photograph of high sea at Bognor.*

William Blake, 74, Midland-road, Bedford.—*Photograph of Samuel Whitbread, Esq. Photograph of Lady Isabella Whitbread.*

RECEIVED.—J. W. BENNETTO; H. W. BENNETT; PHOTIQUE-ART; INQUIRY; HERBERT SWAINS; ONE IN DOUBT; R. W. WICKS; SPARTAN; ARTHUR & CO.; HENRY & CO.; H. J. BUCKLAND; GIBSON & SON. In our next.

A. MARLOW.—See the JOURNAL of August 23, 1895, in which the author of the Tables has an article on the subject.

FIXING.—N. E. W. says: "I am using a saturated solution of hyposulphite of soda for fixing wet plates. Would it do to fix dry plates in the same solution?"—In reply: For dry plates six ounces to one pint is the definite strength usually employed.

HARDTMUTH'S PENCILS.—ARTIST says: "Could you inform me where I should be likely to obtain Hardtmuth's Negro pencils. I have tried Marion's, Houghton's, and one or two artists' material dealers, and have been unable to procure them. If you can help me, I shall be much obliged."—In reply: Try Messrs. Hardtmuth themselves at 12, Golden-lane, E.C.

EMPLOYMENT IN CAPETOWN.—CAPER says: "1. Is there any demand for good retouchers at Cape Colony—preferably Capetown—in high-class houses? 2. Are wages good? 3. Is there any difficulty in obtaining situations in that part?"—In reply: 1 and 2. Generally speaking, our information leads us to suppose that, for really able men, South Africa offers excellent opportunities. 3. Possibly not greater than at home.

MERCURIAL INTENSIFICATION.—G. PRESTON says: "Give me some idea as to how to proceed with intensifying with mercury and blackening with ammonia. I mean as regards quantity and method."—In reply: The negative having been well washed to free it from hypo, bleach it with a saturated solution of bichloride of mercury. Wash well, and then blacken with aqueous ammonia—say half a drachm in ten ounces.

COLOURED PHOTOGRAPHS.—A. M. says: "Can you give me the name and address of firm that executes the coloured view photographs that are now exhibited in most of the municipal towns? I refer to the whole-plate views of Canterbury Cathedral, Hastings, and Cambridge views, &c. In the latter town they are sold for 1*s.*, mounted! At the back there is a remark, 'Not coloured by hand,' &c., but name is not given."—In reply: The pictures referred to are probably those produced by the Photochrom Company, whose address is 63, Ludgate-hill, London, E.C.

DAYLIGHT *versus* OIL FOR ENLARGING.—G. M. says: "I should be pleased to have opinion on following. I do a lot of enlarging on bromide paper, and have occasion to produce several from the same negative. I use daylight. Suppose I got a lantern with oil light, and using rather thin negatives to suit, would the results be as good as daylight? Assuming correct exposure in each case, would the lantern enlargement be so much inferior in quality as to be very apparent?"—In reply: We see no reason why enlargements made by artificial light should be qualitatively inferior to those made by daylight.

ALUM AND P.O.P.; INK STAINS.—S. PORTER asks: "Will you be good enough to inform me on the following two things? 1. Does the use of ordinary alum for hardening P.O.P. prints diminish the detail of such prints? 2. I have, unfortunately, let a large spot of ink drop on a bromide enlargement. Is there any means of getting it out?"—1. We have not found it do so in our own practice. 2. It is very doubtful. There are so many kinds of ink, all of which differ in their composition. If the ink be the old-fashioned kind, made with nutgalls and iron, it is possible that oxalic acid, carefully applied, will reduce, if not remove, the stain.

COLOURING PRINTS.—COLOURIST writes: "Will you kindly tell me of any books on finishing bromides in oil and water colour, and names of publishers with addresses? Water colours lay so very uneven on bromides; is there anything which would harden the film so that wet water colour would not affect it?"—There are no works published on finishing bromide pictures that we are aware of. There should be no difficulty in applying water colours to bromide prints. If the surface is found at all repellent, that may be overcome by washing over with diluted oxgall, as supplied by 'artists' colourmen; or by going over the paper, lightly, with an ink-eraser.

ELECTRIC LIGHT.—E. B. says: "Where can I obtain electric lamps for portraiture? Do they admit of instantaneous exposures as required in baby photography? Can you tell me any studios in London where I may see them in operation? and how many lamps are required, and the probable cost per lamp?"—In reply: Arc lamps may be obtained of Messrs. Gwynne & Co., Brooke-street, Holborn, E.C.; incandescent lamps of Messrs. Adamson & Co., of 18A, Eldon street, Finsbury, E.C. Exposures short enough for your purpose may be obtained with either system, using sufficient power. Both firms will give you full particulars as to cost, and also let you know where the lamps may be seen.

A QUESTION OF PERMANENCE.—G. ADAMS says: "If a firm offers to supply for 6*s.* 6*d.* an absolutely permanent enlargement, and then send a bromide enlargement, which is not permanent, can I safely return it and demand a permanent one, such as a carbon or platinum enlargement? The above offer, which, no doubt, you have seen, appears in the *Star* and *Morning Leader*."—In reply: You seem to suppose that a bromide enlargement is, of necessity, not "permanent." We do not agree with you any more than we should if you said that albumen prints were not permanent. Both kinds of prints, if properly prepared, will remain unaltered for many years. However, answering your question, we should say, No.

BACKING.—A. SQUIBBS says: "Will you kindly tell me the best way to photograph a stained-glass window? I must state that it will have to be done with a wide-angle lens, which I find produces far more halation than an ordinary rapid rectilinear. I have already done it, but, as I photographed it in the twilight to avoid halation, the inside of the church walls, including brass tablet close to window, is very black. I do not find backing a plate always successful; when it is so, I notice that the negative is just as good without backing. What is the best material to use for backing?"—In reply: The following backing mixture is as good as any, and, if employed in conjunction with a thickly coated plate, should yield good results: Gum solution (ordinary office gum), 1 ounce; caramel, 1 ounce; burnt sienna, ground in water, 2 ounces; mix, and add alcohol, 2 ounces. As to the halation produced more by one lens than another, we presume both lenses were not stopped down to equal apertures. Theoretically, *all* negatives are improved by backing.

TONING P.O.P.—PRINTER writes: "Will you please give me a reply to the following queries? 1. Will it be an advantage to wash P.O.P. prints, after taking out of alum, as thoroughly before toning as in the final washing? 2. Will it be a great advantage to have the prints washed after toning and before fixing with the same thoroughness also as the final washing? I have ample facility and convenience for doing both, if any advantage; the latter I am thinking of trying in any case, as we find that the P.O.P. prints do not entirely stop toning even when placed in a salt bath, and we think that they will be likely to stop if dropped as toned into a print washer in action, taking out in batches as required for fixing; and kindly make it clear whether you intend your reply to apply to silver prints as well."—In reply: 1. All that is necessary is that the alum is washed out; further washing is of no good. 2. It is not necessary, so long as the toning action is suspended. If the salt bath does not do that, the best way will be to take the prints out of the toning bath a little before they acquire the tone desired. The treatment proposed will do no harm. P.O.P.'s are silver prints. If you mean prints on albumen paper, the proposed extra washing will be harmless.

*** Several answers to correspondents unavoidable held over.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1908. Vol. XLIII.—NOVEMBER 27, 1896.

Contents.

EX CATHEDRÂ.

An order for 10,000,000 photographic prints is sufficiently large to deserve notice. Numerically the order has probably not been exceeded, and, although each individual print is to be of such dimensions as to allow of its being placed on a box containing cigarettes, the total area of sensitive surface required to be employed is obviously so great as to suggest that in this respect the order also ranks as, what it is the custom to term, a "record" one. A German photographic printing house has been intrusted with the execution of the reproductions, the gelatino-bromide paper process being adopted for the purpose.

* * *

With reference to our leaderette of last week (p. 739) stating that Herr Arthur Schwartz, of Berlin, had adopted Mr. Friese Greene's rapid bromide printing machine, Herr Schwartz informs us that this is not the case. The machinery employed by him at his photographic printing works was devised and patented several years ago. It is fully described and illustrated at p. 831 of our Almanac for 1896, and also in this Journal of August 31, 1895.

A country photographer writes, drawing attention to a report in our issue of November 13, of a serious explosion at Grimsby in using acetylene for portraiture. "It seems to us," says our correspondent, "from the report, that the gas was used as made from a generator. We are contemplating giving acetylene a trial for artificial light portraiture; but, if that sort of thing is likely to take place, we shall fight shy of it, and rather use the incandescent light. Can you," he asks, "suggest how the accident happened, and whether you think acetylene safe to take up after the accident reported?"

* * *

We give our correspondent's inquiry prominence here because it is typical of many that have reached us on the same subject. In the absence of definite information, we are unable to advance an explanation of the accident; but it has been suggested to us that the explosion may have been due to the admixture of air in explosive proportions with the acetylene, a contingency that may be averted by, so soon as or before the gas commences to generate, opening the taps and allowing the air to escape. As to our correspondent's other question, we look upon acetylene as being just as safe to use as as ordinary house gas. The accidents that have taken place abroad with the compressed gas, and the attitude of the insurance companies, in refusing to grant policies on premises where it is used as generated, have in our opinion been productive of a great deal of unnecessary alarm in reference to acetylene.

* * *

The sources from which calcium carbide can be obtained in large quantities have brought us several queries similar to the following:—"Can you tell me whether the carbide of calcium at present on the market is made in England or imported from America? I ask with the view of buying it regularly in large quantities to sell again. If you can assist me with the address of any makers you may know of, I shall esteem it a favour." The carbide is produced, we believe, both in America and Germany; but it is said that it may be purchased in large quantities of the Acetylene Illuminating Company, Foyer's Falls, Loch Ness, N.B., who, no doubt, will quote our correspondents if so desired. As to the transmission of the carbide, our article on the next page of this week's Journal will, no doubt, be read with interest by many.

* * *

We had a note last week on Motor-car day, and the unsuitability of the weather for taking photographs of the cars

on their notable journey. It will be gathered from the tone of our remarks that we did not expect to hear of many successful results. Such, indeed, has proved to be the case. However a friend, Mr. H. E. Farmer, who lives at Purley on the Brighton road, sends us a number of prints from hand-camera negatives that he took of some of the cars as they passed. All things considered, the prints are good, and, as they are certainly interesting, we shall preserve them as a memento of what will, no doubt, one day be looked upon as an historical event.

ACETYLENE AND COMPRESSED GASES BY RAIL.

A RECENT query in this connexion by a correspondent not having met with a response from any of our readers, we have been at some pains to ascertain from official sources the conditions the railway companies lay down as to the carriage of calcium carbide, acetylene, and compressed gases generally. At the outset it is very desirable that our readers should be aware that, apart from any question of carriage or exorbitant charge therefor, the railway companies are not what are termed "common carriers," that is, governed by the regulations of the well-known Carriers Act, for there is a special Railway Clauses Consolidation Act, passed in 1845, and an Explosives Act, passed in 1875, which have a special bearing on explosives and dangerous goods, and any contravention of their conditions renders senders of such goods liable to penalties of from 20*l.* to 100*l.*, according to the goods carried and the mode of transit, the heaviest penalty attaching to carriage by sea.

The first point presenting itself for consideration is as to whether any variation of charges or rules is made by one or other of the various companies. The facts in this case are that, first, as to charges, the main companies have a uniform rate of carriage for all classes of goods, particulars of which (with regard to classification only) will be found in a book of nearly two hundred pages, entitled *General Railway Classification of Goods by Merchandise Trains*. It is published annually, and at intervals between the publication of successive yearly volumes supplementary fly-sheets are issued, bearing upon new rates and classification of goods. These particulars refer to goods trains only; but it may be at once stated that no passenger train parcel is less encumbered with restrictions than goods train consignments.

Secondly, as to rules. There is this difference: Some companies decline to carry, under any circumstances, dangerous or explosive goods that are not declined by the majority of lines.

As before explained, the classes are A, B, C, 1, 2, 3, 4, 5, the first-named being the cheapest for large quantities, the last-named being the dearest.

We shall find that in the 1896 volume there is no mention of carbide of calcium; its first appearance seems to be in the fly-sheet for August of this year. It is placed in Class 3, and has no minimum charge like acids, so the rate is not expensive. It is less, for example, than the rate for ordinary chemicals or drugs packed in hampers. The chief point is the restrictions or conditions. They are as follows:—"Calcium carbide in hermetically sealed tins, packed in strong wooden cases, or in air-tight and damp-proof iron drums." "Must not be carried in closed vans, and must not be placed in the Company's enclosed sheds or warehouses." Further, there must be a consignment note sent to the railway office, declaring and describing the character of the goods sent, when any dangerous or explosive compound is sent to the *dépôt* for dispatch by rail. The goods to be so declared include compressed oxygen and hydrogen, besides others of no interest to photographers. It will thus be seen that it is a serious and punishable offence, either to send, or to omit to declare when sending, any of this class of goods by rail. Acetylene gas (compressed) does not find any place in the list so far, but there is little doubt that in the present state of public feeling the railway companies would decline to carry compressed acetylene at all.

With regard to compressed oxygen or hydrogen, they are classed as 2, and must be sent "in cylinders of wrought iron or mild steel, containing not more than 0·25 *per cent. of carbon thoroughly annealed after manufacture*, of sufficient strength, and efficiently tested, and the cylinders securely protected by one of the following descriptions of packing:—(*a*) Cylinder in closely plaited hemp or coir; (*b*) Cylinder fixed in ordinary wooden box without lid, but with rope handle; (*c*) Cylinder loose in ordinary wooden box with lid, secured by strap; (*d*) Cylinder efficiently protected by closely woven wicker-work, the valve of the cylinder not to project beyond the wicker-work."

In sending by passenger train, all the above packing and consignment notes' conditions hold good, and calcium carbide would be treated as an explosive, like cartridges, which are not permitted to go by passenger train at all.

As our readers are aware, the prohibition (or panic) circular issued on March 1, 1895, was withdrawn, and a new one issued in its place on May 23, 1895. This latter formulates the rule still obtaining with regard to taking the gas as passengers' luggage. This is entirely forbidden, either as personal luggage taken into the compartment by the traveller, or as part of his luggage in the van. If it is taken by passenger train at all, it must go as a parcel, and be paid for as such, and not more than one cylinder in a parcel. This regulation is objected to by many; but, looking at the matter from the railway companies' point of view, it is a pertinent question to ask what the public would say if an accident again occurred through a careless traveller dropping a defective cylinder?

It will thus be seen that, in regard to the particular class of goods interesting to photographers, the conditions of carriage are neither specially onerous nor costly, but that, in the case of those companies who decline to carry at all, there might, of course, be grave inconvenience. These, however, are few in number, and we will close our remarks by an enumeration of them, remembering that the carbide would come under the head of "explosives."

The East London decline to carry all explosives, Great Eastern ditto, Metropolitan ditto, North London ditto.

The late Lord Leighton's Works.—The forthcoming winter Exhibition of the Royal Academy is to be confined exclusively to the works of its late President, Lord Leighton. The late artist's work is more familiar to the greater portion of the public through the engravings and photogravures of it than by the pictures themselves. Therefore it will be interesting to see how the colours of the originals have been translated into monochrome by the different engravers, and also by photogravure. Different engravers differ materially as to how the various colours, such as reds, greens, and blues, should be represented in monochrome, while some scientists aver that they are all more or less wrong. As all the plates, engraved and photogravure, have been approved of by the late artist before they were published, it will be interesting to many who take interest in orthochromatic photography to note his ideas on the subject.

The X Rays in Paris.—The Paris correspondent of the *Standard*, telegraphs that an examining magistrate in Paris has, for the first time, ordered the use of the X rays in a criminal case. It appears that, on the 1st instant, a pseudo-anarchist attacked two *sergants-de ville* with a revolver, and wounded one of them in the nape of the neck. The victim was taken to the Charité Hospital, but the bullet could not be extracted, though the man said he could feel the ill effects of its presence. The magistrate therefore instructed Dr. Descouts to employ the X rays in order to determine the exact position of the bullet. It is often said that "they manage things better in France," but we have an idea that in a London hospital, under similar circumstances, the doctors would not wait three weeks for a magistrate's suggestion to bring the Röntgen rays into use?

Acetylene and Fire Insurance.—Arising out of our leading article on the attitude of some of the fire insurance offices with regard to the use of acetylene by photographers, the subject has twice been brought up at the Photographic Club. At the last meeting Mr. Snowden Ward mentioned that he had been in communication with the office in which he is insured with regard to the experimental use of acetylene. As a consequence, he had been waited upon by its risk surveyor, who said that he saw no reason why his office should make any restrictions as to its use, and that he should so report. It was added, however, that his opinion must not be taken then as being formally official. The office would further communicate officially, the result of which we are unaware. If one office should see no "hazardous" risk attending the use of acetylene, there seems no reason why others should do so. It may be mentioned, however, that the office referred to has for some years past treated photographers' risks, in the matter of premiums, far more liberally than the majority of other offices do. That office is the Westminster.

Voided Policies.—*Apropos* of the above, while the subject was before the Club, a very important matter to insurers was pointed out by one of the members (Mr. E. Crofton), namely, that by infringement of any one of the conditions of a policy the insurance would become void, notwithstanding that premiums may subsequently be paid upon it. In law a policy once voided is always void. This is a matter that may not be very well known to the majority of photographers. The conditions of some policies are such that they are often infringed inadvertently in the practice of photography; but, even if the infringement is but temporary, it is quite sufficient to void the insurance. The only safe way, if the policy has been voided, is to give it up and take out a new one. We commend this subject to our readers, as some insurance offices are very prone to raise as many quibbles as they can when claims are made upon them.

Miniature Painting.—The Society of Miniature Painting, whose first Exhibition, in New Bond-street, was held last month, has had the honour of submitting to the Queen a selection of the exhibits there shown. They were also submitted to the Princess Louise (Marchioness of Lorne). The Princess is an enthusiast in art, and has become an honorary member of the Society. It looks very promising for the future of miniature painting that it is going to hold a second Exhibition so soon after the first. It is to be held in the spring of next year. If miniature painting is revived—and there seems a prospect of it being—it should tend, as we said when the Exhibition was proposed, to resuscitate coloured photographs, which, at one period, were a very profitable adjunct to the portraitist's business, and which, no doubt, sounded the knell of the "Miss La Creevy" style of miniature painting. If colouring is again made a prominent feature of in photographic portraiture, it must not be of the kind that, in the majority of cases, has passed as photographic colouring during the past decade. It requires a good miniature painter to produce a high-class coloured photograph.

One reason why, possibly, coloured photographs of the better class fell into desuetude was that they were made on a more or less unstable base—silver prints. People could not be expected to pay several guineas for a coloured picture that, in a few years, would become very materially deteriorated through the fading or yellowing of the silver base. Such conditions do not obtain now, as any of the permanent processes in vogue at the present time are admirably adapted to the requirements of the photographic colourist, and one may fairly assume that no other would be employed where highly finished work is in question, and for which a good price is paid.

The Late Solar Eclipse.—It will be remembered that ill success, through the weather, attended most of the expeditions sent to observe the eclipse of the sun in August last, particularly our own Norwegian one stationed at Vadsö. The observers, conveyed by Sir George Baden-Powell, in his yacht, the *Otaria*, to Novaya Zemlya, were, however, more fortunate. At the last meeting of the Royal Society, Sir G. Baden-Powell, and Professor Norman Lockyer, read preliminary papers—or first instalments of the results obtained by this expedition. It appears that Mr. Shackleton, who was to make spectroscopic observations by photography, was very successful, as he secured twenty-four negatives, sixteen of which were taken during the disappearance of the photosphere, and about half a dozen during the absence of the chromosphere. The coronal ring and its spectrum has thus been represented. One of the photographs of the corona gives a capital notion of the curious aspect of the eclipsed sun. A further communication from Mr. Shackleton himself is promised, which will be looked for with interest. It will be some time yet before all the discussion on the results, short as they are, of what was expected from all the expeditions can be completed.

ALDEHYDES AND ACETONES IN THE PRESENCE OF SODIUM-SULPHITE IN DEVELOPMENT.

Under the above title, MM. Lumière Frères and Seyewetz contribute to the *Bulletin Belge*, a paper giving an account of their researches on the action of formaldehyde and acetone in the developer.

In 1889, Schwartz and Merklin pointed out in the *Photographic Archiv*, 1890, p. 124, that formaldehyde considerably augmented the reducing power of a developer. Quite recently Helheim has used formaldehyde in the pyro developer as a tanning agent, and confirms the above statement.

The authors of the paper point out that it is not the formaldehyde alone which has this action, but that the presence of sodium sulphite is essential for this accelerating action to appear, and that similar alkaline substances, such as acetate and neutral phosphate of soda, have not this power; and, on the other hand, most of the aldehydes or acetones will give the same phenomena as formaldehyde.

The aldehydes or acetones and sodium sulphite can not only accelerate development, but a latent image may be developed with these and a developing agent of the phenol series.

The explanation given by the author is that the phenol forms an alkaline phenate with the alkali of the sulphite, which is then transformed into bisulphite, which combines with the acetone or aldehyde, forming a bisulphite compound. They have proved that the acetone does not combine with the sodium sulphite, and represent what occurs as follows':—

$$2\left(\begin{matrix}CH_3\\CH_3\end{matrix}\right)CO + 2Na_2SO_3 + C_6H_4\left\langle\begin{matrix}OH\\OH\end{matrix}\right. =$$

Acetone. Sodium sulphite. Hydroquinone.

$$2NaHSO_3 + 2CH_3COCH_3 + C_6H_4\left\langle\begin{matrix}ONa\\ONa\end{matrix}\right.$$

Bisulphite and acetone. Alkaline phenate.

It is probably this liberation of the alkali which permits the phenol compound to exercise its developing power. The bisulphite compound could not be isolated.

Various formulæ were tried with hydroquinone, pyro, para-amidophenol and para-phenylendiamine, and the authors state that, although their researches are by no means finished, yet the following developer will give equally good results as when the alkaline carbonates are used:—

Hydroquinone	3 parts.
Sodium sulphite	10 „
Acetone	10 „
Water	100 „

THE THEORY OF DEVELOPMENT.

I.

THE very able and instructive paper on the above subject by Mr. A. Haddon, in last week's issue, is so full of careful argument, and at the same time so exhaustive, that there would seem scarcely anything left to be said in connexion with the points in dispute; but, as the subject is one that of late years has received very little attention, and moreover, will bear a good deal of discussion before it can be said that any really unassailable theory has been established, I venture to contribute one or two suggestions on points which I think are still open to argument.

In the first place, with regard to the tanning or indurating action of development upon the gelatine film, Mr. Banks and Mr. Haddon are at direct variance, the one maintaining that the action results from the bromine liberated during development, while the other holds that it is due entirely to the oxidised pyro solution employed. Mr. Haddon's arguments and experiments certainly go far to prove that his view is the more likely one, but I venture to think that they fail in being conclusive.

I may perhaps be permitted to refer to a letter of mine in these columns on 16th ult., to which Mr. Haddon alludes in his paper. In that letter I mentioned that Mr. Warnerke some years ago attributed this indurating action in the process, and which is so intimately associated with his name, to the "combined action of light and development." From a remark in Mr. Haddon's paper it seems to me that he wishes to pin me to the statement that the result is due to the direct action of light, which is far from my meaning, since that would involve the belief in the sensitiveness of gelatine itself to light. What I meant, and what Mr. Warnerke meant, was that the hardening action arises from the chemical reaction set up by the developing solution upon those portions of the film where the light has acted, and I go no further than claiming light as the *primary* cause, and this Mr. Haddon's own experiments now demonstrate to be true. The only question is one of detail as to how the operation is carried out.

Mr. Banks attributes the hardening to the effect of the liberated bromine, to which view Mr. Haddon takes exception, and I cannot help agreeing with him. As he says, bromine as such is never liberated during development, whatever may be the change that occurs in the silver bromide on exposure. This appears to be absolutely true, since, granting the effect of light is to form sub-bromide of silver, the bromine given off is scarcely likely to have much, if any, action in the dry state of both itself and the gelatine. On the application of the developer, the first action we must assume to be the oxidation of a portion of the pyro, and the liberation of a corresponding equivalent of hydrogen, which instantly seizes the liberated bromine, if, indeed, it be not the actual cause of its dissociation from the exposed silver bromide. Consequently the bromine is never present in the developer in the free state, nor can it be supposed that, in the presence of a large excess of alkali, the hydrobromic acid formed by its agency has more than a momentary existence. It is, of course, possible to imagine that at the moment of occlusion—that is, before the hydrogen has time to combine with it to form hydrobromic acid—the bromine in its nascent condition may act upon the gelatine with which it is in contact; but it is difficult to believe that such a result as the complete insolubleness of the film should be effected in so momentary a manner, more especially if we consider that, in all probability, it is the nascent hydrogen that forces the bromine from its combination with the silver instead of finding it loose and ready for a new combination.

Mr. Haddon makes another point, too, in saying that the acceptance of Mr. Banks's bromine theory involves the assumption that bromine or hydrobromic acid has a stronger affinity for the gelatine than for the free alkali of the developer, an assumption in every way difficult to reconcile with facts.

Mr. Haddon's view is that the result is due to the tanning action of oxidised pyro, which he clearly proves by experiment to possess that power, but in an exalted degree where the light has previously acted, thus confirming Mr. Warnerke's earlier opinion that the effect was the result of the combined action of light and development. So far I am entirely in agreement with Mr. Haddon, and also to a certain extent when he goes on to explain why the tanning action of the oxidised pyro does not take place over the whole surface of the plate, instead of only in the exposed parts. As he puts it, where development takes place, oxidation goes on more rapidly than in the unexposed parts where no chemical action ensues. Naturally, when the reaction is more energetic, the tanning effect may be expected to be more rapid and more marked, and, while it is going on more slowly over the whole surface, it is only in the exposed portions of the film that under proper conditions it becomes practically useful, as in the Warnerke process. Those who are familiar with that process will be quite aware that practice entirely bears out theory, for, if an under-exposed film be developed right out with the same developer, it will be rendered insoluble over its whole surface; whereas, by using fresh developer in which the oxidation has not gone so far, the general tanning action is reduced without lessening the effect in the exposed portion.

But where I cannot help differing somewhat from Mr. Haddon is in attributing the whole of the indurating effect to the "tanning" action of oxidised pyro. True, the oxidation is greater, as has been shown, in the exposed portions, where the hardening effect is also greatest; but is the whole of that greater action due to the pyro, or may it not possibly be to some extent due to direct oxidation of the gelatine? Assuming that the primary action of the developer is to decompose water, and that the hydrogen goes to the bromine of the exposed film, is it certain that the whole of the oxygen goes to the pyro? I know it may be said here, as in the case of the comparative affinity of bromine for gelatine and for alkali respectively, that the free oxygen is far more likely to fly to such a greedy absorber of it as alkaline pyro than to gelatine; but, since a similar hardening effect occurs where no pyro is present, it does not seem unreasonable to suppose that at least a portion of the work done may be due to other causes.

This brings me to Mr. Haddon's explanation at the close of his paper of the hardening action I mentioned in connexion with solarised gelatino-chloride paper, and here I must humbly differ from him *in toto*. In the first place, I have only to use one of his own arguments against him. He attributes the hardening action that occurs in the exposed portions of a gelatino-chloride print to the chlorine liberated from the darkened parts; but which, I would ask, is the chlorine likely to have the strongest affinity for, the free silver in the paper or the gelatine? Without, however, pursuing that argument further, I may look at it from another point of view. The well-known reaction that follows the passing of chlorine gas through a solution of gelatine to which Mr. Haddon alludes in his paper is one thing, but the action of dry chlorine upon dry gelatine is quite another, and it seems to me very questionable whether, even in the absence of free silver, any combination could possibly take place. Perfectly dry chlorine has been shown to have no action upon silver foil, moisture being absolutely necessary before combination can take place; and though, as is well known, a certain quantity of moisture in the film is necessary for successful printing, it is scarcely sufficient practically to set up any such combination, and, if it were, it would be more likely to be with the free silver.

If we want an analogous instance of difference of behaviour in the dry and moist condition of two substances, we have only to turn to albumen. In solution, this is instantly coagulated by heat or by alcohol, but, in the dry state, it is absolutely unaffected by either. This is easily demonstrated by dipping or soaking a sheet of albumenised paper in strong alcohol, and, after drying, redipping into cold water. The film of albumen will be entirely removed. Or pass a hot iron over the paper, using heat enough to almost scorch the paper, the same result will occur on soaking in water, but if the paper be dipped into boiling water, or into dilute alcohol, the film will be entirely coagulated, and will resist any further treatment with water. In the same manner, I think dry chlorine gas, evolved from the film during exposure, will prove equally ineffectual in rendering the gelatine insoluble.

But I will go further than this, and take a gelatino-chloride emulsion in the jelly state, in which condition of moisture all the ingredients or products of decomposition are free to react upon one another. On exposure to light, in a clean glass bottle, the outer layer of emulsion will be found to become quite insoluble, so far as the discolouration may have penetrated. Now, here, I think, it cannot be doubted that the liberated chlorine would go to the silver and not to the gelatine. But one of the results of the interchange of elements would be the liberation of oxygen, which I assume to be the active agent in the absence of pyro.

One other instance strikes me as I write. Some years ago it struck me to utilise the rich, red-brown colouration of a gelatine film after exposure to light for the purpose of making a dark-room window. I accordingly made a solution of gelatine containing silver nitrate, and this was left for several days in strong sunshine, in order to give it as deep a colour as possible; but, on attempting to remelt it, it was found to have become quite insoluble where the light had penetrated, though the centre portion that was unacted upon, or only partially, melted after some time, and came away nearly colourless. Here, then, was neither pyro nor halogen, but simply the probability of oxidation from exposure to light—that is to say, oxygen was liberated by the reduction of the silver nitrate, and this combined with the gelatine to render it insoluble.

Before leaving this part of the subject, I would say that I by no means

disagree with Mr. Haddon on the main part of his arguments, but I offer these suggestions towards explaining some points which his theory does not cover.

W. B. Bolton.

FOREIGN NOTES AND NEWS.

Restrainers.—Concerning the action of bromides, iodides, and chlorides in the developer, J. Von Norath writes, in the *Deutsche Photographen Zeitung*, that the common idea that bromide acts as a retarder is quite incorrect. It is possible that bromide prolongs development, but this condition may be brought about by other factors. Take a highly sensitive dry plate, and dip it for a few minutes in a three per cent. solution of bromide of potassium. Wash and dry it, and then expose and develop. It will be found that the sensitiveness is much diminished. This he ascribes to the absorption of bromine by the bromide of silver. The greater the amount of bromine present in the emulsion, the less the sensitiveness of the plate. As it is necessary that bromine should be absorbed from the bromide of silver on the exposed portions of the plate, that developer is the most active which absorbs most bromine. It is undesirable to add much bromide to the developer unless correspondingly longer exposures can, or should, be given. But for special purposes, where hard, dense negatives are wanted, large additions of bromide can be made with advantage. Iodide of potassium acts very much more powerfully than bromide, and small additions of this salt to the developer will greatly prolong the time, and increase the contrast. Veiling of the image may be prevented by the addition of only a few drops of a two per cent. solution. A practical application of this property of iodide of potassium may be made in line negatives upon an ordinary dry plate. Expose twice as long as usual, and develop with a solution to which has been added five per cent. each of a 1 in 50 solution of iodide of potassium and a 1 in 200 solution of bromide of potassium. The development is very slow, but produces exactly what is required, a black-and-white negative. Chlorides are also conducive to slow development, but have the property, under suitable circumstances, of producing a brown image. The Eastman Company have taken advantage of this in one of the formulæ for the development of their papers, the brownness of the image being regulated by the amount of chloride of potassium added to the developer.

Screens for the Joly Process.—In the *Photographisches Archiv* we read concerning the great difficulty of this process, the productions of the screens, that Joly prepared them by winding alternate threads of red, yellow, and blue silk upon a glass plate, to which they were then affixed with varnish. A. Baumgartner has obtained a patent in Germany for another process. This is based upon the principle of first printing a grained screen in oil colour, and afterwards treating the uncovered portions with dyes that do not affect the print in oil colour. A transparent support is coated with gelatine, or other suitable substance, and upon it is printed by lithography a blue grain in oil colour. The screen is then dipped in a solution of red aniline dye, which does not penetrate the portions protected by the oil colour. After drying, the screen receives a second printing. This is in yellow oil colour, and overlaps the red and the blue, producing an orange and green grain. If necessary, the unprinted portions of the screen may be modified in colour by again dyeing. In this way grained screens can be produced with red, orange-green, and blue dots without any colourless spaces, and, according to the desired effect, the series of colours may be varied. The following is an alternative process: Upon a sheet of celluloid overlapping dots of red and yellow are printed. It is then coated with blue-stained gelatine sensitised with bichromate of potash. After the back has been exposed to light, development proceeds as in carbon work. The blue gelatine not only adheres to the previously colourless portions of the screen, but changes the yellow grain to green. The red and orange, however, remain unaffected. In this way a screen of similar colours to the first process is produced. If it is wished to make a glass screen, the colours may be printed upon transfer paper and then applied.

Liquid Prisms.—We also read in the same paper that B. Wolter has found o-monobromnaphtalin a good substitute for bisulphide of carbon. It is very transmissive of ultra violet, and has high power of dispersion. Wolter, with such a prism, could trace the spectrum beyond N upon a solution of fluorescine. It is without odour, and its indices of refraction are much less susceptible to variation by changes in temperature.

The Berlin Industrial Exhibition.—Financially, this has not been a success, for we learn from the *Photographische Correspondenz* that there has been a deficit of 1,200,000 marks. It is thought this might have been foreseen, considering the colossal proportions of the undertaking. But Berlin is rich enough to pay for the glory, and the *Correspondenz* thinks all who visited the Exhibition must acknowledge it was magnificently conceived.

Blue Tones for Collodio-chloride.—As a simplification of the process recommended by Hrdliczka for the Vindobona paper, Professor Alex. Lainer recommends the following, in the *Photographische Correspondenz*:—After the prints are deeply printed, wash them in six or eight changes of water for ten minutes, then transfer to a bath consisting of—

Water	1000 c. c.
Hyposulphite of soda	80 grammes.
20 per cent. solution of sulphite of soda	50 c. c.

They should be kept in motion for about three minutes in this bath, and it should be freshly made for each batch of prints. The prints should again be washed in four changes of water, and kept constantly in motion. The toning bath contains no lead. Take 1000 c. c. of water, add 50 grammes of sulphocyanide of ammonium, and, when dissolved, add drop by drop, with constant shaking, 50 c. c. of a one per cent. solution of chloride of gold and potassium. The prints turn brown, then blue in the half-tones, and finally deep blue in the shadows. The prints take on a considerable quantity of gold, and the toning is consequently very thorough. The bath should not be poor in gold, and the toning should be complete in five minutes; if slower, more gold; and, if necessary, more sulphocyanide must be added to the bath. More intense shadows may be obtained by using a concentrated solution of sulphocyanide of gold, made almost at boiling point and diluted before use. The prints also seem to lose less in this bath. The sulphocyanide of ammonium and gold is prepared by adding to a diluted solution of sulphocyanide of ammonium small quantities of neutral chloride of gold and potassium until the red precipitate formed is redissolved.

Aluminium Printing Plates.—Considerable attention has been given to aluminium in Germany as a substitute for stone, and recently, at the Vienna Photographic Society, C. Kampmann, of the Vienna Technical School, read a paper upon its application to photo-mechanical work, and exhibited a variety of specimens. Zinc has been found wanting as a substitute for stone, but aluminium would seem to be of great promise, and offers great advantages in its lightness and freedom from limitation of size, as compared with stone. Joseph Scholz, of Mentz, has worked out the process, and has given it the name of Algraphy. It is protected by patent, but may be worked by any one who buys the plates of him. It has attracted the attention of the Austrian Government for cartography, and the specimens shown were described by Herr Kampmann as quite equal to prints from stone, or even somewhat better. Experiments have also been made with aluminium as a substitute for glass plates in collotype, at the Vienna Technical School, under the supervision of A. Albert. He says that silicate of soda and beer formed an excellent substratum, and that the gelatine adhered so well to the plate that punctures of the film did not spread, even under pressure. Even without any substratum, the film adhered well to the plate. The plates were of the thickness of ordinary good cardboard, and, if dried in the oven on sheets of plate glass, they remained flat and the films were even.

Retouching.—In Liesegang's Photographic Almanac we see a hint from Paul von Janko that may be of service. Instead of varnishing the negative, he recommends the use of the varnish with the pencil. A drop of varnish is spread very thinly upon a glass plate, and this is touched from time to time with the point of the pencil. As soon as the pencil fails in its work, it is again applied to the spot of varnish, and the latter is renewed as often as it becomes hard. Retouching in line or point can be done and the varnish is not visible on the negative.

Photography and Crime.—We also see in Liesegang's Almanac a very interesting communication from Dr. Paul Jeserich. A man named Wetzestein was accused of murdering several women, and a number of hairs from the hands and clothes of one victim, an old woman, were sent to Dr. Jeserich for examination. There were

about forty hairs, and after considerable investigation seven were found that did not belong to the victim. Upon comparing the latter with the hair of the accused, it was found that they corresponded in thickness of the shaft, formation of the root, pigment cells, arrangement of the fibres, &c. The agreement was so perfect that Dr. Jeserich declared them to be hairs of the accused. The evidence of the micro-photographs was so damaging, that the defence asked for the appointment of a second expert. Professor Waldeyer was selected (a man in whose judgment Dr. Jeserich had full confidence), and all the hairs were sent to him without any information concerning the evidence already given. When the day for the communication of Professor Waldeyer's results arrived, they exchanged reports, and found that they both agreed that seven of the hairs were not the victim's and corresponded in all respects with the hair of the accused. Wetzestein was convicted and executed.

CYCLING AND PHOTOGRAPHY.

[West London Photographic Society.]

Some three years ago my friend, Mr. Varden, and myself read before you a joint paper on *Round West London with Cycle and Camera*, and from remarks which have lately been made, I find that a similar paper is expected to-night; and though I am at a loss as to how such an impression arose, I must, in the first place, apologise for not doing so. Besides, I am afraid that the only parties who obtained any real benefit from the said paper were the joint authors, and perhaps indirectly through them the members of the cycling contingent, as they have more than once visited several of the places mentioned and illustrated on that memorable occasion. Possibly you may, however, think me wrong in this view, as I have some indistinct remembrance of a certain Survey of West London which is, I regret, in rather a moribund condition, and which may look upon the said paper as its parent; and though I disclaim the authorship of this Survey, I look forward to a better outlook for it under the care and supervision of our friend Mr. Dixon, and hope it may be the greatest and most useful work that this Society has ever undertaken.

My endeavour to-night shall be to place before you some of the advantages, as well as the disadvantages, of combining the two hobbies, and also some remarks on the apparatus, both on the cycling and photographic sides of the question.

A few weeks ago, in one of the cycling journals, were printed copious extracts from a book of Nathaniel Hawthorne, in which a description of a railway journey was given. The hero, an aged scholar, travelling for the first time, moralises on the nomadic tendencies of the human race, and winds up with these words which, though applied then to the iron-horse, are far more applicable to the steel steed:—"These," said he, "are positively the greatest blessings that the ages have wrought for us. They give us wings, they annihilate the dust and toil of pilgrimages, they spiritualise travel. Transition being so facile, what can be any man's inducement to tarry in one spot, when he may just as easily dwell where the fit and beautiful may offer him a home?" I have claimed that these words more truly apply to the cycle than the railroad, for who has not sat in a railway-carriage and been whirled past nooks and spots where *pictures* seem waiting to be taken, and felt the desire springing up, I wish I could stop the train here and get that bit with my camera, and then go on again; but, if wishes were horses, beggars might ride, so we must stay where we are, or at most take a note, and pay a visit at some future date, possibly only to find that atmospheric effect is changed and the view altered. But to take an example.

Some of you, doubtless, will recollect a short time ago meeting some cyclists all with cameras. It was a lovely spring morning and the roads were in splendid order, and the high speed of seven or eight miles an hour was kept along some four miles of a main road, then turning down some old-fashioned English lanes, past a red-tiled church shaded by lofty elms, under which a stream flowed in which some cattle were standing and browsing on its banks. Here a halt was called, and the photographic possibilities discussed; but, the conclusions being principally negative (the effect being due to colour, not light and shade), they again proceeded further in search of the beautiful—through a sleepy old town nestling by its church, which this time was perched on the brow of a hill and overlooking a wide valley, the scene of several conflicts in the Civil War, on to an ancient hotel with recollections of the coaching days, where another dismount was made and the inner man refreshed with biscuits and cheese and a glass of milk or ale. On a few miles more, and another rustic village, with church and almshouses, looked tempting, and so the machines were stacked. Here the vicar, looking from his windows, saw them, and kindly invited them to enter the church, himself shortly after joining them, showing and explaining the different objects of interest—ancient monuments, chained Bibles, &c.—while some photographs were taken, both outside and in. But the time had passed too quickly and so it was necessary to hurry on, which was done at a higher speed—two more dismounts and some more views being taken on the road—and they arrived at their destination, tired and hungry, but quite ready to do ample justice to the savoury dinner which was soon smoking on the table in front of them. After dinner the cameras were erected, and they wandered through the woods for which the place is famous, meeting some friends who had come down by rail. Then back to the inn and a good cup of tea, followed by pipes and tales; and then, with lighted lamps, off home on their return journey, the end of which was accomplished at a seventeen miles bat, possibly as a protest for having dallied earlier, certainly a good end to a jolly day.

But their friends by rail—what of them? In the morning, an hour before the cyclists, crowding into a dirty train, with five or six on each seat and as many standing; then a rush upstairs and downstairs to another platform, to find that they need not have hurried, as the other train was late. The other train, decidedly an improvement on No. 1, keeps them half an hour, and then all is scramble and off they go, all in different carriages; stopping here and there, they may jump out to try and join some of their friends, and have to stand till the next station for their reward. Whisked past the villages where the cyclists will shortly be exposing their plates, seeing only the church spire and the cottage roofs, they arrive at the nearest station, then a long dusty walk of four miles, quite unphotographic, and they reach the rendezvous.

By some one's blunder they had expected the cyclists to be there before them, and, had the road been similar to that they had walked, it is quite probable they would have been; so they waited some time, the more so as a grey pall seemed to have dropped from the clouds and covered everything (which cloud was only dispelled by a sharp shower shortly after the arrival of the cyclists); then had dinner and off to the woods.

It is kinder to drop the curtain over the long, weary road back to the station and the crowded journey up to town.

By the way, why is it that those who do not cycle think that the greatest enjoyment of cycling is to hump your back, fix your eyes on the tyre (looking out for punctures, I suppose), and grind your nose on your wheel? I think cyclists are to blame for this, for their conversation is something about their wheels or their speed, or the surface of the way, and seldom or never about the beauties of the road or country through which they pass.

So much for the cyclists' advantages; now for the other side.

Firstly, the question of time. Cyclists are bad timekeepers; it is always the unexpected that happens—the delay is occasioned by some accident either to themselves or some one else—so if you arrange to go by train to meet a party of cyclists, give them plenty of margin, unless you are travelling by the lines south of London, in which case this is not necessary. The chain is only the strength of its weakest link, and in club riding the speed is that of its slowest member. The last two times I rode into London by the Bath road may help to show how great is the difference—the one time it took us a little over three hours to do fourteen miles, while the same stretch was done on the other occasion under three-quarters of an hour.

Secondly, an accident. This is not uncommon, though I think it is a matter for congratulation that I only know of one case of serious accident, since I began to cycle in 1877, among my personal friends. I have, however, a lively recollection of two of our vice-presidents riding a tandem tricycle down a hill at the foot of which was a ford; when the front rider saw this, instead of using the brake he applied his toe to the chain, but in the wrong way, so giving his foot a nasty squeeze, besides causing the chain to mount on the cogs and lock; his partner at the same time tried to use his feet (his legs were more than the usual length) as a ground brake, with the result that he tore the sole from the right boot. The locking of the chain caused the key that held on the wheel to give way, splitting the hub, with the result that fortunately they collapsed a few feet from the edge of the water. Seen from behind, the matter looked terrible, and till we found no one was hurt we were serious enough, but then the remarks were ludicrous, especially as we had about three miles to go—one bicyclist wheeling two bicycles, the bicyclist wheeling the damaged trike holding it together as he went along, and the two damaged riders following with the others, the one hopping and the other with the sole of his boot going flap, flap, flap. Since writing the above I have been over the road we then walked, and was struck with the thought of how terribly woe-begone we must have been, as I had no recollection of what it was like. An accident of this kind, however, does not often occur, and we learnt experience, for never again would we trust two novices on one machine. Slight accidents, such as punctures, we have been on our runs wonderfully free from.

Thirdly, there are the worries arising from the peculiarities of the different members and also riders one meets. For instance, one likes to scorch, and probably does not know the roads, and so takes the club miles out of its way along dreary roads, through waiting at the wrong corner, or has possibly to be brought back, while the members wait for the wanderers' return; another likes to crawl; while a third has a fancy for riding down milestones, and is a source of danger to all who are following; and still another constitutes himself the guide, and we find ourselves some dark night describing a circle. These, however, are mere trifles, and often cause most fun. So much for members, now for those we meet. The worst are the hangers on. In our runs, for reasons noted hereafter, there are generally two or three tricycles. Now, a bicyclist merely calls another bicyclist who passes him a scorcher, even if he is only riding at ten or eleven miles an hour, but if a three-wheeler going at this rate dare do such a thing down goes his head and up his back, and off he goes for a

short distance. Coming up from Ripley at a steady twelve miles an hour, we were much amused by one such whom we passed on the level, or going up hill, no less than six times between the Talbot and the Angel, Ditton, to be passed ourselves whenever the grade was down. After getting through Kingston the trike moved ahead, and, passing for the seventh time, made such speed through Petersham that we passed the bicyclist at the foot of the hill leaning on his bike and mopping his brow—looking perfectly astonished. At the same time we meet these peculiarities in every-day life, so that it is hardly fair to call it a disadvantage of cycling, except to the extent that is owing to the *camaraderie* of the wheel.

We have now dwelt long enough on this subject, and so pass on to the apparatus—firstly, cycling; secondly, photographic.

First, the machine, of whatever kind it is, must be a pneumatic. True you court delays through punctures, but the difference in the comfort, freedom from vibration, &c., make it quite worth the risk. Next as to shape. Firstly, the high machine—good old Ordinary, as it is called. This is strongly advocated by one of our members; and, though I must agree with him that it is by far the most comfortable machine to ride, the danger of a sudden dismount, generally by way of finding yourself on your back with the machine on the top of you, places it practically out of the running; besides, it is not so speedy as the smaller wheels. Next we have front-drivers. This is a modified form of the good old ordinary, having the front wheel of thirty-six to forty-two inches diameter geared up to sixty or sixty-three, which, the saddle being placed further back, are not so liable to give you a "cropper." Then, with smaller wheels still, and generally equal sized, we have the Bantam. All these machines have one great advantage over the next class (the rear drivers or safeties) in their practical (though by no means absolute) freedom from the demon "side slip." What this is, no one who has not experienced it can tell. You are joyously riding along a road that is slightly wet, when suddenly you find yourself seated (not very gently) in the mud, while the machine is sliding along gracefully about twenty yards from you, and you cannot for the life of you tell how it happened; but, if you don't know what it is, be careful and do not laugh at a friend in such a plight. I once did, and I found myself alongside of him, while my machine was keeping company with his, thus giving both of us a good lesson in side slip. With this one objection against it we may look upon the safety as the more desirable mount; at the same time, it may be as well to warn those who think of getting one against a rage that is beginning for a very light machine. Some two years ago the best makers were turning out roadsters which only weighed twenty-two to twenty-eight pounds, but they found that the strain twisted the frame and made the driving harder, and so the ones they are now making weigh from twenty-eight to thirty-five pounds. We then come (as it would not do for me to bring tandems before you married men) to the last machine, "the tricycle." This in speed and weight is very little behind the safety, and the only disadvantages are the three tracks when you come to a bad road, and the most serious one the space required for storing. For street or traffic riding it is, however, quite without equal, and one of my friends uses one regularly, keeping his bicycle for country roads. Many people think any one can ride a tricycle, and true it is that it will stand more bad usage than any other machine; but riding is quite another matter, and the trike has to be learned just as carefully and thoroughly as the bike.

But now, to apply these machines to our purpose, we must without hesitation give the palm to the three-wheeler. It can carry anything up to twenty-four or even thirty inches square and be none the worse for it. On one special occasion I rode forty-five miles in three hours, carrying my whole-plate, weighing seventeen pounds, so that I can fairly speak from experience. Next, I think, we must place the G.O.O., then front-drivers, and then safeties. In all these cases we are confined to smaller cameras, nothing larger than half-plate being possible. I place safeties last, as, if the apparatus is carried on the machine, it is bound to alter the steering, even though a considerable amount is carried in the frame, which it does not do in the others.

And now, before passing to the photographic side, let me advise you, if you want a machine, to get a first-class one, and, if you have not enough money to run to a new one, rather purchase a second-hand one than a new *second-grade* one. You can generally find out something of the history of a machine if you can take a friend who is a rider, and he will see a lot that you would pass over. My own machine is, as many of you know, a Referee tricycle with the triple head, which is not only stronger but also lighter than the ordinary single head, and weighs—break, mudguards, valise, &c.—a few ounces over forty pounds, or, weighed as machines usually are in racing order, thirty-seven and a half pounds, and though I have travelled nearly 12,000 miles on it, I have not spent one shilling on repairs. This will show you the advantage of getting a first-class machine in the first instance.

But now to turn to the photographic section. First, plate-carrying apparatus. In the first place, we may dismiss all cameras which are made on the "well principle" as practically useless, as the vibration puts them out of gear. I saw some plates which were taken with such a camera. It was the friend who tilts at milestones who, in some unexpected way, became mixed up with his bicycle—his hands were on the ground, while the spokes of the front wheel were round his wrists, those of the back wheel being similarly round his feet, and he was unable to move, and so appealed to another member to help him. This one had the camera in his hand, and the position was so ridiculous that he took a snap-shot, to find on development that the hands and head, considerably out of focus, were on one plate and the body and feet on another; and anything more disappointing could hardly have happened, as he had told all the other members of it. My own experience is exactly similar, and I could show you a brass slide on which the plates used to run with a beautiful series of "U's," gradually increasing in depth from No. 1 to No. 12. We are thus confined to roll-holders, bag-changing, and dark slides. Roll-holders would be the method, *par excellence*, were the films perfect; but any one who has the same experience of them as some of our members will be careful ere getting one of these, to say nothing of the difference in price of the films. Bag-changers come next; they may be used either with cut films or plates. Cut films are an advance on rollable films, but still not equal to plates. With plates, the only difficulties are the weight and the vibration causing them to make a dust by grinding the edges of the case; this latter may be overcome by passing a sponge lightly charged with glycerine round the sides in the dark room before putting in the plates. Bag-changers have the advantage that they are self-contained and without loose parts. Dark slides are still better than bag-changers in my opinion, as you can carry half a dozen small sized ones in your pockets, and they may be charged with any different kind of plate to suit the circumstance, while in the other case you must expose in order. So much for the plate carrying apparatus. Next we must consider the lens. Any good lens will do, just what the photographer is used to. At the same time, it should be fairly rapid, as probably the exposures will be entirely shutter ones.

But now I must ask your permission, ere speaking of the cameras themselves, to make a digression. I have seen several photographs taken from the machine, especially some fine ones by our first President, Mr. W. England; but such a method is not to be recommended except to the veteran photographer, who can take in the view with a glance and shift his position without studying his ground-glass or view-meter, so as to get the best result. What we have found best is, supposing on our wanderings we come across a spot which seems to lend itself to picture-making, to stack the machines, and to have a look round and discuss the probabilities; then, if the verdict—a question in which the lighting has consideration—is favourable, we proceed or retrace our steps to the nearest quiet inn and stable the machines, order refreshments, and, while they are getting ready, visit the spot with our cameras and make the most of our time. Back to the inn for lunch, then a short smoke and a chat, followed, perhaps, by more work, and then on again—another stop, and then dinner. Some of us have some idea where these spots and inns are before we start. Then some more work, and then on again till tea (one member suggests at Eastcot), and then home in the dark, possibly well pleased with ourselves—certainly the better for our outing. With this method of working you will see that it is immaterial what size of camera we use so long as we can carry it on our machine; at the same time we must confess that the more we study the question the more for this class of work are we inclined to favour small sizes. We may, however, dismiss at once the pocket Kodak as too small. The next size is $2\frac{3}{4} \times 3\frac{1}{4}$, or the fourth of a half-plate, a size we rather fancy, as lantern slides can be made direct from it; besides, using a lens of the usual angle, say, a four inch, gives such depth of focus with almost microscopic sharpness, that with care enlargements equal if not even superior to large direct prints may be obtained. The next size, lantern plate, $3\frac{1}{4}$ square, is strongly advocated by our past President, Mr. J. A. Hodges, though we do not care for it, being the same fault as we have to find with 5×4, viz., too square. A new cut film camera is shortly to be placed on the market by Messrs. Beck—we believe the size to be $2\frac{1}{2} \times 3\frac{3}{4}$—which is again a good shape for landscape work, being $1\frac{1}{2} \times 1$, and the same proportion as the favourite landscape size, $7\frac{1}{2} \times 5$. Next comes the popular quarter-plate, the 5×4, already disposed of, and the half-plate. Lastly comes the $7\frac{1}{2} \times 5$ already mentioned; but above this size we hardly think it advisable to go.

Another consideration in regard to the camera is how it is to be carried. This question only arises in regard to the safety; with the tricycle anything can be carried. With the front driver there is only the backbone to carry it on, and the simplest method is one of the multums of the early days of 1878, unless in the case of a small camera, when it can be carried in front. With the safety, however, we have already mentioned that carried in front it alters to some extent the steering, and the other method is, slung on the top bar between the legs. This seems the best way, as there is the minimum of vibration in this position; however, we are tied down that the camera and case must not measure more than four inches, otherwise it will interfere with the action of the legs. The only other method of carrying is by a knapsack on your back; but, judging from what I have seen and my own experience, I do not recommend it.

And now to consider our cameras. In the first place, box cameras larger than quarter-plate or measuring more than four inches have been disposed of; second, for the sizes larger than that we must have folding cameras, and for the same reason discard the square cases usually sold for half-plate and 5×4. Most modern cameras fold up into something like two and a half to three inches, and I found it a good plan to wrap the camera in a piece of waterproof and fit it on to the bar by two straps; the three

dark slides make up into a similar parcel wrapped in the focussing cloth and suspended by two more straps; then a long strap is passed round the neck under the first and over the second strap on the slides, and again under the first and over the second strap on the camera round the central pillar, noticing to keep it well down so as to stop any tendency to swing, and similarly back along the other side of the apparatus to the neck, where it is buckled. The great objection to this is the time it takes to get the apparatus packed and unpacked, and so I made a light wood frame with waterproof canvas back and stiff front which locked with a key, and which when opened allowed the camera and slides to be lifted out at once. So much for the larger sizes; for the smaller sizes either box or folding cameras may be used. I prefer the folding, as with it you have the opportunity of using different lenses, which is a great advantage. The box camera, however, has the great advantage that it is always ready for use.

And now, in closing, let us sum up what we may consider necessary as the complete outfit for a cycling photographer.

First, a good cycle, either two or three wheels, complete with gear case, mud-guards, and brake, weighing in the one case thirty, in the other forty pounds, pneumatic tyres, and fitted with spanners, pump, repairing outfit, and lamp, not forgetting a cyclometer, to give you some idea of the distance travelled. A case for carrying the camera should be fitted to the frame, and luggage carriers to the handle bar for the tripod and lens case.

Second, a light tripod which would be rigid (it requires to be invented yet) and fold up into small compass—most on the market are too short and not steady enough.

Third, a battery of lenses such as Taylor, Taylor, & Hobson's Combination, with possibly a tele-photo attachment. I have more than once found it useful.

Fourth, a light camera and half a dozen slides, preferably Edward's, which are very thin and light, probably not taking more space than the usual three wooden ones. The camera should have a long extension, and preferably be half-plate.

Fifth, a shutter to fit all the lenses, both time and instantaneous, with a trigger, as well as a pneumatic release, and also a finder to attach to the top of the camera, so that it could be used in the hand.

Sixth, in addition I should have a small box camera, say, quarter half-plate size, which could easily be carried in the pocket, or attached to the lens box.

This apparatus should not weigh more than five or six pounds all complete, and the reason for my choosing the larger size is that I believe more careful and more serious and better work is done, than is the case with the smaller size. I have intentionally left out of the question all the apparatus required at home, as this is a necessity of the photographer whether he is a cyclist or not; but as cyclists have so many more opportunities at smoking concerts, &c., of popularising their art by lantern displays, &c, let me impress upon them to use every opportunity to do so, and also to bring them to our meetings till every photographer shall be a cyclist, and every cyclist a photographer.

I. Stein.

OUTSIDE STUDIO WORK.

V.

The taking of portraits in outside situations has always been an attractive source of amusement with many ladies and gentlemen, and much pains are sometimes taken to secure good results in this branch of photography.

That really excellent portraits are obtained in outside situations when a few simple contrivances are brought into play to aid the operation is well known, and, when such pictures are shown alongside indoor studio exposures, it very frequently happens that those obtained by outside means are voted the palm for superiority.

In this kind of work, like all other branches of photography, the first and most important of all operations is the lighting of the subject.

In inside studio working it often happens that long and patient experiments have to be conducted by an intelligent operator before he is able to select the best methods of lighting a face or full-length subject, for, with the constant changing of the source of light during different seasons and varying hours of the day, the arrangements connected with the selection of the best positions a sitter should occupy, as well as providing means for the shielding of light by partly opaque screens, often gives no end of trouble and anxiety before the most suitable positions are finally hit upon and selected.

And if this prove the case in inside situations, where every contrivance that can be thought of is brought into operation to aid in securing the best results, how much more necessary is the provision of similar aids when the operation is being performed in outside situations.

As I write I see examples of outside portraiture before me that were taken over thirty years ago, and I can recall the pleasure and excitement that followed the rigging up in the garden at that distant date of the extemporised studio, by which means most excellent results were obtained long before the introduction of the fast bromide plate.

To my thinking there is a keen enjoyment in outside portraiture by means of an extemporised studio which is entirely lacking in the conduct of such work indoors, and, when any one enters into this work with a spirit of determination to secure the best results, it may be taken for granted that numerous makeshifts will be tried in the hope of being able to light a face or costume to the best advantage.

The fault in outdoor portraiture, where no special provisions are made to artistically light up a face or figure, invariably lies in the production of too much flatness, a result caused by the absence of one main source of light. No doubt, much may be done by selecting a spot where more or less top light only reaches the sitter, such as in corners of buildings or in proximity to high walls, where such are found near the gables of houses; but top lighting does not suit every class of face, and, at times, such has its disadvantages, especially where the eyes are of a sunken character.

It is not always possible, however, for a worker to secure the advantages of a naturally suitable situation for lighting a face in outside portraiture; but, on the other hand, there is generally some shady spot to be found near most country houses, even although there are no gables or high walls to be taken advantage of in the situation. These shady places should be selected whenever possible, and then, by means of screens, a main source of light be brought to bear upon the spot selected for accommodating the sitters.

Of the many different methods of arriving at this result, I need only mention one or two makeshift arrangements, which I have seen employed with most excellent results, and the rigging up of which not unfrequently affords a considerable amount of pleasure and satisfaction to those interested in carrying out the operations successfully. A situation having a northern exposure is to be preferred at all times; but, in cases where such are not available, it does not follow that arrangements cannot be carried out on that account, the difference being, that in the one case suitable conditions are provided with much less trouble than in the other.

I have often stood in olden times at many country fairs, admiring the system of erecting booths as displayed by our itinerant brethren, and need I say I have profited, in many instances, by what I have seen at such places, for it is, as a rule, good to follow the lines upon which a practical worker has to rely for the earning of his bread and cheese?

I think I cannot, therefore, do better than suggest, to any one contemplating the outlay of a little money and trouble in the rigging up of an extemporised outside studio, the advisability of spending a copper or two in a visit to any well-appointed photographic booth, so frequently seen at country fairs, and which are here to-day and away to-morrow; such an inspection will teach any one a lot in a few minutes, simply because, in the erection of these canvas studios, more or less brains and practical experience are combined and displayed in every item that comes under one's observation.

About the first thing that will strike an observant visitor in search of information is the position invariably selected, whereby as much side light from the sunny side is capable of being screened off without any great trouble or expense. This, it will be found, is generally accomplished by means of the pitch of the cross supports that rise from the side poles at either end of the studio, and by means of which not a ray of direct sunlight is permitted to enter the booth. Outside, all may be glare and sunshine, and the eye quite pained with the full glare of such, but, once inside and under the shelter of this often-patched and weather-beaten welcome retreat, nothing but a delightfully soft, subdued light meets the eye, with a strong, concentrated, main light coming from just the direction best suited according to the time of day and season of the year—this very often means an opening in the roof of the booth, which is easily provided for by unhanging the canvas at such places as will admit not only the proper quantity, but likewise the admission of the same from a sufficiently high-side pitch, somewhat in front of the spot selected upon for posing a sitter.

One of the funniest sights, and, I am not ashamed to confess it either, one of the best lessons I ever got in outside portraiture, was derived from witnessing the erection of several photographic booths at Brodick Fair, that pandemonium of fun and frolic, and where every cheap Jack's trade under the sun is represented. I have seen at Brodick eight to ten well-appointed canvas booths erected, and all doing a roaring trade in less than half an hour. The marvellous way that every bolt and nut was placed into position with such precision was truly a sight to be remembered, and, as far as the lighting of the sitters was concerned (and

this is the main point in portraiture), not a fault could be found with any one of the productions given out for the modest sum charged by the good lady of the establishment, who, by the way, plays a not unimportant part in the business either; for, notwithstanding, that she does look after the dollars, she is always a mark for the good-natured banter which is invariably in full swing between opposition booths (as many imagine, but which are often one and the same copartnery), and by which fun and frolic visitors are unknowingly made to enter one or other of the studios wearing their happiest expression, for such fun and frolic means nothing more nor less than good business in the long run, and many an extra half-crown pulled from a pocket by such means.

A local gentleman has somewhat recently taken out a patent for a portable form of outside studio, in which the main features are the employment of coloured panels in a large hood or umbrella, capable of being erected at any height, and placed at varying angles as found desirable, according to the direction in which it is required to screen the light. In many respects the idea is a good one, but the presence of a high wind would tend to cause anxiety as to the stability of the hood No doubt, however, the reflections caused by using various-coloured filters tend to give a variety of effects in outside lighting, which is a distinct advance in this kind of work.

There are many simple contrivances that any one can adopt in retired places, such as the employment of a couple of high winter dykes, or clothes horses. By folding these into such positions as will permit of their enabling a top-side screen of thin book muslin being erected at a suitable angle overhead, and by staying the clothes horses firmly on the ground by means of pegs and ropes, too much top front light can be cut off by means of erecting cross poles carrying a white sheet, one side of the interior being lined with any dark-coloured material, such as a large table cover, the other having a white lining.

A good background is a necessity, but this is easily provided by stretching either suitable paper or cloth over such an article as a clothes pole fitted up at the end of the winter dykes. Of course, contrivances of this description are fair-weather adjuncts, but by such homely, simple means results in portraiture are obtained that will vie with, and often surpass, results obtained in costly appointed studios.

It is often urged that equal results in portraiture are got by means of view lenses to those obtained by the more costly portrait combinations. I am no believer in such statements; there is a roundness and plasticity in a portrait taken by means of a good portrait combination that is not obtainable by the other instrument, and no one knows this better than those who are in the habit of operating with each of the above forms of lenses.

If equal results could be got in portraiture with cheap view lenses, as are obtained with the high-priced portrait combinations, the day of portrait lenses would be a thing of the past. There is a softness and modelling in a head taken with a good portrait lens that is not possible with a view lens. In many respects this kind of work affords much pleasure and amusement when gone about with a little forethought in rigging up an extemporised studio. T. N. Armstrong.

EDWARDS'S IMPROVEMENTS IN PHOTOGRAPHIC-FILM MANUFACTURE.

Mr. A. C. Edwards says:—

"The object of the present invention is to improve means or apparatus employed in the manufacture of photographic films with a view to prevent the latter curling or cockling during the coating, setting, and drying of the gelatine emulsion.

"In carrying the invention into effect I may use a machine similar to those already in use for coating glass plates or films attached to glass plates, and I employ, in lieu of the ordinary travelling band, a band coated with a tacky or adhesive substance.

"I find that a very suitable coating for the travelling band may be made with a mixture of a solution of glue or gelatine and sugar or glycerine, such as the ordinary printer's roller or graph-copying compositions, but any other coating having a tacky or adhesive nature may be employed.

"The flexible film is fed to the machine and is pressed into contact with the travelling band by a roller or otherwise. It then receives its coating of gelatine emulsion in any usual manner, and passes forward sticking to the travelling band, which retains its flatness and resists the tendency of the film to curl up.

"By the time the film reaches the end of the travelling band the gelatine coating is 'set,' and the film may be removed for drying, or the film may be left in contact with the travelling band until dry.

"It will be understood that long lengths of film may be coated by means of my invention, or short lengths of film may be fed to the tacky or adhesive band, by hand or in other convenient manner, and be coated, thus obviating the necessity of attaching each short length separately to a plate of glass or other rigid material, as hitherto practised.

"The claims are:—

"1. In means or apparatus employed in the manufacture of photographic films the use of a travelling band having a tacky or adhesive surface to receive the film while the latter is being coated and the gelatine emulsion is setting and drying.

"2. In means of apparatus employed in the manufacture of photographic films the use of a travelling band having a tacky or adhesive surface."

THE HACKNEY PHOTOGRAPHIC SOCIETY'S EXHIBITION.

Probably a more accurate opinion may be formed of the general progress of photography, as applied to pictorial representation, from the study of the successive exhibitions of an active local society, such as the Hackney Photographic Society, than from the study of a series of exhibitions of more world-wide notoriety, the Exhibition of the Royal Photographic Society, for instance. The latter attracts, and always has attracted, the best of the work of the best of the workers, amateur and professional, throughout the country; but, from its nature, it is safer to regard it as indicating the prevailing fashion in artistic photography than as indicating the general progress of the bulk of those who practise photography. The works exhibited on their walls are but a small selection, about one-fourth, of those offered for exhibition, and, naturally, the individuals who are appointed to make the selection would be chosen from those who are known to be level with the ideas of the times.

The Hackney Exhibition is one in which there is no selection, but every picture sent in is accepted and hung. There is an opportunity, therefore, of inspecting the worst the members do, as well as the best, a severe test for a Society in which a large proportion of the members are beginners; but the Society is to be congratulated on the result. The Exhibition, which was open to the public last week, was undoubtedly in advance of any previously held, and the Members' Classes were noticeable for the scarcity of work, which was not in some way commendable. The leading members of the Society have gained a reputation by their works outside their own district, and their influence on the less advanced members, for their good, was everywhere apparent on the walls of the Exhibition. If there was a tendency shown to imitate too servilely their leaders, both in style and treatment, on the part of the less experienced members, it is a less objectionable fault than firing off plates without aim or object, and trusting to luck for the results.

As might be expected from the geographical situation of the Society's home, a considerable proportion, if not a majority, of the landscape pictures were characteristic of the scenery of Essex and the eastern counties; and, although from that fact the Exhibition suffered a little from want of variety, it was impossible not to admire the spirit of appreciation common to many of the members of the atmospheric effects which constitute one of the principal charms of flat, marshy districts. But, while fully recognising the pictorial value of the mists and leaden skies, and commending the members for their success in treating their subjects under these aspects, we could not help feeling that we should like to see a little more of how the county looks under a genial sun, when the trees and hedges are clothed with verdure, the swamps dried up, and the roads not impassable to foot passengers.

We have mentioned that there is very little work that could be spared; but, on the other hand, so many of the members show work so nearly equal in merit that to choose any for special commendation is difficult. Among the pictures which particularly appealed to us were those by W. Rawlings, J. Carpenter, W. Selfe, Dr. Frank Jeffree, Dr. Roland Smith, J. J. Westcott, F. Palmer, W. A. J. Hensler, J. O. Grant, W. Fenton-Jones, L. S. Wilks, C. A. Russell, F. E. Roofe, and J. E. Hull.

The stereoscopic slides were all beyond the average and free from the usual technical defects. The Lantern Slides were a most admirable class. The Novelty Class, in which a silver medal was offered for the best original device in the way of apparatus, is always an interesting feature in the Hackney show. Here we found an ingenious plate-rocking contrivance actuated by a small electro-motor driven by a current from an ordinary *Leclanché* battery, exhibited by Mr. Ashton Gill; a tap attachment useful in washing negatives; and a carefully thought-out lantern slide making camera by Dr. Roland Smith, to which the medal was awarded. A collection of radiographs by Dr. Gerard Smith also was worthy of notice.

In the Open Classes, the General and Portrait Classes includedm any old acquaintances of those who visit Exhibitions. It will be sufficient to mention the principal exhibitors to convey a fairly accurate idea of the quality of the work. The Champion Class, for pictures which have previously received awards, was comparatively poor. It is curious that the Champion Class at Exhibitions should so often be weak; and, with regard to some of the pictures, one is tempted to wonder, if that obtained an award, what must the others have been like? The Lantern Slides Open Class contained some very fine examples; but the class, as a whole, was fairly beaten by the Members' Class. The total number was about the same in each.

The principal exhibitors in the Open Classes were Mrs. C. Weed Ward, W. Smedley Aston, Chas. M. Wane, W. J. Byrne, T. Morley Brook, C. F. Inston, J. Bulbeck, P. S. Lankester, H. Mitchell, J. Gunston, H. W. Bennett, Mrs. W. Gardner, E. Seamell, Geo. Lafayette, J. H. Gear, W. Thomas, Edgar R. Bull, A. Brooker, J. T. French, and Willis Booth.

The body of the hall was, as usual, devoted to trade exhibitors, the principal stalls being held by Messrs. R. & J. Beck, of Cornhill; Henry Park, of Haggerston; T. H. Powell, of Denmark-hill; the Cresco-filma Company; the Prosser-Roberts Drug Stores, of Camberwell; Thorn & Hoddle, of Camberwell New-road; the Scientific Hand Camera Company, of Queen Victoria-street, who all had interesting displays of their well-known specialities; and Messrs. J. O. Grant & Cocks showed accumulators, induction coils, and other electrical apparatus used in connexion with X rays.

On each evening of the Exhibition the Society had provided for the amusement of its visitors, in addition to vocal and instrumental music and lantern exhibitions, demonstrations, at intervals, of the X rays, by Dr. Gerard Smith and Mr. J. E. Greenhill. The cinematoscope was also at work in an adjacent room. The general arrangements of the Exhibition were admirable, and Mr. Fenton-Jones and his colleagues deserve more than a passing word of praise for their completeness.

The Judges were Messrs. Thomas Fall, J. A. Hodges, and Rev. F. C. Lambert. In some cases the awards were very amusing examples of the eccentricity of genius.

List of Awards.

As under the regulations no member could take more than one award, when a member's name appears more than once, only the more valuable medal was actually received.

Members' Class A. (For Pictures taken since the last Exhibition).—Silver medal, *Marsh and Mead*, J. Carpenter. Bronze, *A Forest Pool*, W. A. Hensler. Certificate, *The Forest—Early Winter*, W. F. Fenton-Jones.

Class B. (For Pictures taken during membership).—Silver, *On the Grand Canal, Venice*, W. F. Fenton-Jones. Bronze, *Solitude*, F. E. Roofe. Certificate, *Family Gossip*, W. F. Fenton-Jones.

Class C. (Hand-camera Work).—Silver, *Ploughing*, F. E. Roofe. Bronze, *Derwentwater*, J. E. Hull.

Class D. (Stereoscopic).—Silver, A. D. Fort. Bronze, L. S. Wilks.

Class E. (Lantern Slides).—Silver, W. A. Hensler. Bronze, W. A. Hensler. Certificate, L. S. Wilks.

Novelty Class.—Silver, Dr. Roland Smith.

Open Classes.

Class F. (General Work)—Silver, *'Tis evening; all around is still; Save for the music of the bubbling rill*, J. Gunston. Bronze, *Ely, Organ Staircase*, J. Bulbeck. Bronze, *An Autumn Evening*, P. S. Lankester.

Class G. (Portraiture and *Genre*).—Silver withheld. Bronze, *At-home portrait*, P. S. Lankester.

Class H. (Champion).—*Silvery Morn*, J. H. Gear.

Class I. (Lantern Slides).—Silver, J. H. Gear. Bronze, A. Brooker. Certificate, E. R. Bull.

Technical Section.—Silver medal, Messrs. Thorn & Hoddle for acetylene gas generators.

The Inquirer.

**** *In this column we from time to time print questions that may be addressed to individual contributors to our pages, or such as are sent to us with the view of eliciting information from a variety of sources. We invite the co-operation of our readers in rendering this feature of the* Journal *useful and instructive.*

Re-exposure of Plates.—Hopeful asks: "Is it true that there is a reliable method by which plates that have been exposed to light, either in the camera or otherwise, can be restored to their original condition, and fitted for exposure? If so, it will be a great boon to others besides myself."

Coloured Screen for Landscape Work.—Exam. writes: "In an old work on photography, I find mention made, though in a rather indefinite manner, of a practice said to have been 'adopted by some workers' of using a green-glass screen before the lens when photographing landscapes or foliage. Is this plan any good? and, if so, must orthochromatic plates be used?"

Duration of Hand Exposure.—J. B. says: "I should like to elicit the opinions of readers of The British Journal of Photography as to the probable duration of the quickest exposure it is possible to give by uncapping the lens by hand. I have heard opinions expressed that vary so widely that I am at a loss to reconcile them. Of course, I am aware the time will vary with different manipulators, but what, in the case of an ordinary smart operator, is the probable hand exposure in taking a horse or dog, for instance?"

Ammonia in Gelatine Emulsions.—In reply to "Historicus," A B C writes: "I believe the first direct use of ammonia for the purpose of giving sensitiveness in gelatine emulsions was made by the late Dr. Van Monckhoven in 1879, from whom the idea was speedily taken up by English experimentalists. Dr. Monckhoven's process was described, I think, in the *Bulletin de l'Association Belge* in the early or middle part of 1879. But previous to that—in, I think, 1876—a leading article in The British Journal of Photography on Johnston's ammonio-nitrate collodion emulsion process gave a detailed account of experiments with ammonia in connexion with the then new gelatine emulsion." [See Mr. York's letter last week.]

Xyloidine.—(To "Ignorance.")—Xyloidine is the nitro substitution product prepared from starch by treatment with nitric acid, and is of practically no use for photographic purposes. Although soluble in ether and alcohol, it dries to a granular opaque film, useless for negative purposes. Celloidine is the name given to a commercial preparation of purified pyroxyline, which is apparently first dissolved, clarified, and neutralised, and finally solidified into cakes. It is usually supposed to be a pure and reliable form of pyroxyline. Papyroxyline, made from paper, has been considered to possess advantages in the direction of easy fluency and freedom from structure, but these qualities depend entirely upon the details of its manufacture.—Syntax.

Wooden Bath.—In reply to "Wet Plate," J. Barnes writes: "If the bath is a large one, the best and most satisfactory method will be to line with glass, the wooden casing having been previously well saturated with several coats of (not too thick) shellac varnish. Saturation with shellac, if properly done, also answers well for large baths without the glass lining, but for small ones paraffin wax is preferable. The method of application is to melt the wax in a suitable iron or other dish on a flat stove, raising the temperature as high as may be convenient, and then to immerse the bath or dish to be waterproofed, which should be previously thoroughly dried and warmed. As the wax penetrates, bubbles of air will escape from the wood, and the immersion should be continued until these have ceased, when the bath is taken out, allowed to cool, and the superfluous wax scraped off. Obviously, this plan cannot be applied to large sizes."

Conversion of Printing Bath.—(To J. Phillips).—"The conversion of the printing bath to negative purposes is a very simple matter, theoretically, as it is only necessary to get rid of the organic matter it contains and bring it to a suitable strength. The trouble involved will depend upon the extent to which it has been used. The first operation will be to boil it in a porcelain basin, allow it to cool, and then filter. Now add a few grains of carbonate of soda, together with a few drops of liquid ammonia, and let it be freely alkaline. Shake it up well in a clear glass bottle, and then place the dirty-looking mixture in strong daylight until it first blackens and then becomes clear, when it should be filtered and afterwards rendered very faintly acid with nitric acid. It may be necessary to repeat the 'sunning' process where the bath has been very foul. The only method of adjusting the strength is by quantitative analysis; 'argentometers,' so called, are of no use, as they are unable to ignore the soluble nitrates, other than that of silver, invariably contained in an old bath."

Our Editorial Table.

Handbuch der Chemigraphie.

By Wilhelm F. Toifel.

A. Hartleben, Vienna, Pesth, Leipsic.

This volume forms one of the series of Hartleben's Chemico-technical Library, and is the second edition of the work. It deals with the processes of etching in relief in their many varieties, upon zinc, copper, and other metals, for letterpress. Those who wish for information concerning the production of line and screen plates will find this a very handy volume, as the author not only gives full information with regard to materials and manipulations, but has brought the work up to date.

THE PARADE: 1897. AN ILLUSTRATED GIFT-BOOK FOR BOYS AND GIRLS.

Edited by GLEESON WHITE. London: H. Henry & Co., Limited, 93, St. Martin's-lane, W.C.

THE boys and girls for whom, in this beautiful book, Mr. Gleeson White and Messrs. Henry have set themselves the pleasant task of catering are fortunate in respect of the artists and authors who have endeavoured to interest them, for of both kinds of workers some of the ablest of the day contribute to *The Parade*. Until very recent times "annual" literature for young people was usually either mawkish or namby-pamby, while it assumed on the part of its readers not merely tenderness of years, but intellectual feebleness and stupidity. Mr. Gleeson White and Messrs. Henry wisely recognise that there is a large class of young people who ask for and are capable of appreciating different literary fare to that usually vouchsafed to them by the Tract Society and similar bodies, and the result is this tasteful, sprightly, and interesting book, in which, if we mistake not, oldsters as well as youngsters will take delight.

AMONG the authors are John Oliver Hobbes, R. Le Gallienne, Barry Pain (with one of his inimitable school tales), Max Pemberton, F. Norreys Connell, Mrs. Molesworth, and many others, who, between them, contribute brightly written tales, poetry, music, &c., while, of the pictures, Aubrey Beardsley, Alan Wright, L. Housman, Starr Wood, N. Jungman, H. T. de Mattos, and numerous other clever people claim the authorship. Carefully edited, beautifully bound and printed, it may with safety be predicted that a wide welcome awaits the *Parade* for 1897. At any rate, it deserves it.

MESSRS. HENRY & Co. also send us *The Happy Owls*, told, drawn, and lithographed by Th. Van Hoztema. This consists of a series of humorous illustrations (in colours), showing how two stolid owls surprised others of the feathered creation by being happy without fighting or excessive eating and drinking.

The Tyrants of Kool-Sim, by J. Maclaren Cobban, a stirring and absorbing tale of adventure, and two of Mary E. Mann's charming and idyllic stories, *There was once a Prince* and *When Arnold Comes Home*, are among Messrs. Henry's recent fictional publications. The two former have already achieved popularity, and all may be safely placed in the hands of that awe-inspiring product of propriety, the young lady of fifteen.

THE ACTION OF LIGHT IN PHOTOGRAPHY.

By Captain ABNEY, C.B., D.C.L., F.R.S. London: Sampson Low & Co., Fetter-lane, E.C.

THE full title of this work is *Evening Talks at the Camera Club on the Action of Light in Photography*, by the President, Captain Abney, C.B., D.C.L., F.R.S., which might, we think, have been abbreviated to the extent indicated by the heading of this notice. The book consists of a series of chapters that treat, separately, many of the phenomena of light in its photographic action. Thus, molecular and atomic motions; spectrum wave-lengths; absorption spectra; light in the dark room; and halation, are among the subjects dealt with that are of immediate interest to practical photographers, many of whom, however, will, no doubt, find it convenient to pass over some chapters that we have not mentioned. Photometry—or, as it is more correctly expressed—the measurement of opacities, and colour measurement and luminosity, are also among the sections of the book, wherein the action of heat and cold, intermittence of exposure, and very intense light on sensitive surfaces, likewise receive detailed reference.

If there is not anything absolutely new or novel in Captain Abney's book, it is replete with interest to those given to the study of the theory of photography, while even "the photographer who," to quote from the preface, "as a rule is not too fond of the theoretical considerations that underlie his craft" will find in it much to instruct and something to fascinate him. In connexion with recent articles and discussions that have appeared in our columns, it is of interest to note that Captain Abney appears to favour the sub-salt theory of development. There are seventy illustrations and an appendix of tabular matter relating to experimental results in the book, which should find a place in the library of all interested in the scientific aspects of photography.

MESSRS. ARTHUR & Co., of 19, Thurnham-street, Rocky-lane, Liverpool, send us samples of their AI retouching medium and negative varnish. Both preparations appear to be admirably adapted for their respective purposes. By the use of both it is claimed that plenty of work can be got on the film, and it does not come off with the varnishing.

News and Notes.

ERRATUM.—In the leaderette on *Rapid Printing*, p. 739 of the JOURNAL for last week, for "centimetres" read "millimetres."

PHOTOGRAPHS OF GARDENS AND PLANTS.—Prizes to the amount of nearly 160*l.* have just been paid to the various competitors in the 1896 competition by the Editor of *The Garden* and *Gardening Illustrated*. The same series of prizes will be offered during the coming year.

PHOTOGRAPHIC CLUB.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock on Wednesday evening, December 2. *Carbon Printing without Transfer*, a demonstration by Mr. James A. Sinclair. Visitors are welcome.

MR. ARTHUR C. BALDWIN, who is known to very many of our readers in London and the country, informs us of the termination of his engagement with the Eastman Photographic Materials Company. Mr. Baldwin, we believe, proposes engaging in business on his own account, and will have the best wishes of his many friends for his success.

MR. W. R. BLAND of Duffield, Derby writes: "There is a vacancy in the membership of the POSTAL CAMERA CLUB. Albums circulate monthly with regularity. The Club has members who are exhibitors at the Royal Photographic Society, and the Salon, and other leading shows, and therefore advanced workers only are requested to reply. A copy of the rules of the club will be forwarded on application to me."

Patent News.

THE following applications for Patents were made between November 11 and November 18, 1896:—

GAS JET FOR LANTERNS.—No. 25,085. "Improvements in a Gas-jet Arrangement for Optical Lanterns." G. HOLDSWORTH.

ENLARGING LANTERNS.—No. 25,086. "Improvements in Lanterns used for Making Photographic Enlargements, Reductions, or Copies." G. HOLDSWORTH.

CAMERA STANDS.—No. 25,136. "Improvements in and relating to Photographic Camera Stands." W. W. BEASLEY and C. PERROTT-SMITH.

SCREEN KINETOSCOPY.—No. 25,278. "Improvements in Apparatus for Taking and Exhibiting Animated Photographs." J. ADAMS, E. HOLLANDERS, and C. J. LEATHER.

PRINTING FRAMES.—No. 25,579. "Improvements in Photographic Printing Frames." C. A. McEVOY.

SHUTTER.—No. 25,616. "An Improved Photographic Shutter." Complete specification. A. T. KYBERD.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

November.	Name of Society.	Subject.
30	Bradford	Lecturettes by Six Members.
30	Camera Club	*To Lyonesse with a Camera.* Rev. J. Courtney Gale.
30	North Middlesex	Annual Exhibition (*Conversazione*).
30	Richmond	*Practical Pictorial Photography.* A. Horsley Hinton.
30	Rotherham	Imperial Company's Competition Closes.
December.		
1	Gospel Oak	Home-made and Novel Apparatus.
1	Hackney	*The Evolution of the Gelatine Plate.* A. Mackie.
1	Halifax Camera Club	*Holiday Tour in Northern Italy. Gems of Photography.* Thomas Widdop.
1	Isle of Thanet	*Lantern-slide Making.* John A. Hodges.
1	Lewisham	*Stereoscopic Photography.* Professor Carlton J. Lambert, M.A., F.R.A.S.
1, 2	North Middlesex	Annual Exhibition.
1	Rotherham	*Vertical Projection.* J. Leadbeater.
1	Wolverhampton	*In the Wilds of Norway.* T. H. Cox.
2	Borough Polytechnic	*Paper Negatives.* P. C. Cornford.
2	Croydon Camera Club	*Moving Pictures, &c.* W. Friese Greene.
2	Leeds Camera Club	*Ancient versus Modern Printing, Toning, and Washing.* Mr. Gaunt.
2	Photographic Club	*Carbon Printing without Transfer.* J. A. Sinclair.
3	Camera Club	H. Brereton Baker.
3	Leeds Photo. Society	Annual Meeting and Members' Lantern Evening.
3	Leigh	*The Hand Camera.* M. F. Burrows, J.P.
3	Liverpool Amateur	*Intensyication and Reduction.* F. Anyon.
3	London and Provincial	*Colour Filters.* E. J. Wall.
3	Oldham	*Stereoscopic Photography.* W. Schofield.
3	West Surrey	Social Night.
3	Woodford	*Hand-camera Work.* W. Thomas.
5	Southport	Exhibition of Slides.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

NOVEMBER 19,—Mr. P Everitt in the chair.

Mr. F. Goddaer was proposed for membership.

The HON. SECRETARY referred to the paper recently read dealing with the present position of the Jackson-Harmsworth Arctic Expedition, and said he had been enabled to show prints of the original negatives illustrating the meeting of Jackson and Nansen and other features of the country.

Mr. LEWIS MEDLAND showed a selection of slides of Great Yarmouth and its neighbourhood, anticipating the visit of the Photographic Convention arranged for next year. He showed that there was an abundance of material in the district, embracing sea and landscapes, shipping, and places of antiquarian interest, taking his audience over the probable routes of the excursions, including a trip to Norwich and the Broads. He concluded with some views in and near Southwold, in all some 140 slides, by the collodio-bromide process, being thrown on the screen. Slides by the Chairman, Mr. Bayston, Mr. Hill, and Mr. Wiss were also exhibited on the screen.

The CHAIRMAN in proposing a vote of thanks to Mr. Medland said he was sure that, if the Convention got as far as Southwold, they would agree with him that it was well worthy of a visit.

PHOTOGRAPHIC CLUB.

NOVEMBER 18,—Mr. R. P. Drage in the chair.

Two new members were proposed, viz., Mr. George Hana and Mr. George J. Wright.

Mr. SNOWDEN WARD said that he had just had a conversation with an assessor of risks for the Westminster Fire Office. This official stated, but in an unofficial manner, as he explained that there was no office regulation upon the subject yet, that his office had not placed any restrictions upon the proper use of acetylene, and he did not think they would do so; but he suggested that the best course for any photographer who intended to use the new illuminant would be to write the Westminster Fire Office, stating his intention, the quantity of gas he was likely to make, the quantity of carbide he should use, the method of storage, and, lastly, the kind and size of generator he should employ. Mr. Ward said he believed that the Westminster Fire Office and the Sun Office were the pioneers in dealing with the individual risks of photographers.

The Paget Prize Plate Company sent a number of packets of their lantern plates, both slow and rapid series, for distribution amongst the members, who were asked to try them and bring their results to a future meeting. They also sent a gratuitous supply of their book called, *Paget Lantern Slides; a Manual for their Use*, which contains full instructions for making slides both by contact and in the camera.

Mr. THOMAS FALL gave his lecture entitled,

BIRDS AND ANIMAL LIFE.

The dissertation was illustrated by a number of very excellent slides of dogs, birds, and horses. Mr. Fall related a series of experiences with animals, and anecdotes about them, which revealed him to his audience as an enthusiastic lover of the animal world.

On December 2, Mr. James A. Sinclair will demonstrate the *Artigue Method of Carbon Printing without Transfer.*

MANCHESTER PHOTOGRAPHIC SOCIETY.

NOVEMBER 12,—the President (Mr. T. Chilton) in the chair.

Mr. B. J. Beckton was elected a member.

Mr. H M. WHITEFIELD exhibited the apparatus used in the generation of acetylene gas, and gave a description of the process, afterwards demonstrating the manufacture of the gas, and using it in the optical lantern. Slides by Mr. H. V. Lawes from hand-camera negatives were shown by aid of the new light. The disc was six feet in diameter and for the size well illuminated. The apparatus was kindly lent by Mr. J. T. Chapman.

Messrs. A. E. CASSON and HARRY WADE gave their experiences on Wellington & Ward's new negative paper, showing results from personal work with the paper. Considering the bad weather that has prevailed during the past few weeks, the work was satisfactory, although it was proved by many exposures that the light at this time of the year was too dull for successful work on this paper, which requires a longer exposure than glass plates. The makers sent down for inspection negatives which proved that negatives equalling glass plates can be obtained, and future meetings should see results by the members from the packets distributed.

Croydon Camera Club.—November 18.—No more profitable lecture has been given at the Club than the truly admirable discourse upon

PICTURE-MAKING WITH THE CAMERA,

with which Mr. HORSLEY HINTON regaled a crowded attendance of members on Wednesday, November 18. As a rule, the subject of art is, in the eyes of the average man, a sufficiently forbidding one. Hence it says much for the attractive force of Mr. Hinton's name and talents that, in the first place, he should have drawn a full house, and, in the second, held his auditors' close attention whilst he for over an hour talked to them of pictorial art and its expression by means mainly, but not entirely, photographic. Had not the President of the Club, in introducing Mr. Horsley Hinton, said so, surely no photographer would be likely to forget that the lecturer is one of the foremost exponents upon the exhibition walls of the pictorial possibilities of landscape depicted with a camera. We are unable to even summarise most of the points spoken on; it must here suffice that Mr. Hinton dwelt with much emphasis and persistence upon the difference between using the camera as a kind of recording angel of natural truths and employing it for the attainment of an ideal expression of some mood, moment, or passage of nature, which the artist-photographer seeks to fashion into a decorative and personal statement. The lecturer proceeded, at much detail, to explain some of the means whereby he made the camera and photographic materials respond to his wishes. A palpable hit was, that the power of personal control was valueless, or nearly so, unless the photographer knew what modifications or alterations were conducive to the artistic betterment of the photograph. In this regard Mr. Hinton dwelt upon the great value of simplicity and singleness of purpose, inasmuch as the prevailing or natural tendency in photography is in the direction of pictorial verbosity—too many facts crying out for recognition. The lecturer's remarks gained much point by a selection of his large platinotype landscape studies, which were exhibited at the Photographic Salon. Two of these, *Flowery Wastes* and *Sweet Wilderness*, were employed to show how a full daylight scene may be so photographically sophisticated as to give the impression of grey evening. In discussing the foregoing, the President (Mr. Hector Maclean) made a series of half-humorous, but occasionally serious, remarks respecting what had gone before. He began by quoting Ruskin's aphorism, "Life without industry is guilt, and industry without art is brutality," and proceeded to plunge into a maze of friendly criticism. The suppression of detail of which many leading photographers are so fond was, he maintained, a confession of weakness, a confession that selective sharpness of focus and partial suppression of detail are beyond the present means of control. Not only are "familiar objects" welcome and helpful in a composition, but fine detail is not incompatible with the higher forms of art, as witness Brett or Meissonier. "Change their pictures into the smudgy shadowings of George Davison, and they would be absolutely valueless either from the art or any other standpoint". Mr. Maclean was also somewhat fervid upon photographic falsifications. He drew a distinction between alteration and falsification — between saying less or emphasising more, and making night of afternoon. To transpose nature into the keys of art is one thing, but to depict the sun as a moon is not a transposition, but a pictorial imposture. He wound up with some impressive words, urging that the "vehicles of expression," "light, shadow, and atmosphere," were not the end, but the beginning, of a great picture. Mr. HINTON having briefly replied, in consequence of being obliged to catch a train to Guildford, the meeting accorded him a loudly expressed vote of thanks. Mr. Adolph Langfier was elected a member, and several other names handed in. Mr. Kough exhibited three interesting and well-executed snap-shots of motor cars passing through Croydon on the occasion of the memorable motor-car parade to Brighton.

Putney Photographic Society.—A meeting of the Society was held on November 4, Mr. H. Faulkner in the chair.—A set of American slides had been lent by the Royal Photographic Society, and these were passed through the lantern. The set includes some very beautiful slides, which were much appreciated by the members.

Richmond Camera Club.—November 16.—Mr. ARDASEER gave the first of a series of elementary lectures which have been arranged for the session, his subject being

MAKING A NEGATIVE.

He remarked that this was a large order for one evening, but gave many practical hints as to apparatus, exposure, development, &c. At the same meeting Mr. Gibson showed some enlargements on bromide paper made without a condenser, the illuminant being magnesium ribbon, of which only six or eight inches were used for an exposure when enlarging to two diameters, ground glass being placed behind the negative, and the burning ribbon moved across and across, so as to cover the whole surface as evenly as possible.

Woolwich Photographic Society.—November 11, Colonel C. D. Davies presiding.—The Rev. F. C. LAMBERT delivered his second lecture on the

PRINCIPLES OF PICTURE-MAKING,

dealing with the arrangement of light and shade. He pointed out that there must be a principal light and a principal shadow. The strength of a picture depended upon its shadows. Shade was really an absence of light. It had been estimated that in nature there was a difference of from 1700° to 1800° between the darkest cavern and the whitest snow, but our whitest paper and our blackest platinum had only a range of about 350°, it was therefore impossible to accurately represent nature—we must give and take. The Rembrandt School sacrificed the high lights so as to give the shadows their full range. Turner's method was the reverse of this. To place the darkest dark against the lightest light was a favourite method, and gave strength, but was against breadth in a picture. At the conclusion, Mr. Lambert had projected upon the screen some splendid slides, which he analysed to illustrate and emphasise his remarks.

Darwen Photographic Association.—November 12, the Rev. Henry Irving occupied the chair.—The subject was

PLATINUM TONING,

by Mr. F. FIELDING, of Blackburn. The lecture, which was thoroughly entertaining and instructive, was enjoyed by all present. Mr. Fielding toned about twenty-four prints gelatino-chloride and collodio-chloride, the latter being superior in every respect, besides being, as the lecturer said, much easier to work.

Eastbourne Photographic Society.—November 16, a pleasantly chatty lecture on

LANTERN SLIDE-MAKING

was delivered by Mr. ALGERNON BROOKER, of Hastings, on the part of the Britannia Works Company, Ilford. He said that negatives for this purpose should be very soft and full of detail, anything like chalkiness or intense contrast was to be carefully avoided. With a view to getting the best kind of negative, the use of isochromatic plates was strongly recommended. Backing plates, both in taking the negatives and also for obtaining the very finest results for lantern positives, was also desirable. He said that he mainly confined his exposure to Ilford lantern plates, and specially noted the effects which were to be obtained on Alpha plates with their great range of tone. An interesting feature of the demonstration was the screen exhibition of some results obtained by an ingenious method of local toning devised by Mr. Brooker himself, in

which the special qualities of Alpha plates in giving various colours were taken advantage of to produce an effect closely resembling the natural colours of the objects photographed. This process, applied to flower work, gave some startlingly naturalistic results. The lecturer's remarks were pointed by examples of what to avoid as well as those to copy, also by instructions as to the method of improving and getting the best out of a given negative. Altogether the lecture was as instructive as entertaining, and an attentive audience testified their appreciation by a unanimous expression of approval.

Halifax Camera Club.—November 11.—Mr. Alexander Keighley gave a lecture on

ART IN PHOTOGRAPHY.

The lecture was illustrated by numerous lantern slides of the very best work and of many sketches made by the lecturer to explain the various points of what to do, and what not to do. Two men with cameras go to the same scene, one of them returns with more than a photograph, a picture, full of poetry and artistic composition, proper lighting, and with a suitable figure to give it life; the other, being of a more mechanical mind, returns with a photograph, through no fault of the camera or mechanical knowledge, but merely ignorance of the laws of art or of perception, the figures unsuitable and badly placed. To sum it up, it is this: That one is an artist with an artistic perception; the other has commonplace ideas, possibly through not being trained. In the first place, one must know how to handle his tools, and be able to produce a technically excellent negative, and, having such negative, be able to produce any effect on the finished print. After this, he must train his mind to create artistic pictures, study the works of the great workers, and, by constant examination of them, learn what is required. Artists have, by lives of study, framed certain general rules which can be acted upon, and must be borne in mind, and the observance of which experience has taught them are the necessities of real art. A photographer may just as readily expect to be able to produce artistic photographs without diligent study and experience as if he brought an easel and a box of paints and set out to paint a masterpiece. Fitness of details is a point which is too frequently overlooked. A fashionably dressed lady hardly agrees with the surroundings of a fishing scene; and, again, the figures should possess diversity of occupation and activity, and at any cost avoid uniformity. Uniformity should be avoided in landscape, roads, and buildings, as well as in figures, and the principal object should never be in the centre, with, say, objects of equal height on each side. By turning to an angle, the central figure or building is improved, whilst the natural perspective relieves the monotony of the side objects. Straight lines should be in some way broken up, or the attention directed from them, by the introduction of a prominent object. Too many perpendicular or horizontal lines ruin a picture. The chief lines should also balance; if all running in one direction, the impression of instability is given, and the picture appears as if falling. The balance of objects is of great importance. A principal figure should, if possible, be supported by a secondary object not equal in prominence or occupying so important a place in the picture; neither should the principal object occupy the centre of the picture, a position about a third of the length from either end gives the strongest point. As well as applying to objects, this also governs the placing of the high and low lights of the picture, although more freedom is allowed in this respect. The arrangement of grouping in a picture by any eminent artist, although containing a great number of figures, is not done in any hap-hazard manner, but is based on geometrical form, as also are, in many cases, the accessories. The form of a pyramid or diamond (with the axes diagonal, not perpendicular), or even of an arc of a circle, or with the principal lines radial, may be used. Greater prominence can be given to a comparatively small object by causing the lines of a picture to converge towards it. Beauty of form exists in varying degrees of beauty, in different shapes, in proportion to their possible variety: thus, a square has but one shape, and possesses but small beauty; an oblong or an oval gives more variety; whilst the egg shape gives almost an infinity of combinations. If a picture of a human body be taken, it will be found to consist almost entirely of the egg-shaped lines, and to be the most beautiful of any possible picture. In the same way, in landscape, the perspective, consisting of the curved lines, is most pleasing to the eye, such as the winding of a road or river. The lines of a picture should lead up to the point of interest, which should not have a distant feature immediately behind it, otherwise the feeling of atmosphere is lost. How much to include is one of the greatest errors made in photography, and there are few prints which would not be improved by judicious trimming. Have a principal object, and give it just sufficient prominence, taking care that the light and shade, as well as the object, balance. The position of the light is a subject of great importance, and one about which few rules can be laid down; the artistic perception must be brought to play on each individual case. The balance of effect, choice of effect, time of day, are all points in which rules are impossible, except to observe the precepts briefly mentioned above. The lecturer concluded by saying that photography was now recognised by critics and artists to give ample scope for the exercise of some of the highest powers with which man is endowed. The production of more excellent apparatus gives one more time for forethought and careful consideration, as it is in every way as necessary for the photographer as for the artist to think out each individual subject.

Leeds Photographical Society.—At the ordinary monthly meeting a very pleasant evening was spent, when the Rev. J. BEANLAND gave his lecture on

PLATINUM WORKING.

Some beautiful specimens of printing in platinotype were shown by Mr. Richard Keene, of Burton-on-Trent, who, it will be remembered, took several photographs of Temple Newsam during the visit of their Royal Highnesses, the Duke and Duchess of York. Most remarkable amongst them were those of the grand staircase and corridor, fireplace, great hall, Darnley Room, blue drawing-room, view of the gardens from the terraces, the picture gallery, arranged as a dining-room, and the photograph of the house party. The Platinotype Company also forwarded some special prints to illustrate the subject of the lecture, as well as several exposed samples of paper, which were satisfactorily developed (hot-bath process) by Mr. Beanland in the presence of his audience. One item in the syllabus for Tuesday evening had to be omitted, owing to Mr. Bourne's' ill health; but the gap was very ably filled by Mr. S. D. MCKELLEN, of Manchester, who was visiting our city, with some of his latest productions in the way of

PHOTOGRAPHIC APPARATUS.

He pointed out the good points of a half-plate camera and three hand cameras, giving at the same time an historical account of the various patents taken out since 1883. He said the Automatic Magazine Hand Camera, which combines simplicity of mechanism with absolute infallibility in working, allows a dozen glass plates in sheaths, or two dozen cut films in sheaths, to be used at pleasure without changing the mechanism, removes the exposed plate or film, lays it down in the receiver, grips it so that it cannot shake about, and places the next plate or film in correct position for exposure. An indicator records how many plates have been exposed, all with the simple turn of a key, and with absolute certainty. The changing movement, which is performed in a moment, is independent of the position of the camera, it may be pointed upwards or inclined downwards, the plates may be changed all the same. Here the infallibility of the apparatus comes in. Gravitation has little to do with it. Nothing has to be thought about but the simple turning of the key completely round. He also informed his audience that a new feeder had just been invented and patented by Mr. Abel Heywood, of Manchester, consisting of a sight piece with a sight hole, which stands at the back on the top of camera in such a position that it will be easy to place the eye to the hole. A wire frame the exact size of the sensitive plate is placed at the top of the camera, the distance from the sight piece being the same as the length of focus of the lens. In use, the camera is held against the chest or shoulder, and the eye placed close to the sight hole, everything then seen through the frame will be in the photograph. In this position the picture is taken from the natural elevation, and much truer perspective is obtained than when the camera is held with the eye looking down upon it, as with the reflecting feeders. When the picture is secured, the eyepiece and frame are folded down out of the way. A ground-glass focussing screen is rendered absolutely unnecessary, even with stand cameras. At leisure, some time when not photographing, the camera is set up in the ordinary way on its legs, with lens complete. The correct focus is found on the ground glass for the nearest distances by the ordinary rack-and-pinion work. A line or pointer is marked on the travelling rail, and a corresponding line on the baseboard exactly opposite the pointer line, as before. As many of these scales are marked as there are lenses in use with the camera. When the camera is set up at any future time, and the pointer racked to any of the marks, and the proper lens inserted, it will be correctly focussed for the distance indicated by the pointer. By the use of the Heywood finder, the composition of the picture can be viewed through the frame in a much better manner than on ground glass, and the focussing cloth is done away with. Besides all this, the dark side may be inserted in its place ready for the exposure the instant the proper position of the camera is obtained. This finder is also made in pocket form to erect on the camera body when required, and when not in use can be detached and folded up. At the close of this display of apparatus, Mr. Godfrey Bingley showed, by means of the lime light, with Mr. A. W. Atkinson's assistance, a number of slides taken during the Convention week, these being the work of Mrs. C. W. Ward and Messrs. Fall, F. W. Hindley, Scorer, and W. D. Welford. Several members brought specimens of their own work for trial in the optical lantern. The PRESIDENT (Mr. P. Gilston) gave some wholesome advice to hand-camera workers, who, he suggested, sometimes presented their photographic apparatus and took advantage of "friend and foe" alike in undesirable postures. A little practice of the golden rule would prevent a little friction at times. The proceedings were brought to a close by a vote of thanks to Mrs. C. W. Ward, Mr. McKellen, and the other gentlemen for their able contributions to the evening's enjoyment. Arrangements were made to hold a competitive Exhibition of members' work in the Leeds Mechanics' Institute on January 19. The meeting was well attended, but details of the Exhibition arrangements will be forwarded to absentee members in due course.

Liverpool Amateur Photographic Association.—November 19.—Mr. GEORGE E. THOMPSON delivered his new lantern lecture,

THROUGH BARCELONA TO MAJORCA.

The lecturer's discourse consisted of an unaffected and sprightly narrative of a recent visit to Majorca, "the fairest island of the Mediterranean," and to Iviza, another of the Balearic group. The places described included Palma, the capital, which is rich in architectural antiquities; Manacor and the great Stalactite Cavern of Arta; the Monastery of Valdemosa, with its memories of Georges Sand and Chopin; Miramir and the Archduke Ludvig's residence, and Soller, with its romantic surroundings. The series of photographs illustrating these rambles was generally pronounced to be the finest Mr. Thompson has shown, and the lecture was received with enthusiasm by a crowded room, a vote of thanks proposed by the Association's PRESIDENT (Mr. J. Sirrett Brown) being carried by acclamation.

Plymouth Photographic Society.—November 13.—The Society was greatly interested and instructed by an exposition and demonstration of the Röntgen or X rays by Staff-Sergeant Bruce, of the Medical Staff Corps.—The President (Mr. E. H. Micklewood) having alluded to the mingled surprise and incredulity with which the early announcements that it had been discovered how to photograph the bones of a living person were received, and having sketched the present position of X-ray photography, Mr. Bruce proceeded to give a concise history of the discovery and of the steps which led thereto, in which, as he pointed out, our own countryman, Professor Crookes, the inventor of the special vacuum tube which is used, has no small share. Mr. Bruce also described the action of the apparatus he had with him, demonstrating in a very satisfactory manner the action of the electric current in vacuum of various degrees, and of the changes incident to different chemical vapours replacing air in the tubes. He then, by means of lantern slides thrown on the screen, showed a variety of pictures, radiographed hands, feet, and other subjects, showing that under the influence of the X rays the organic parts viz., the flesh, muscle, &c., practically become transparent, leaving the inorganic bones only to resist the passage of

the rays. Mr. Bruce then demonstrated the process by taking radiographs of the President's left hand and Mr. J. T. Trend's right wrist, the former having had the top joint of the middle finger destroyed by passing between cogged wheels, and the latter an imperfectly set broken wrist. These radiographs, having been developed by Mr. Micklewood, very clearly showed the abnormal condition of the bones. The results were most successful, as might have been expected, for Mr. Bruce has a most splendid set of apparatus, which worked without a hitch. Mr. Bruce concluded a highly interesting and successful demonstration by exhibiting the wonders of the radioscope, an instrument by means of which one can at once see the condition of the bones when not too deeply imbedded, and can literally see the bones of one's hand, even through a book two inches thick. The object to be examined is held near the excited Crookes' tube, and the radioscope applied to that, and now, on looking into it, the bones, or, in the case of a purse with money, keys, &c., only the inorganic objects seem to be left; and, as the lecturer pointed out, such an instrument could be of immense service to the surgeon on the field of battle in enabling him to at once determine the position of a bullet. On the motion of Mr. J. D. Turney, seconded by the Chairman, Sergeant Bruce was heartily thanked for his lecture and demonstration.

FORTHCOMING EXHIBITIONS.

1896.	
Nov. 27	Romford and District Photographic Society. A. John Ormiston, 4, Laurie-square, Romford.
,, 30–Dec. 1, 2 ...	North Middlesex Photographic Society.
December 3, 4.....	Aintree Photographic Society. E. P. Heron, 2 Tilney-street, Orrell Park, Aintree, Liverpool.
,, 29–Jan. 2.	Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.
Dec. 1896–Jan. 1897	Bristol International. Hon. Secretary, 20, Berkeley-square Clifton, Bristol.
1897.	
January 14, 15	Weymouth and District Camera Club. E. C. Bennett, 10, Newberry-terrace, Weymouth.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

ACETYLENE.

To the EDITORS.

GENTLEMEN,—As there has been much abuse of the explosive properties of acetylene, perhaps a few plain facts put before your readers will help them to form a fair opinion.

Perhaps you will allow me to quote a little of my experience. I have been connected with this gas in America for the last three years, therefore I may be able to prove that acetylene is not the dangerous compound your correspondent would have your readers believe. Your correspondent claims acetylene to be liable to spontaneous explosion; such is not the case, neither will it explode by the generator receiving a shock. This will prove it. I filled an iron ball with acetylene to a pressure of five pounds to the square inch, and then subjected it to a series of blows from a large sledge-hammer. Although the ball was bent all shapes, there was no explosion, neither has there ever been to my knowledge through this cause. Acetylene has a chemical action on *pure copper*, but none of a dangerous kind on brass. Series of experiments have been conducted by me before the Chemical Society of New York, and they all go to prove this. Several insurance companies in England are at present willing to insure houses, &c., lighted by acetylene, and, no doubt, in a short time, all will do so. I may add there were last year 730 people using acetylene as a general illuminant in New York, and that only three accidents occurred—two through escapes and one through a generator being charged with a candle close by, conditions under which coal gas would have acted just the same. Explosions are often caused by the generator having no back pressure valve; if this is not fitted, when the carbide is exhausted and the pressure gone, the lights are liable to fire back to the gas-holder and explode same. No generator should be purchased without such a valve. The recent explosion at Grimsby was from this cause. Acetylene gas is far healthier to burn than ordinary coal gas, and, when inhaled, its effect on the human body and the lower animals is far less dangerous than coal gas.

In conclusion, allow me to request your readers to make a practical test, and I am sure they will agree with me that acetylene is an ideal illuminant both for general and photographic purposes, and under proper conditions just as safe as coal gas.—I am, yours, &c.,

Putney, November 18, 1896. PERCIVAL C. FREWIN, F.C.S. U.S.A.

THE PHOTOGRAPHIC SALON.

To the EDITORS.

GENTLEMEN,—Nothing could be more regrettable than the excessively offensive personal tone that Mr. Horsley Hinton has chosen to adopt in replying to my letter in your issue of the 6th instant. The increasing absence of courtesy in social intercourse is one of the most lamentable features of modern times; from a certain class we expect nothing better, but that a man in Mr. Horsley Hinton's position—the Editor of a paper that from the nature of its object, circulates of necessity amongst those of refined tastes—should descend to such expressions as a "pure fabrication," "not very reputable performance," in addition to others almost equally objectionable, is in the highest degree regrettable. It should rather have been his aim to have kept the pages of the artistic and technical press as refined in tone as possible. Nothing can be gained by the introduction of insulting personalities into a discussion; it advances no principle, but, on the contrary, indefinitely retards it, by diverting attention from the original theme of the debate, and ultimately losing it altogether in the ever-increasing bitterness of the personal attack. My letter contained no personal attack of any kind; and, having no wish to follow the undesirable example of Mr. Horsley Hinton in replying, I can ignore the intentional discourtesy, I hope, and reply to the subject-matter in detail. Since, however, the statements in my previous letter are supported from the Salon catalogue, and *Mr. Horsley Hinton's own writings during the last six or seven weeks*, I can fairly claim that he should at least withdraw the worst expressions in his letter, the "pure fabrication" and the "not very reputable performance."

In the first place, Mr. Horsley Hinton devotes just a third of a column in contesting a statement that he attributes to me (see the first four lines of his letter), that the Salon Committee send "invitations to contribute" and "then do not accept what is sent in," ending with the words, "If, therefore, Mr. Bennett or any one else says an 'invitation to contribute' was sent, that statement is untrue." *Now, this is just what I did not say*, as a reference to my letter will show. I was careful to use the expression "send in," this being taken from an editorial note to Mr. Oliver's letter in the *Amateur Photographer*, October 9, 1896, p. 290.

"NO ONE IS INVITED TO EXHIBIT at the Photographic Salon, he may have been asked to *send in*. Ed. *A. P.*"

And I am justified in attributing to Mr. Horsley Hinton the editorial articles and notes that appear in that paper; since his name is printed on the first page of each number as Editor, he is responsible for them. What is gained by misquoting a letter in order to refute the misquotation? I notice that Mr. Alfred Maskell adopts a similar method in the latter part of the third paragraph of his letter replying to Mr. Evans; it certainly conveys the impression that the writers find the original statements indisputable. But, although the statement that I did not make is said to be untrue, I am asked to point to any single word or sentence in the Salon prospectus that even implies an "invitation to contribute;" though, after all, is it not a mere quibble to attempt to discriminate in this manner between an "invitation to send in" and "an invitation to contribute," or an "invitation to exhibit?" The third paragraph of the familiar prospectus which is sent out as an invitation each year refers to the photographs "sent in" as "*pictures entered for exhibition;*" naturally, what else are they sent in for? This prospectus is unquestionably an invitation to its recipients to contribute their best work to the coming exhibition, and whatever else he may call it, the interesting fact remains. In saying that I protest against the "unfairness of the Committee in sending invitations . . . . and then not accepting what is sent in," he ignores or misunderstands the whole import of my letter. The only inference to be drawn from the prospectus is, that a selection will be made from the works contributed *on their merits alone, irrespective of whom the sender may be;* and my contention is that this is certainly not the case, and that the disproportion existing between the number of works exhibited individually by members of the charmed circle and non-members respectively, is no criterion of their relative merits. This does not necessitate "rascality," as Mr. Horsley Hinton assumes, but I admit that in one sense it implies incompetence to judge or select; for no man can be competent to decide between his own and his rival's work. Mr. Horsley Hinton argues that the Committee is composed largely of men of recognised ability—a point that I have never questioned; but, while he holds the opinion that really able men are only to be found in the Linked Ring, I would contend that very many fully equal exist outside this magic circle.

"Its own members include most, if not all, of the best men."—*Amateur Photographer*, September 25, 1896, p. 247.

The "Links" form one section of the photographic world only, and not, as Mr. Horsley Hinton would have us believe, the whole of it. He says that they are asked to "judge, lecture, write, and exhibit," as a proof of the current estimate of their ability. As a matter of fact the majority of the judges at exhibitions announced at the present time are not members of the "Ring," while not one in ten of the lectures at the leading photographic societies is given by a "Link."

It is this assumed superiority over all other photographic workers so frequently and so aggressively asserted, coupled with the fact that it consists mostly of men whose views and methods of working run very much in the same groove, that condemns the Linked Ring as a final or standard authority when works of varying character are competing for premier honours. In comparing their own with their rivals' work, they invariably judge their own to be far superior, though their decisions are frequently reversed by other competent but less prejudiced judges. The Links, or many of them, are so convinced of their own superiority over other photographers, that there is at least the danger of their developing mannerisms and conventionalities in their work that would in time rob

it of all pictorial value. It is an open question whether there are not already indications of such conventionalities, and also of mutual imitation.

Mr. Horsley Hinton is certainly in error in stating that the Pall Mall and the Salon are *equally* "open" exhibitions. At the latter, members' works are accepted because of their membership; at the former, members' and non-members' contributions are judged on an absolutely equal basis, and in hanging the same equality is maintained. This is the crucial point of the whole argument: that the prospectus in inviting contributions is so worded as to induce photographic workers to send in under the impression that it is an open exhibition, while in reality a large proportion of the space is already engaged by the Links' own contributions, some of which have little but their eccentricity or careless technique to recommend them. In assuming that, had the Links sent their works to the Pall Mall instead of the Salon, they would have had as many accepted, he expresses an opinion that he would have great difficulty in producing any facts to support. He admits "that the respective committees judge from a different standpoint." Fortunately for photographic work they do. It is pleasant to think that there is one point in his letter whereon we can agree.

One of his greatest inconsistencies is his suggestion that all letters from private persons attacking either the Pall Mall or the Salon should be suppressed, since one of the greatest offenders in this respect is Mr. Horsley Hinton himself. Though he writes in this instance as a private individual, he cannot disassociate himself from either his writings as Editor of the *Amateur Photographer* or as a member of the "Linked Ring." In his paper he scarcely ever alludes to the Royal Photographic Society without some sneering or more or less contemptuous reference, giving his readers to understand that it is an effete, poor, and third-rate institution, while no flattery is too great for the rival society. This might be excusable in a private individual, but the Editor of a public review should be an impartial critic. In reviewing the opening of this year's Salon, he devoted nearly a page to a consideration of the high artistic qualities of the works generally, and the lofty ideals and aims dictating their conception and execution (see *Amateur Photographer*, September 25, 1896, pp. 247 and 259).

In striking contrast is his article the following week chronicling the opening of the Pall Mall Exhibition. Perhaps he had used up all his expletives expressing admiration in writing of the Salon; certain it is that sneering and ill-natured sarcasm run through the whole of it; there is not a single word to indicate that the exhibition is even worth visiting, but much to convey the opposite impression. The following extracts require no comment:—

"The unprejudiced and competent visitor will find it difficult to select out of the 360 entries more than six works of first-rate pictorial merit; the conclusion looks like—well, no, we will not call it failure, there may be intermediate degrees between triumph and defeat," &c.

". . . . Should what we suggest come to pass, and an exhibition of scientific and mechanical photography be held in a new place, and the pictorial in Piccadilly, what will the Pall Mall do then, poor thing?"

And, alluding to the progressive spirit of the younger members—

"If they don't get the bit in their mouths and gallop the whole thing into a ditch."—*Amateur Photographer*, October 2, 1896, p. 268.

If these extracts really represent Mr. Horsley Hinton's opinion, no competent and impartial critic would endorse it.

At the termination of the Salon Exhibition he wrote that it had

"justified its existence by the general success which the public have secured for it."—*Amateur Photographer*, November 6, 1896, p. 365.

But a week later the same public support was considered no indication of the quality of the Pall Mall show, the mass of the paying public, we are told, being unable to distinguish.

"It is for the masses to applaud and to pay, and for the few to understand."—*Amateur Photographer*, November 13, 1896, p. 385.

How can he with any consistency advocate the suppression of letters attacking the Salon? Those who live in glass houses should never throw stones.

The most serious paragraph in Mr. Horsley Hinton's letter, however, is that in which he couples two statements of mine together, stigmatising them as "pure fabrication, and not a very reputable performance either."

Taking the latter statement first, I wrote that the one article of faith in which there appeared to be unity among the Links was their hostility towards the "Royal;" I can only judge from their writings, and at different times they have expressed the most widely diverging views on almost all questions of art and technique, but on this one theme they appear unanimous; Mr. Horsley Hinton's previously quoted articles being fair samples. Is it that they are jealous of its unquestionable success?

The other "disreputable fabrication" that is charged against me is that, 'like many others, I appear to regard the Salon Committee and the Link Ring as synonymous." Well, I can only quote Mr. Horsley Hinton again:—

"The Linked Ring, or Salon Committee, now numbers some fifty members . . . . . the names of the Committee, which are printed on the first page of the catalogue. . . . ."—*Amateur Photographer*, September 25, 1896, p. 247.

"The Linked Ring, otherwise and more publicly known as the General Committee of the Photographic Salon."—*Amateur Photographer*, October 30, 1896, p. 345.

And for accepting these statements as true, I am called——well, Mr. Horsley Hinton really ought to improve his memory, the latter of these statements having appeared just ten days before the date of his letter!

In conclusion, I desire to impress on Mr. Horsley Hinton that I am neither "an indignant person," "a discontented correspondent," nor "one whom some imaginary grievance has rendered spiteful." Personally I have no grievance whatever. The fact has been emphasised that the Linked Ring is a private society; still, its exhibition is public and must conform to, and be judged by, the same standard as any other public organization. The leading Exhibitions, most of all, should be so conducted as to give no cause for misunderstanding or suspicion of unfairness.

Turning for a moment to Mr. Charles Moss's letter, which, from its courteous tone is at least more pleasant reading, I would say that the vigour of Mr. Horsley Hinton's reply is the best indication of the necessity of attempting to prove a self-evident fact. I agree with Mr. Moss that the more difficult a prize may be to win, and the keener the competition, the greater the honour in winning it—I will even go further, and say that the more desirous would a good and enthusiastic worker be of entering the contest; but the moment that any other consideration than merit is allowed to influence the decisions, the whole value of the competition is lost.—I am, yours, &c.,

HENRY W. BENNETT.

November 17, 1896.

COLOUR PHOTOGRAPHY.

To the EDITORS.

GENTLEMEN,—Mr. Ives charges me with "questionable methods of crying my own wares." Mr. Ives must be well aware, as well as most of your readers, that my letter was written as an answer to the article on *Transparencies in Natural Colours* in this JOURNAL, and wherein direct references were made concerning myself and my work. It is not my policy to *cry* my wares; I prefer they shall speak for themselves. The first condition for successful optical projection demands that the picture shall be upon a single *plane*, and I did not think it possible for one composed of six films (three films of gelatine upon three of celluloid) to fulfil these conditions. I also thought it *was a fact* that a print in bichromated gelatine or albumen produced a brown image, and that three such would make a vigorous positive. I had no *intention* of making a "miestatement," and I must leave this to the fair judgment of your readers.

Just another remark, and I will not further occupy your valuable space. Mr. Ives quotes from a private communication of mine (without my permission), and says I wrote him wishing to obtain one of his photochromoscope cameras," &c. That is so. It was my intention at that time (nearly a year ago) to bring out a method of three-colour printing for the *reproduction* of my own *colour photographs!* as they were expensive to produce. I have *never* required such a camera for the production of my *colour photographs*. Thanking you very much in anticipation.—I am, yours, &c.,

J. WALLACE BENNETTO.

PHOTOGRAPHY AND POLYTECHNICS.

To the EDITORS.

GENTLEMEN,—Mr. Matthew Surface, in your issue of November 20, disputes some of my statements respecting the polytechnics. He asserts that they are still mainly occupied in instructing photographic *employés*. According to the last report of the Examination Department of the City and Guilds of London Institute, 168 candidates presented themselves for examination in photography. This number represents, roughly, the professional photographers who passed the various polytechnics in England. Considering that the photographers between the ages of fifteen and twenty-five number some 3000, the comparison will give an idea of what such institutions are doing for the scientific education of photographic *employés*. From this it is evident that they depend mainly on outsiders.

Mr. Surface fails to see what harm can come from this to the genuine professional. It does great harm, because it multiplies photographic assistants at a greater rate than the natural expansion of trade requires. The apprenticeship system, I admit, errs in the opposite direction; but this is on the right side, for it does not increase the pressure of competition. As a result of the too rapid multiplication of assistants, the photographic labour market is overstocked, and what economic value polytechnic teaching may have added to the assistants is destroyed by excessive competition. Of course, if Mr. Surface wants to see photography reduced to the level of say—music, in which profession only men of genius, organ-grinders, teachers, and manufacturers can earn a competence, these economic considerations will have little weight. The effects do not stop with the assistants. At one time photography was the dumping ground for all the blind, lame, and halt in the kingdom. When a man lost a leg or an arm, it was said, "he will never be any good again at his trade—make him a photographer." In many cases

this was done. The fashion has changed, and in part, owing to the facilities offered by polytechnics, persons with a little capital, on the look out for a respectable and genteel occupation, instead of selecting a tuck shop, tobacconist's, dressmaker's, &c., plump for photography, and open a high-art studio in Mayfair or Whitechapel, according to their means. In this manner an excess of capital is introduced into photography, competition amongst employers becomes severe, and profits and prices fall. As a result, we have "unfair competition," and 4*l.* 4*s.* enlargements for 6*s.* 6*d.* From the point of view of the public this is a magnificent triumph of modern progress; but to the photographer the triumph is by no means so apparent.

In the second paragraph Mr. Surface merely restates my own position. As I said, the power to apply scientific principles is only possessed by the few, and not by the many; hence to teach scientific principles to those who can only use and appreciate the philosophy of the back kitchen is sheer waste of time. All our resources should be devoted to finding, and then instructing, the man who has the ability and can appreciate the scientific principles in their application to practice; hence the standard should be lowered for the average student and raised for the man of real ability. As Professor Huxley pointed out long ago, the aim of education is to find your man of genius. When found, he should be provided with all the requirements for the study and investigation of scientific principles. Such a laboratory, with men in it of the capacity of Abney, Eder, and Vogel, is called for at the present moment in photography rather than hundreds of men of average capacity with no real grip of remote scientific principles.

Coming to the third paragraph, Mr. Surface thinks that common politeness should be taught in the home. The meaning I attached to "professional etiquette" was hardly that of common politeness. A man may be a paragon of manners, and yet a fearful duffer in dealing with sitters, his negatives showing that he has only succeeded in boring his sitters most horribly. My meaning was more the "management of sitters," the art of obtaining pleasing portraits, and this can only be learned by serving in a studio under some experienced operator.—I am, yours, &c.,

JOHN A. RANDALL.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2, *York-street. Covent Garden, London.*

PHOTOGRAPH REGISTERED:—

P. Charleton, Garrison Studio, Newbridge, Co. Kildare, Ireland.—*Photograph of Bob, the drum horse, 10th Prince of Wales Royal Hussars.*

ACETYLENE; CALCIUM CARBIDE, &C.; INQUIRY; H. J. BUCKLAND, and others. See under Ex Cathedrâ.

PHOTIQUE ART.—1. The process described is the ordinary photogravure process. 2. No; if the patent is really invalid, any one is at liberty to work the process.

THE SPARTAN.—We are somewhat of your way of thinking, but your letter is perhaps a little too violent in tone for an anonymous communication; hence we do not print it.

FOG.—S. CLARKE. If the view was taken in a fog, there is no way of treating the plate so as to take away the fog, and leaving the negative as if it were taken in fine weather.

SHELLAC SOLUTION.—In dissolving ordinary shellac, whether bleached or not, there is always a sediment of matter that is insoluble in alcohol. Allow that to subside, and decant the clear portion.

LENS.—LEEDS. Names only. Orthoscopic, Orthographic, and Caloscopic are all the same lens under different names as adopted by their various makers. They are not at all identical with the triplet.

MATERIAL FOR BACKGROUNDS.—A. Z. asks: "Would you please tell me where I can purchase calico wide enough for backgrounds?"—At any large furnishing warehouse. Better ask for "unbleached sheeting."

RETOUCHING.—NOVICE. The surface of a negative may be roughened by rubbing it over with finely powdered pumice or cuttlefish powder. We fancy, however, you would find it better to use one or other of the commercial retouching mediums.

COPYRIGHT.—F. B. J. Of course, you have no copyright in the picture. How can you have? The sitter paid your late employer in the ordinary course of business, and you, as his servant, took the portrait. It seems to us that you are trying to be a little too "smart" on leaving your employ. If you attempt to make the portrait copyright, and show it in your window, you may find yourself in trouble in more ways than one.

MICROSCOPIC WORK.—T. ARGENT. The objectives you have will do very well indeed for photo-micrography. We should recommend you to practise first with the inch and a half, on large subjects, till fairly perfect; then go on with the eighth, and, when proficient with that, use the still higher power. Beginners frequently make the mistake in essaying the use of high powers at the commencement, and then get disheartened by their results.

"PHOTOGRAPHISCHER ALMANAK."—E. FENSKE says: "Can you inform me where I could get the *Photographischer Almanak* for January, 1897 which you are reviewing in your last issue, and what is the price?"—In reply: Of E. Liesegang, Düsseldorf. Price, we believe, 1 mark.

FOGGY NEGATIVES.—O. MCNIEL. The only way we can account for the fog is the dark-room light. The lamp may be perfectly safe with slow, or even moderately quick plates, but may be just the reverse with those of extreme rapidity. Put a plate in a dark slide, pull out the shutter half way, and expose to the lamp for a minute or two, then develop, keeping as far from the light as you can get. We shall then expect that one half of the plate will be fogged, while the other will be clear, or comparatively so.

COLOURS.—J. H. MOODY writes: "Will you kindly inform me where I can get the colours used for colouring views, such as are usually seen in railway carriages and sold at most of the principal stationers? Also, if directions are sent with the same colours?"—Colours suitable for colouring photographs are sold by all artists' colourmen. They do not differ from those used by painters generally, therefore no directions for use are supplied with them. It is more than probable that the pictures our correspondent refers to are produced mechanically, and are not photographs coloured by hand.

MEALY PRINTS.—C. BENTON. The acetate of soda toning bath, with albumen paper, may be expected to yield mealy prints if it is used directly it is made up. This bath should not be employed until it has been made at least twenty-four hours—forty-eight is better. Over-toning is also a source of mealy prints. Some ready-sensitised albumen paper will not bear toning beyond a red-brown stage without the prints possessing this defect; but, if the toning be not carried beyond that point, no mealiness will be seen. Prints from weak negatives are more prone to mealiness, if deeply toned, than those from vigorous ones.

ELECTRIC LIGHT FOR LANTERN.—R. H. W. (Herts). Yes; battery power can be employed for the electric light in the lantern, but we fear that you will find that it is more trouble than most amateur lanternists would care to undertake. The Smee form of battery would be quite unsuitable for the purpose. The best would be the Grove or the Bunsen. Thirty to forty cells will yield a good light, and a smaller number would suffice for a smaller screen. If you must have electric light occasionally, would it not be better to hire secondary batteries, ready-charged, if they are to be had in your neighbourhood?

PRESS FOR COLLOTYPE.—W. RIED. There are many kinds of presses that may be used for collotype printing. An ordinary lithographic press may be used, so may the Albion press as used for typographic printing. In fact, one of the establishments that turn out some of the best collotypes produced in this country uses no other. Winstone & Son, Shoe-lane, make a press specially for collotype work, which may, no doubt, be had from Penrose & Co. Call on them. In Germany, when hand presses are used, they are similar in principle to the English litho presses and have a scraping pressure. So far as we are aware, they are not stocked by the dealers in this country.

OIL LANTERN.—J. TILLEY complains that his lantern "stinks abominably every time it is used." He says he has had new burners, and it is just the same as before. He asks if all lamps burning paraffin oil behave the same. No, they do not, if kept in proper order. In most cases, offensive fumes may be traced to want of care—the wicks not evenly trimmed, or not nicely adjusted while burning, for example. In the majority of the cases, the smell is due to the dirty state of the outside of the lamp. The oil on its surface vapourises, hence the smell. The whole of the outside of the lamp, and the wick tubes, should be wiped scrupulously clean with a dry rag before the lamp is lighted, then there will be no smell from a well-constructed apparatus.

RETURNING MONEY.—ONE IN DOUBT says: "I should esteem it a favour if you could answer me the following:—A photograph is taken of a lady and child; the child, we find, on developing, has moved; the negative, by accident, gets broken. A post-card is sent requesting another sitting, as it is not satisfactory. The husband writes, saying his wife cannot sit again, being unwell, and demands the cash paid to be returned, otherwise he will issue a County Court summons for the same. The query is, Is the photographer legally bound to return the cash paid? and, if not, could the said individual, do you think, recover the same in a County Court?"—In all probability, yes. The sitter paid for portraits of herself and child, which you fail to supply through no fault of hers. You broke the negatives; therefore, if she cannot or will not sit again, you should return the money you received, as you are unable to fulfil your part of the contract—supply the portraits.

COPYRIGHT. CRAYONS.—J. P. writes: "Will you kindly answer the following questions?—1. How can a photographer ascertain, for certain, whether a photograph (which he is asked to copy) is copyright, and what is the cost; and, also, would he have to send the particular photograph anywhere—Copyright Office, or elsewhere—for inspection? 2. What is the process of finishing enlargements in crayons; are crayons employed on bromides and carbon prints? also, what kind of crayons are used, where can I get them, and in what book, or article, can I get information on crayon finishing?"—In reply: 1. Only by searching the register kept at Stationers' Hall. The simplest way would be to write to the one who took the photograph and ask the question. 2. Crayons are employed on bromide as well as carbon prints. No special crayons are necessary. Those supplied by artists' colourmen, in the ordinary way, are what are used. We know of no work now in print dealing with the subject. The best way would be to get a few lessons from an artist who does this class of work.

*** Owing to our brief absence from town, several communications for the JOURNAL must stand over till next week.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1909. Vol. XLIII.—DECEMBER 4, 1896.

Contents.

EX CATHEDRÂ.

Our correspondence this week is of an unusually rebellious nature. We do not know whether to ascribe this to the effects of the bleak and autumnal weather, which may easily be understood as having a depressing and irritating effect upon photographers, or to the possibility of our having acquired, we hope rightly, the reputation of possessing an ear of sympathy for the trials and troubles of our professional readers; but in the complaints to which we make reference below we recognise so much for which photographers may legitimately claim publicity in our columns, that we have little hesitation in giving them place. Shall we add, Of each of the letters it may be said, as it may be said of many others that we constantly receive, that it is an argument and a plea for the establishment of a central, representative, and effective body to which professional photographers might turn for support when their interests are unfairly assailed?

* * *

First of all, Mr. C. A. Jackson, photographer, of Middleton and 2, Clegg-street, Oldham, says, with reference to the following letter, which he encloses, that it may be of interest to us—which it is—and that he is not in need of "so good a tip." It will be observed that the authors of the letter, Messrs. R. Boscawent & Co., photographic and novelty publishers, dating from 41, Cyrus-street, Goswell-road, London, E.C., ask for the payment of the tangible sum of 10*s*, in return for which they undertake to place the photographer who parts with that sum in possession of an "idea." We have only to remark that the world—yea, even the photographic world—is full of "ideas," and that many of them are extremely dear at 10*s*. each.

* * *

However, Messrs. R. Boscawent & Co. shall plead their own case:—

"We are," they say, "desirous of making arrangements with a photographer in your town for the working of an idea, which has met with a very large measure of success in London and other parts. Only one firm in your town will be furnished with the necessary particulars and information, and, subject to the conditions named below, we make you the first offer. At the present time we have not approached any other photographer in Middleton with reference to this matter, and, should you be enabled and disposed to take it up, we shall have no occasion to communicate with any one else on the subject. The work is within the compass of any professional photographer, and the value of the idea referred to chiefly consists in that it creates a big demand for photographs. The conditions necessary to our giving you the requisite instructions are:—

"1. That you have, or can obtain use of, half-plate or whole-plate outfit.

"2. That you agree to allow us 10*s*. on every 10*l*. net profit.

"3. That you remit us 10*s*. previous to our sending you the necessary information and instructions.

"The reason, we may mention, for the last-named condition lies in the fact that, although the idea is, and has been, most remunerative, it is not, and cannot be, patented or protected in any way; and, for the same reason, the carrying out of the second condition will be entirely a matter of honour on your part. We guarantee the work *very* profitable, and it would, moreover, be a big advertisement for you, and give you considerable advantages over any competing house. On receipt of remittance for 10*s*., together with a statement that you agree to pay the commission named, we will *at once* place you in possession of the fullest necessary information to permit of your proceeding with the work, for which no outlay of capital beyond the 10*s*. mentioned is necessary. Unless we hear from you promptly, we shall conclude that, for some reason or another, you are unable to interest yourself in the matter, and

shall act accordingly. The possession or use of half-plate or whole-plate outfit is *absolutely essential*."

* * *

Next, Mr. Thomas Pinder, photographer, of 100, Yorkshire-street, Rochdale, encloses us a circular which he says was sent to each householder in his town by a grocer, who has about forty shops. Mr. Pinder adds some observations about the religious standing of the grocer which it is not necessary for us to reproduce; and he also asks for any remarks that we might like to make. We need say no more than this, that some years ago a tobacconist of our acquaintance gave away photograph coupons with the tobacco he sold us, and that we experimentally proved that neither the tobacco nor the photographs were as good as we could have obtained in the ordinary way elsewhere by paying the ordinary prices.

* * *

But we append the circular sent us by Mr. Pinder. It bears a curious resemblance to many other circulars which we have the best reason for believing come from a common source.

"Have you a photograph of relative or friend which is constantly fading? Would you like it enlarged into a beautiful portrait worth a couple of guineas, free of cost, for those who regularly use —— Tea. With every quarter pound of tea we give a 3*d.* check. When you have got six shillings' worth of checks, bring them—together with your photograph—to any of our branches, and in about fourteen days you will receive a beautiful enlargement, along with the original photograph. We have a choice variety of frames suitable for these enlargements at 4*s.* 6*d.* each."

* * *

Finally, a copy of the *British Almanac* (of course no reader will confuse this with The British Journal Photographic Almanac), published by Messrs. Charles Letts & Co., is placed before us. Were we reviewing this work, we should have nothing but praise for it, as it is an admirably compiled publication. But we turn to page 367 of the work, and we find it stated there that, in order to increase the popularity of the book, the publishers have arranged with the photographers named in a subjoined list to supply *gratuitously* a cabinet-size photograph of the owner of each volume. The conditions governing the use of an annexed coupon are then recited.

* * *

For reasons that we give below, it might be thought that the list of photographers who have agreed to take photographs for nothing is a large one, and embraces all the best firms in the profession. Will it be believed, then, that in London only *four* photographers have agreed to take photographs on the off-chance of thereby obtaining subsequent orders, and that in the whole of the provinces—English and Scotch—not more than forty-six photographers have been found possessed of the same ambition? We must confess ourselves disappointed with this paucity of numbers, for, turning back to our issue of September 11, we find that we quoted Messrs. Letts as saying that "the most general opinion of the photographic profession" was that "the scheme should prove a most excellent one from the photographer's point of view!" Yet—such is man's ingratitude—only fifty photographers have availed themselves of the scheme! But more: On September 18 we quoted Messrs. Letts as saying that they were "literally inundated with applications from the very first photographers throughout Great Britain, and the only difficulty will be to make a selection!" So the very first photographers of Great Britain number fifty, and are sufficient to constitute an inundation! But we are more merciful than Messrs. Letts, and we therefore withhold the names of these fifty photographic philanthropists.

IS THE RULED-SCREEN SYSTEM THE BEST FOR PROCESS BLOCKS?

At the last Photo-mechanical Meeting of the Royal Photographic Society a by no means bad suggestion was made, namely, that experimentalists should give attention to some of the old processes, such as those by which excellent results could be, and were, produced in years gone by. Pretsch's, for example, was quoted as being deserving of notice. During the past few years great improvements have undoubtedly been made in the production of half-tone blocks, but only in one direction, the ruled-screen system. So firmly has this method now become established that few, if any, at least of those who work commercially, give any thought whatever to any other. Photo-mechanical workers, we are sorry to say, like photographers generally, are very conservative in such matters. So long as they get good results they seldom care to seek for anything superior, and this appears to be the case with the ruled-screen system of making half-tone typographic blocks.

Although excellent blocks are now produced by this system, yet they are open to many objections. The uniform, mechanical, net-like grain is very objectionable from an artistic point of view. The blocks are more difficult and costly to print, when the finest results are required, than are engraved wood blocks. For instance, a paper, ink, and printing that would yield good prints from ordinary wood blocks will not do at all, for high-class work, for process blocks, the relief is too low, and the grain too fine, for rapid working in a machine, with a medium-quality paper and ink. Greater skill, or rather a great deal more care, on the part of the machine man, in the "making ready" and the working of process blocks, is necessary than is the case with engraved wood blocks. It is this that has caused some of the best illustrateds to revert to line blocks for so many of their portraits.

Will that continue? Will workers go on trying to improve one process only, and giving no heed whatever to any other that may be made available, and possibly with great advantages in working if the same amount of skill and attention were expended upon them as has been done in the ruled-screen method? In proof that other methods are available, one has only to refer to back volumes of the Journal, or the records of the Patent Office, to be convinced, and our older readers to be reminded, of the fact.

The Pretsch method was referred to at the meeting just referred to. This is a swelled-gelatine method, in which the grain, instead of being a uniform mechanical one, is a discriminating one, more open in the lights than in the shadows, in the deepest of which there is practically no grain at all. It may very well be asked why, if this process of five-and-thirty years age is now suggested as a promising one at the hands of experimentalists, it has been so long in abeyance. There are more reasons than one why this is the case. One is that the time was not commercially ripe for it, the process was "too previous," a demand did not exist for it, though it materially helped to lay the foundation for that class of work. Another reason probably was that, at that period, the properties and characteristics of chromated gelatine were not thoroughly

understood, hence the results could not be relied upon. As a consequence the blocks were frequently inferior in quality, thus entailing delay and loss.

There is also the Placet method of chemical graining. In this method, as in that of Pretsch, the grain is a discriminating one, and, in the hands of novices, it will probably yield more uniform results, though not better than Pretsch's when the principles involved in that are thoroughly understood. Placet's process seems to have been completely neglected alike by practical workers and experimentalists, but why it is a little difficult to understand. It may, however, be that, like some other photographic processes, it was invented before its time commercially, and, as it was not worked, became almost forgotten.

There is the Swan method of producing relief blocks, which was patented by him in 1879. This is a screen and a swelled-gelatine process combined, and it has the advantage that the original negative itself becomes the swelled and lined matrix from which the printing block is moulded. The process of Swan is capable of yielding very good results. It was re-invented some years after the patent had lapsed, and was patented afresh. A limited company or syndicate was formed to work it, but we believe the concern did not prove a very flourishing one. A company was formed some thirty-five years ago, it may be mentioned, to work Pretsch's process, but it proved a commercial failure. It does not follow, however, because a company fails to successfully work a process commercially, that the process itself is at fault, because the failure may be due to lack of skill on the part of its workers, or, maybe, to want of business tact in the management.

At some future time we may recur to this subject, and point out other photo-mechanical processes that have been neglected which might profitably receive attention, inasmuch as the principles involved in them are better understood now than when they were first invented.

Photographs of Flying Bullets.—Our readers are doubtless familiar with the wonderful photographs by Professor C. Vernon Boys, F.R.S., of flying projectiles from rifles, &c. (taken by the electric spark), in which the wave of air accompanying the bullet was remarkably clearly depicted. Professor Mach has sent to the Editor of *La Nature* a similar kind of photograph, taken by the Professor's son by an entirely different arrangement. *Nature*, last week, contains an illustration of the photograph, and a reproduction of a sketch of the apparatus by which he "took the photograph of the bullet by using a spherical silvered glass mirror. . . . . The bullet causes a sonorous wave, by which the Leyden jar is mechanically discharged and produces the spark."

Forms of Tubes for Röntgen-ray Work. — In *La Nature* last week will be found a long descriptive article upon the various forms to which, in the process of gradual development, the original Crookes' tube has been brought. No less than thirty-two tubes are pictured and verbally described. Nineteen are based upon the utilisation of the direct action of the rays, ten on the reflected action, and three on a combination of the two. Naturally, prominence is given to the names of French makers, though we find two with the name of Crookes appended, one with Wood and one with Tompson. The "focus tube" so much adopted in this country, which is usually associated with Mr. Jackson's name, is neither illustrated nor alluded to in the text. The good work done by the first-named class of tubes before the advent of special forms is justly noted, though it is properly pointed out that, though the results were good, they were slow and the sharpness of image was least.

The New Element Lucium.—The shareholders in the Incandescent Gas Light Company will, no doubt, read with a great deal of pleasure an article by Mr. Crookes, F.R.S., the Editor of the *Chemical News*, in that journal, describing a close analytical examination of the alleged new element lucium, so named by its discoverer. As before described to our readers, the discoverer anticipated that it could be used to make mantles for incandescent burners, and as a new substitute entirely, avoiding any infringement of the Welsbach patent. Mr. Crookes' examination, however, would seem to show conclusively that lucium is practically a mixture of ytterbium with a small amount of didymium, erbium, and possibly some others of the rare earth metals. It may be remembered that sodium thiosulphate ("hypo") was used for throwing down the supposed new element, and Mr. Crookes says of this, "The error has arisen by considering the sodium thiosulphate separation as a complete one, whereas yttria partially comes down if the solutions are strong and heated.

Another Lost Chance for the Photographer.—According to the *Standard*, a French traveller in the Indo-Chinese region has captured a native savage of the race called Moï, who is the veritable missing link. He climbed trees like a monkey with the sole of his foot to the tree, and, beyond all, he had a tail. M. Paul d'Enjoy, the traveller in question, seems to have been able to converse with him, it is not stated how, and he learnt that most of the Moïs have tails, but through intermarriage with ordinary mortals the appendage is not general. M. d'Enjoy does not state whether the savage could wag his tail, nor, if afraid, tuck it between his legs, and altogether the account is received with incredulity. What appears to us the gravest cause for doubt is the fact that, while nowadays nearly every traveller is a "button-presser," we have not a single word about a photograph of this missing link. We may be sure that, if it should be proved that these Moïs really exist, the irrepressible interviewer, with camera in hand, will soon be at his heels.

"The Devil's Signature."—Under this heading is described in the *English Mechanic* a violent controversy which is being carried on by a leading Roman Catholic paper in Germany and the Catholic Director Künzle, of Feldburg, in the Tyrol, as to whether a signature claimed to have been made by the devil can ever be accepted as genuine. The newspaper claims that it is impossible to secure a genuine signature of his Satanic majesty. Künzle retorts that the paper, in making such a statement, is untrue to Catholic teaching and traditions, and his point of view is backed up by the Prince von Löwenstein, the stated President of the Catholic Congress of Germany. Now, of course, we have nothing whatever to do with such a controversy; but there the signature is, and what we would ask is, What are the photographers about that they have not, by guile or stratagem, obtained a photograph of the signature under discussion? Surely there is a fortune for the man who can sell broadcast through Europe cabinet pictures, say, with the inscription below, *The Devil's Signature*. Then the illustrated papers, what would not they offer for sole permission to publish? It is a grave question whether such a picture—for this signature with its adornments is a picture—would subject to copyright.

DIGRESSIONS.

No. XII.—The Picturesque and the Beautiful.

The picturesque and the beautiful are the chief materials on which the pictorial photographer exercises his art. As "music is the food of love," the qualities about which I am about to discourse are the food of the artist. The other artistic emotions (except the merry ones), such as sublimity and terror, are perhaps beyond the power of photographic expression. Possibly the time may come when our friend the scientist will supply us with a louder thunder and a more vivid lightning; we will then endeavour to wield them with pleasure, and, who knows? we may reach the sublime. It is to be hoped that the lower qualities, from which the exaggerated impres-

sionist used to draw his inspiration—such as it was—the ugly and sordid, the music hall and the coster, will cease to exist as a subject for art treatment.

At the end of the last century and the beginning of the wonderful one we are now bringing to a conclusion, the relation of the picturesque to the beautiful was a favourite subject with authors who belaboured each other with much amiable ferocity. Witness Alison on *Taste;* Burke, on the *Sublime and Beautiful;* Knight's *Analytical Inquiry into the Principles of Taste:* Repton's *Letters;* Price, on the *Picturesque;* Gilpin's *Essay on Picturesque Beauty;* and many others. These books, some of them portly volumes, referred principally to landscape gardening, but, to get at where to plant a bush, it seemed to be necessary to review all art from the beginning, and, in designing the plan and elevation of a shed, it appeared desirable to discuss the Great Wall of China, the pyramids of Egypt, the colonnades of Palmyra, and the aqueducts of Rome; therefore we have in this field of literature a good deal of "fine confused reading" which I shall probably make use of as I go on. I may, perhaps, as well mention that Downton Woods and the Hay Mill, near Ludlow, known to many photographers, are the result of the experiments and planting of John Payne Knight, the author of the *Inquiry*, who owned the castle and estate about a century ago.

It is possible there are some who are not able to recognise much difference between the picturesque and the beautiful, and others compromise the matter by talking of the picturesque beauty of a scene. There are few words whose meaning has been less accurately determined than the word "picturesque," and, in the language of America (which is derived from the English), I am not sure that it exists at all, certainly not with the same spelling. But there can be no doubt that picturesqueness is a very real and distinct quality.

The word was originally applied to every kind of scenery or object which had been, or might be, represented with good effect in a picture; but it has long since acquired a more extended meaning. Thus we have picturesque language, and many things we now call by the name which are quite unpaintable.

The picturesque has a character not less separate and distinct than either the sublime or the beautiful. The difference between the three qualities may be broadly described as—the picturesque, rough, or rugged, or irregular; the beautiful, graceful; the sublime partakes more of grandeur and awe, but may be dismissed from present consideration as not being within the limits of our art.

The words "picturesque" and "beautiful" would cover the greatest and best qualities a photographer could desire to get into his pictures, and to have a clear idea in the mind of what these qualities are and their causes would be a great help to their attainment. We will now, therefore, attempt to throw together a few ideas of what picturesqueness really is.

Roughness, or ruggedness, joined to irregularity, are the most efficient causes of the picturesque.

This will appear clear if we take a view of those objects, natural or artificial, that are allowed to possess the quality, and compare them with those which are allowed to be beautiful.

For instance, there has just passed down the road a family of hoppers; it is raining steadily with the persistence of an autumn that follows a rainless spring and summer. The miserable father and mother and wretched children are a sad sight. Nothing could be further from the beautiful, but they are very picturesque. As a contrast, a charming young lady, adorned for her first important ball, may be beautiful, but, even if not charming, she could not be picturesque, although she may be very paintable, or make a delightful photograph. It must not be understood, however, that misery, as in the case of the hoppers, was necessary to picturesqueness. The most picturesque model I ever had was certainly the most jolly.

Now for an example from landscape architecture. A temple of Grecian design in its perfect state, either in painting or reality, may be beautiful; in ruin it is picturesque. Time usually converts a beautiful object into a picturesque one. Weather stains, lichens, partial incrustations, mosses, break up uniformity of surface, give a degree of roughness and variety of tint; variations of weather crumble stone, and give a degree of ruggedness; the primness of beauty deserts the object, and gives place to the pictureque. A geometrically planned garden, with smooth turf, nice-trimmed walks and shrubberies, may possibly be beautiful, but could never become picturesque until it was neglected, overgrown with wild plants and creepers, and ivy mantled the statues and fountains.

Symmetry and regularity accord with beauty, but are adverse to the picturesque, and among the causes of the superior picturesqueness of ruins, compared with entire buildings, the destruction of symmetry is by no means the least powerful.

The origin of most of the picturesqueness of the world, from the humble cottage up to the highest Alps, is decay. It is also the cause of much of the best poetry. The contemplation of death, and especially the approach of death, seems to be eminently adapted for producing that pleasing melancholy which is certainly poetical, and seems to have a charm for most people. Poets dwell more on the sadness of parting lovers than on their meeting; jocund day standing on the mountain-tops may be occasionally mentioned by the poet, but he touches the feelings with a more thrilling sensation when his theme is a sunset. Why people should prefer to be touched to "the sacred source of sympathetic tears" as the highest form of pleasure, rather than be

> "A happy soul, that all the way
> To heaven hath a summer day,"

is too tremendous a question for me to consider here, but there can be no doubt it is a fact. In our small way, nearly every exhibiting photographer found that out for himself a few years ago, or, unhappy thought, did he purloin the idea from his neighbour? and we were deluged with dying days, mellow eves, twilight musings, rising mists, and midsummer nights. One effect was that suitable quotations from the poets were driven to a premium.

Now, I have not a word to say against this melancholy movement, except that we have had too much of it, not of the true kind, but of the inferior imitation; indeed, I very heartily applaud it. Anything that tends towards poetry in a photograph is to be commended. The difficulty came in, as usual, with the uninspired imitators. They seldom went to nature to find poetry for themselves, or to absorb the feeling with their own souls, they went to find something like that subject of their neighbours, because they thought they could do it as well. That mine was full of nuggets, but it has panned out. We want another general subject now. Cannot we do something with mid-day or even afternoon? If one or two would do something beautiful that looked easy, there would surely be plenty of followers. Milton made as good poetry out of *L'Allegro* as *Il Penseroso*, though it has always troubled me that he gave foreign titles to these two delightfully English poems—an affectation that has never yet died out.

In photography it is so difficult to be original, so easy to "level up," or seem to do so. Not only in single pictures, but in whole exhibitions, imitation is rampant. As it is probably all for the good of photography, and may possibly, in the future ages, lead to something more original, I am, indeed, proud to see my own pet child, the Salon, imitated in every item of outward dress, the cut and fashion, even to the numbers hung and the arrangement of bays they are hung in, the body but, unfortunately, not the soul, by those who once did not wish it well, reminding us of Tennyson's playful little verses:—

> "To and fro they went,
> Through my garden bower,
> And, muttering discontent,
> Cursed me and my flower.
>
> "Then it grew so tall
> It wore a crown of light,
> But thieves from o'er the wall
> Stole the seed by night.
>
> "Read my little fable;
> He that runs may read;
> Most can raise the flower now,
> For all have got the seed."

But I am running away from my subject in my usual reckless way. It is well I headed these poor essays "Digressions."

Beauty is the so much more enchanting and popular quality that the word "beautiful" is often wrongly applied as the highest commendation to whatever gives us pleasure or raises our admiration, be the cause what it will. The ordinary human being seldom uses the word "picturesque," it is always beautiful, if, indeed, it is not jolly, heavenly, stunning, or one of those slang terms that of late years have been added to the vocabulary of the worshippers of the beautiful.

The power of beauty has been the theme of the poets for ages. Beauty has a different effect on different people; the appearance of things depends very much on the mind of the beholder, as also does the effect. When Milton's Satan first saw the beauty of Eve, he was struck "stupidly good." A good phrase, but the effect was but transient. With many people beauty consists of only "what is worn." Yesterday I met a daughter of Eve with a structure on her head made of swan's wings, set upright, with an outward leaning, a sort of imitation of King Arthur's helmet, on which "the dragon of the great pendragonship blazed." However preposterous this wonderful construction appeared to others, it is easy to conceive she thought it beautiful. Fashion, even in the worship of the beautiful, changes, and we are almost compelled to acknowledge, with the poet—

"There's no such thing as that we beauty call:
It is mere cozenage all;
For, though some long ago
Liked certain colours mingled so-and-so,
That does not tie one now from choosing new.
If I a fancy take
To black and blue,
That fancy doth it beauty make."

H. P. Robinson.

FOREIGN NEWS AND NOTES.

Faded P.O.P. Prints.—N. Ley points out that gelatino-chloride prints which have faded may be restored, to a great extent, by physical development. If mounted, they should be stripped off the mounts by laying on top of the print a piece of blotting-paper soaked in water, which should be kept constantly damped. After removal from the mount, the print should be soaked in water, and the whole of the mountant washed off, and the print allowed to soak till it is thoroughly and evenly wet. If the print has been much handled, it will be advisable to rub the surface with benzine before stripping. The print should be laid in a clean dish, and flowed over with a mixture of aristogen, which is an acid solution of hydroquinone, and a few drops of silver nitrate solution to which some acetic acid has been added. As soon as about half the required intensity is attained, the prints should be washed and fixed, as they dry rather darker. If the whites show any tendency to deposit, a weak cyanide bath should be used to clear them up.

Argentaurum.—A big syndicate has been formed in the States to work Emmens' process of converting silver into gold, or a metal similar in appearance. This recalls Carey Lea's experiments with photo-chloride of silver; and now Edison is stated to have produced a metal which has the colour, weight, and ductility, besides all the other physical properties, of gold. Tesla is stated to have attained the same end by allowing the X rays which were produced from a silver electrode to fall upon a silver plate. Professor Fra Remsen, of the John Hopkins University of Baltimore, has been at work on the same subject, and is now constructing special apparatus for this purpose. It appears that Emmens has converted his silver, with a loss of twenty-five per cent. in weight, into a metal which is not silver and is not gold, but has all the physical properties of gold. It is said to be a new element.

Acetylene.—The importance of this gas has been fully recognised in France, and M. Reyner has incorporated with *Le Journal de petit Photographie le Journal de l'Acétylène*. The principal constructors of acetylene generators have also formed themselves into a Society, La Société Technique de l'Acétylène et des Industries qui s'y rattachent. The Prefecture of the Police has also called a committee of the leading men in the scientific world, and drawn up rules for the manufacture and use of the gas. The manufacture can only be undertaken by authority, and in isolated establishments, like explosives of the first class, and rules to be observed by the workmen have also been drafted. The above-mentioned committee contained such well-known names as Troost, Vieille, Girard, Schützenberger, Moissan, Levy, Dumont, &c.

A New Collodion Paper. — Ley suggests, in the *Photographisches Archiv*, a new method of preparing collodion paper, which has the advantage of never rolling up and never blistering. In a porcelain dish, the ordinary mixture of sulphuric and nitric acids, such as is used for making collodion, should be placed, and a sheet of paper allowed to float on it till it has been nitrated through half its thickness, the acid should then be well washed away, the wet surface coated with solution of barium chloride, and again well washed. On drying, one has a kind of baryta paper, which, when coated with a collodio-chloride emulsion, will, on its surface, partly enter into solution, and the sensitive film will thus be firmly held, and not be likely to frill, whilst the unaltered paper will prevent its curling.

Waterproofing Wood and Card.—A writer in a Russian journal suggests the following methods of making wood and card watertight: 1. Coating the wood with a mixture of potassium bichromate and gelatine, and exposing to light. 2. Immersing the article in a warm solution of paraffin, to which some solution of gutta percha in benzole has been added. 3. Painting the wood with a mixture of asphalt and gutta percha-benzole solutions and exposing to light. 4. Coating with a mixture of 100 parts of resin dissolved in eighteen parts of boiling nut oil. 5. Painting with a mixture of caseine, quicklime, and albumen, well mixed together. After coating with any one of these substances, the film should be rubbed down with pumice, then painted with good oil paint, rubbed down with pumice, and then varnished.

A New Fire-proof Paper can, according to the *Correspondenz*, be made by incorporating ninety-five parts of asbestos fibre, which have been bleached in a solution of calcium permanganate, and afterwards treated with sulphuric acid, with five parts of wood pulp. The mixture is then pasted by lime water and borax, and spread in the usual way. This paper, it is said, will withstand even a white heat without charring.

The X rays again.—Sehrwald states that not only the diamond, but also all amorphous carbon and all organic compounds rich in carbon, are very transparent to the X rays; further, that the halogens, chlorine, bromine, and iodine, are in the pure state very opaque to the X rays, and that all chemical compounds of the halogens are more or less opaque in proportion to their percentage of haloid. Chloroform and bromoform are extremely opaque, the latter even in thin films casting as heavy a shadow as brass. Cyanogen, on the other hand, is rather transparent. Carbon, hydrogen, oxygen, and nitrogen, are all transparent, and the author states that the shadows of animal tissue are partly dependent on the hæmoglobin and the proportion of chlorine that they contain.

Formaldehyde in Alkaline Developers. — MM. Lumière Frères and Seyewitz have been testing the truth of the statement that formaline added to the alkaline developers acts as a tanning agent, and, whilst they have confirmed this, they state that its use is accompanied by such deep colouration in the case of pyro, di-amidophenol, hydroquinone, and eikonogen, that its use is not to be recommended; only in the case of para-amidophenol and metol should it be used.

A New Remedy for Burns.—Dr. Thiery, of Paris, has discovered that a saturated solution of picric acid is a splendid remedy for burns; it instantly stops all pain, and prevents the formation of blisters, the only disadvantage being the deep yellow staining of the skin, which can be removed with aqueous solution of boric acid.

Intensification.—Paul V. Janko has been determinining the various degrees of intensity given by the best known intensifiers, and has drawn up the following table.

Bleached in	Blackened by	Ratio of Intensity
Cupric Bromide	Metol	15 : 14
,,	Hydroquinone	15 : 13
,,	Pyrogallol	15 : 12
,,	Silver nitrate	15 : 8
—	Mercuric iodide (Edwards)	15 : 10
Mercuric Chloride	Sodium sulphite	15 : 14
,,	Ferrous oxalate	15 : 13
,,	Hydroquinone	15 : 12
,,	Hyposulphite, or with ammonia	15 : 11
,,	Ammonia	15 : 10
,,	Ammonia, the plate being dried before blackening	15 : 8·5
,,	Ammonium sulphide	15 : 7
—	Uranium	15 : 6

The uranium intensifier gives the greatest increase, next ammonium sulphide, a result which agrees with practice.

PHOTOGRAPHERS AND COPYRIGHTS.

The leading article on the subject of copyrights that appeared a short time ago in these pages contains many valuable hints, which it may be useful to expand by some personal experieuces, as the subject is one of continually increasing interest. A glance at the illustrated papers of to-day and those of a decade ago will show that a large number now virtually owe their existence to photography and photographers. If photography were to become non-existent, or not available, their functions would be gone in the majority of cases, and they would cease to exist; but, concurrently with the springing up of so many new weeklies of the class alluded to, their requirements in regard to photography have become more exacting, and so great is the competition among photographers, and so many the non-professionals who cater for the Press, that any one desiring to have a share in the work must be alert to seize his opportunity and use the utmost celerity in getting his results into the publisher's hands. Personally, I may say I have been very successful in finding suitable subjects, and have received many scores of copyright fees; but it is generally a severe tax on the energies of both myself and staff to get work through quickly enough. It will be instructive if I say that in the majority of cases the negatives have been taken, retouched, printed from, circulars, when necessary, written and lithographed on the premises, and all dispatched on the day of taking. When a subject is one of passing interest only—be it of persons, things, or places—it is of no use sending to the papers a few days after the event; the sender would be asked if it happened before the Deluge.

So far as to the business part of this work. The question of copyright is next to be considered. It will be found that in nearly all cases the editors will treat photographers with the utmost courtesy, liberality, and honesty. No one need hesitate to intrust a valuable picture to their keeping, even though the exigencies of speed of production may not have permitted a proof to be registered before sending the picture. Ordinary business tact, however, will suggest that not more than a day should be lost in carrying out that essential formality. There really need not be any delay, for it is so easy to get a developed print off in a very short time, and it is by no means necessary that the print sent with the registration form should be a specially good one. Any print, however imperfect, will, if necessary, answer the purpose; indeed, as a matter of fact, it is not absolutely essential that any print at all should go, if a sufficient description could be given of it; but, actually, it is very advisable on all accounts that one should be sent. The photographer should always have ready at hand a sufficient supply of registration forms; these he can obtain by post upon writing to the Registrar, Stationers' Hall, Ludgate-hill, London, E.C., and enclosing one penny for each form, with a sufficient sum for postage. Judging from inquiries I have received, it will be news to many photographers to know that it is not necessary even to employ an agent or intermediary to conduct the registration. When a form is duly filled up with *one* accompanying photograph, and posted to the Registrar as above, he will carry out all the necessary formalities, and will also, if reply postage be sent to him, send a receipt for the money (one shilling) needed for such registration—a receipt for the money, but not for the registration form nor the photograph.

There remains to be considered the question of piracy, and how to act. Here, again, promptitude is desirable; as soon as an infringement is discovered, steps should be taken. The matter should be placed either in the hands of the Photographic Copyright Union, or it should be given to a solicitor familiar with this branch of practice. A few special experiences narrated will perhaps be useful in aiding the photographer interested to come to a decision as to which mode to adopt.

Some little time ago the Autotype Company found one of their copyright pictures pirated. The head of the firm placed the matter in his solicitor's hands, and, in two or three days, obtained heavy compensation —if I recollect rightly, fifty pounds—without going into court.

Again, Mr. Whitlook had a case. I am informed that he took it to the Photographic Copyright Union, and they would not do anything with it. He then put it in the local court and gained half his case, appealed to a higher court, and gained on both counts he claimed on.

Quite recently a paper, with a very large circulation, pirated one of my photographs, that of Mr. Gladstone and Li Hung Chang together at Hawarden Castle — one of the most popular and saleable portraits published for some time past. Being a member of the Union, I placed the matter unreservedly in their hands, and signed a document authorising them to take any necessary steps, and undertaking to abide by the decision of the Union officials as to the compensation to be accepted. (The Union specially recommend photographers to put all copyright arrangements in their hands, as being more likely, by reason of their experience, to obtain better terms than the photographers themselves.) In my case, the offer of compensation they received and transmitted to me was the sum of two guineas, out of which would have to come solicitor's charges and, for the Union, twenty-five per cent. off the remainder. They asked me to wire if I would accept it, or if I wished them to claim the solicitor's fees extra. They did not suggest anything further, nor say they thought more could, or should, be obtained; hence the case may be considered a typical example of the extent to which country photographers' interests are looked after by the Union. Although I had undertaken to abide by their decision, I could not but try to urge them to do something better, and I wired that the offer was absurd, and that several legitimate users had paid me six guineas for permission. I also wrote to the same effect, and that fifty guineas was a just claim, and a hundred none too much. I pointed out that, if a captured thief escaped by simply paying the value of the goods he had stolen, the enforced payment could not be called a punishment, and that I understood the Union wished to stop piracy by, *inter alia*, punishing pirates.

Eventually, after further parley and letters, the Committee's decision was written to me by the Secretary: "*The matter has been laid before my Committee, and they are of opinion that, under the circumstances*" (note this expression,—G. W. W.) "*that the amount, 10l. in cash, is adequate compensation. Please let us have your confirmation of this per return, and cheque for 10l., less the Union's commission shall be sent.*" I wired acceptance, and wrote complaining very strongly of the most inadequate sum they had obtained, which, I stated, I had accepted as I had no other option. They demurred to this remark. I leave it to my readers to say, after perusing the following extract from a document the Union sent for my signature at the outset, whether I was not right: "*I agree to leave the matter in the hands of the Union and their solicitor for settlement upon such terms as they think reasonable.*"

As the Union take twenty-five per cent. of the compensation obtained by their agency, I received seven and a half guineas, which is just twenty-five per cent. more than legitimate uses paid—a sum so extremely inadequate that I pointed out to them that it was a direct incitement to future piracy.

It will be asked, What was meant by "under the circumstances?" They were: First, an admission by the pirate that my picture had been used; secondly, an explanation that the manager of the paper, who looked after this part of the work, was away at the time; third, that they paid copyright fees regularly, and would have done so in this case when the time came (!); fourth, they accidentally omitted to put my name under the picture, but could easily remedy that by mentioning it in a future number; lastly, they said my maximum fee was two guineas, the only proof of which statement they gave to the Union being a two years' old quotation of mine for a set of my copyright pictures, *that had then had their day*, of some quite different subjects. Not one word of explanation why they had not asked permission to use the picture. The reason of this is obvious when I point out that a woodcut had been made of my photograph, and in it the figures were placed closer together, and the lower portion cut away, a sort of thing that might readily escape discovery.

Now, as it is quite possible the Photographic Copyright Union may have something to say in this matter, it will be an excellent opportunity for them to show that piracy compensation plums are not confined to the London members of the Union, and to answer two questions to which no one would be more pleased (and surprised) to see an affirmative reply than I should.

1. Have any provincial photographers obtained large compensations through the Union? If so, what are their names? I do not ask for amounts, that might be a private matter, but not so the names.

2. Have they any example of one of their London members being satisfied with the net sum of twenty-five per cent. extra as compensation for a piracy of a valuable copyright picture (say one for which the papers have paid them over 5*l.* each for use) of a copyright of a subject important enough to be taken by three papers at once for the same week-end issue (a most exceptional thing, as any one who has had much to do with the subject of my article is aware)?

Finally, I may be asked, What my advice is to country photographers as to how to proceed in case of piracy? I prefer to leave the above-recited facts to speak for themselves, first pointing out that the Photographic Copyright Union will not take any case whatever into court about the result of which they feel a doubt; it is obvious, that when they decide to take a case up, it would be morally certain to succeed if the law has to be invoked. It should further be remembered that they take twenty-five per cent. of all compensation obtained without going into court, and thirty-three and a third off the net result if they do go successfully into court. My own opinion is very strong as to whether or no I should use the Union; but, as I may be biassed, I do not give it utterance. I would have preferred to publish my correspondence with the Union *verbatim* in these pages, but the Union Committee, on being asked if they were willing, objected to the publication.

In conclusion, I may add another question. At the General Meeting the President, rebutting the accusation that the Union existed for the benefit of a London clique, said that seventy-five per cent. of the compensation was obtained for provincial members. Will he say that these members do not number more than seventy-five per cent. of the total membership; for, if they do exceed that proportion, the argument would go against the Union.

G. Watmough Webster, F.C.S., F.R.P.S.

THE THEORY OF DEVELOPMENT.

II.

I now come to the consideration of the theory of development proper, that is, the action of the developing solution in forming the visible image, and, though it is not, strictly speaking, a part of the subject, we shall have to glance briefly at the various theories of the action of light in preparing the way for development.

Mr. A. D. Pretzl has recently referred to an article of mine, published in 1870, in which, while I attributed a purely chemical action to alkaline pyro, silver development, or, as we now term it, "physical," was, partly at least, ascribed to electrical action. When that article was written, I was, as I am now, strongly of opinion that, if our knowledge were only wide enough, we should find a purely chemical explanation for every single point in connexion with the action both of light and development; but at that time, although the action of alkaline pyro seemed to me clear enough, the deposition of the silver on the film in physical development did not seem to me explicable, except on the supposition of some electrical attraction resulting from the action of light; or, in other words, I recognised, or thought I did, two distinct effects, the one chemical, the other physical. Perhaps now I can agree with Mr. C. H. Bothamley that, when an experimenter comes to a problem he cannot understand, he attributes it to electrical action.

There are supporters of both the chemical and physical theories, either or both of which may be correct, for it is quite possible that there may be two distinct effects produced by light; but, though at the period I speak of the physical theory was the more generally propounded, I think of late years the tendency is rather in the direction of the chemical, the immediate action of light being held to result in a partial decomposition of the silver haloid, instead of an electrical or molecular disturbance of the particles.

So far as chemical development is concerned, there seems little reason to go beyond a purely chemical explanation of all the phenomena, since the supposed formation of a sub-haloid, whether it be possible to isolate it or not, meets every requirement of the case. That the subsequent action of the developer is to completely eliminate the halogen scarcely requires demonstration, and the first step in the direction of that purely chemical act would certainly seem to be more probably chemical than physical; but, when we turn to the alternative method of development, in which the original haloids are left intact, and the image is formed at the expense of the developer, or, at least, of the free nitrate of silver, which practically forms part of the developer when it is in action, there has long appeared to be a difficulty in accounting for the deposition of the metal only on those parts of the film where the light has acted without having recourse to some electrical or other physical form of attraction. Of these the electrical always appeared to me the more reasonable, for some of the earlier hypotheses, based upon molecular "disturbances" and "vibrations," were, I venture to think, fantastic, if not absurd, in their conception. For instance, one theorist likened the exposed film to a tray of pebbles varying in size according to the degree of isolation, the whole in a state of rapid vibration, after the style of cinder-sifting, and the metallic silver in the act of deposition from the developer was supposed to be in the form of fine sand. When this shower of "sand" fell upon the tray of vibrating "pebbles," it was shaken down into the interstices, a greater quantity finding its way between the larger pebbles, where the light had acted most powerfully, and so on, in proportion to the variations in size, thus forming the gradations of the picture. The idea was, no doubt, ingenious, but, at the same time, rather comical.

It is a long time since I last saw the article which I have referred to; but, speaking from memory, I think I based my idea of electrical attraction upon some experiments alleged to have been successfully made by Mrs. Mary Somerville and Morichini, but repeated with negative results by others. In these experiments fine needles, one-half of their length covered with opaque cardboard, were exposed to sunlight under blue glass and also to the blue rays of the spectrum, when they became magnetic, the exposed portions forming the positive pole. It appeared to me, failing any other explanation of the phenomenon, that some such action would serve to account for the deposition of the reduced silver of the developer upon those portions of the film that had been impressed by light, but I am free to admit that I should have much preferred to have found a chemical explanation.

At the time I wrote, and indeed until I saw the passage quoted in Mr. Haddon's recent paper, the hydrogen theory of wet-plate development published in Brande and Taylor's *Chemistry*, was quite unknown to me but, looking at the question from that point of view, I do not think it is at all impossible to reduce even "physical" development to a purely chemical process and to dispense entirely with all ideas of electrical disturbance or attraction. By this I mean that I think I can at any rate partly see the way to explain how the reduced silver is chemically deposited on the exposed portions of the film, though I am far from claiming that my suggestion forms anything like a complete solution of the difficulty. It is, in fact, offered only as a suggestion.

We start with the idea that the action of light is to reduce the iodide or bromide of silver to the state of sub-iodide or sub-bromide. In the presence of excess of silver in the wet plate, the liberated halogen will be taken up by the free silver, or, in the case of a dry plate, by some other absorbent, which, as Mr. Haddon has pointed out, is absolutely essential to the formation of a developable image. In the case of a wet plate, it may be supposed that the liberated halogen is instantly seized by the free silver in and on the surface of the film, with the result that fresh iodide or bromide of silver is formed, and this may be partly mixed with the sub-iodide or sub-bromide if the film be rich in silver, or, more probably, it will be formed on the surface, to which it is attracted by the layer of silver solution.

W. B. Bolton.

OUTSIDE STUDIO WORK.

VI.

In previous articles I have referred to a few of what may be termed unusual classes of subjects a photographer has to deal with, and the accomplishment of which requires the use of other than ordinary kinds of apparatus.

There is another class of subject which at first sight, to some operators, may appear easy enough in accomplishing, but which, on fully thinking over, entails some risk of failure, provided no previous experience has been acquired at similar work. I refer to the photographing of the launching of ships. No doubt there are many instances where such is capable of being executed without any serious trouble or liability to failure, such as where every facility is afforded a photographer beforehand for undertaking the work in well-appointed ship yards; and, when this occurs in conjunction with a light that suits the occasion, both in direction and brilliancy, the function is generally one that affords

much pleasure to a photographer; but how often does it happen that such favourable circumstances fall to the lot of an operator? There are launches and launches, and there are ship yards that are so situated as to make it almost impossible to work other than directly in the eye of the sun, or up against even a very poor light. It has been well said that time and tide wait for no man, and, in the launching of ships, a photographer has little or no choice in the matter but to select the most convenient spot he can, and trust to luck for the light. I have said there are launches and launches; by this I mean there are a class of launches of which the general public and thousands of photographers have no absolute knowledge or experience of. I do not now refer to the commonly understood idea of launching a vessel, by means of allowing her to glide gracefully down the way until she reaches her native element. When such a launch takes place, there is plenty of time and opportunity for a cool-headed operator to act with caution on some well-thought-out plan, such as the previous selection of the exact spot the hull should occupy when the shutter is set free. These may be properly termed slow launches, and, with ordinary precautions, offer no insuperable difficulty in accomplishing. There is another class of launches, however, which it has fallen to my lot to photograph for many years back, to accomplish which successfully calls for at least some experience in this particular kind of work, for the entire operation of launching such vessels is quite different from the sending a vessel slowly down the ways into the water; and any one who has never seen the kind of launching I refer to cannot possibly form anything like an idea of the enormous speed or velocity vessels are made to take the water. I refer to the launching of large and small-sized vessels broadside into the water, an example of which may be seen in the *Strand Magazine* for September, 1896. The launching of vessels broadside into the water is, of course, only resorted to in situations when there is no room to send them down the ways end on; but it is a very common practice in some parts of Scotland, especially at Paisley, on the Cart, and in several instances on the Forth and Clyde Canal, such as at Kirkintilloch, where steamers of considerable dimensions are regularly built and launched in this manner. An operator who imagines that there will be ample time to study well the appearance of a hull in the act of being sent into the water broadside, will certainly stand aghast and look very foolish when he finds the whole thing over before he has time to release his shutter. The first time I was face to face with work of this kind, I was told that I would not have any time to come and go on, so fast did the large hulls travel into the water, but I certainly had no conception of the enormous velocity with which a ship is made to jump from dry land into the stream. Jumping is the most suitable expression I can find to convey anything like an idea of the speed of the operation to my readers.

In the illustrations referred to as published in the *Strand Magazine*, when I photographed the launching of this large-sized steamer broadside on into the River Cart, I can safely assert that a period of not more than three seconds was allowed to transpire between the time the dagger was withdrawn and the hull struck water. The speed with which this huge mass jumped into the water was simply appalling. No one could conceive it without having had previous experience of similar launches, whilst, from a spectacular point of view, it is grand in the extreme, clouds of spray being driven as high as the housetops. I had occasion to photograph one of these launches at Kirkintilloch about a month ago, and I think they were jumping them in faster than ever.

The speed being so great, it stands to reason every preparation must be made beforehand, and the lens focussed on the exact spot in the water which the hull is likely to occupy; here, again, mistakes are almost certain to follow a want of experience. The first launch of this description I had to photograph showed me plainly that the hulls don't jump so far into the stream as any one would imagine, and the liability of choosing a position too near the middle of the stream for the hull to strike at is very likely to happen if the operation has not been previously witnessed. The true point where these hulls strike the water is much nearer the bank upon which they are built than many would imagine. It is here they strike first with such frightful velocity, throwing up immense sheets of water that often rise over the decks, and which is by the roll or force of contact driven into immense clouds of spray. After the first impact with the water, the huge mass, for just a moment, takes a diving motion, then as quickly recovers again with a rolling motion, and finally settles down motionless in the middle of the stream, the whole thing being over in an incredibly short space of time, totally unlike the slow graceful motion of an ordinary launch end on. Such launches as I am referring to call for a cool head and certain preparations beforehand, such as the arranging for the signal being given to stand by already at the supreme moment, when the final dagger is withdrawn. When this is given, there is not a moment to lose, and by this time, the shutter ought to have been set, and the door of the dark slide withdrawn, the plate being free for exposure. In other cases I have had to execute launches of this kind, where the supreme moment consisted in the cutting of a strand by a sharp axe. In this instance, a gleam of the steel as it rises in the workman's arms is seen, then a thud and a cut, and the monster mass, uncontrolled, leaps into the water in a single second. It is in work of this kind that the benefit of absolutely sound practical apparatus is seen. I am far from decrying the use of any shutter that is constructed with a flexible blind, for I know quite well that such handy shutters have done good work, and are very convenient, but I know likewise that I can point to failure clearly attributable to such fogging an extremely sensitive plate, through the absolute necessity of the door of the dark slide having to be withdrawn for a long time, leaving no protection to the plate, but the blind of the shutter. "Once bitten, twice shy," is an old but very true saying, and so I never think of trusting a fast plate to a shutter that, in any sense, is liable to a pinhole, or to pass light in any way. These remarks apply also to cameras, and especially the bellows and fronts of the same. All apparatus must be in perfect condition to permit of a very fast plate being exposed for a lengthened time of uncertainty inside the camera, waiting the moment of exposure; if there is any weak point about the bellows, camera, lens fittings, or shutter, I know of no greater test than to expose a plate inside such for say fifteen minutes, when the apparatus is fitted up in strong sunlight outside. I am aware there are innumerable cases where the cap of the lens may be utilised to protect a plate when the shutter alone stands between such and the daylight, or a good felt hat may be made to do duty in this matter, but in work of the kind I am referring to, even such an act as the removing of a cap from the hood of a lens is not to be thought of, for an operator should have positively nothing to do but release the shutter. "Funk" is a word vulgarly used sometimes in connexion with photography, but I often think there is a great deal of it going about these times, and the best means I know of avoiding it, is to have nothing to get into a funk about. In this class of work, however, it is very liable to happen if the most complete and simple arrangements are not all made beforehand.

T. N. Armstrong.

PHOTO-MECHANICAL NOTES.

In the making of a suitable negative for the half-tone process the so-called "cutting," or clearing, is largely resorted to in wet-collodion work by the most practical operators, and especially by those operators who follow American methods, and much of the sharpness, cleanliness, and vigour of American half-tone work is due to this operation.

In brief, the operation of "cutting" is the application of a solution of iodine after the fixing and washing of the plate, and following up the iodine with a weak solution of cyanide of potassium. It will be seen from subsequent remarks that the two solutions can be combined, but in any case the principle is the same, the silver in the film is converted into the state of iodide, in which condition it is readily attacked by the cyanide in the parts where the deposit is weakest.

It must not be supposed that this action is one of reduction, and that the general density of the plate is weakened. Such would be the case if we were dealing with ordinary negatives taken without the screen, but in a negative consisting of half-tone dots the action of the iodo-cyanide is a distinct improvement, without any disadvantage whatsoever. At the same time it is to be understood that the operation would be of little avail unless followed by intensification. This may seem strange to those unacquainted with the practice of half-tone negative making, as it appears very like taking away part of the silver deposit by one operation and replacing it by another. Such, however, is not the case. What happens is that we remove the deposit from a part where it is not wanted, and build up a fresh deposit where it is wanted.

To fully understand the reason for the practice, a screen negative should be examined under a microscope or powerful glass after development. It will then be seen that the dots consist of little heaps of silver granules; in the centre of the dot the granules lie thickest and form absolute density, but towards the edge there is a gradual separation of the granules, forming a sort of fringe of imperfect density round the opaque part of the dot. Scattered granules will also be seen over the parts between the dots, where there should be transparency, these stragglers really forming a veil. Now, the result of the iodo-cyanide application is to remove this fringe and veil, and thus the dots are very much sharpened, whilst the spaces around them are rendered exceedingly transparent. It will be well understood that any intensification that follows can neither veil the clear spaces nor enlarge the dots, but will rather increase the

opacity of an already fairly opaque dot, and especially the opacity at the edges, so giving the effect of sharpness.

For photo-etching and photo-lithographic printing processes, where the parts representing the whites of the picture have to be washed away from the print, this sharpness is very essential for securing clean and vigorous work. In the enamel process keen-edged dots and clear spaces are indispensable qualities of the negative, without which the process bristles with difficulties. Thus the importance of the operation of "cutting" in negative-making cannot be under-estimated, and some hints on the practice of it will not be out of place.

There is only one possible way of making up the iodine solution, and that is to take one grain of iodine and two grains of iodide of potassium to each ounce of water; iodine being sparingly soluble in water, the addition of potassium iodide is necessary to bring about perfect solution.

The potassium-cyanide solution should be one in forty as a stock strength, a little being taken and diluted to suit the character of the negative.

Those who prefer to have the two solutions combined should make them up separately as above, then take a third bottle of pint capacity, and pour into it fifteen ounces of water. Add to this sufficient of the iodine solution, drop by drop, until the water assumes a sherry colour; then add the cyanide a little at a time until the solution is decolourised.

A method of working which is sometimes preferred, because giving more control over the "cutting" solution, is to keep the iodine and the cyanide in separate dropping bottles, and make up the dilute combined solution in a measure at the time of development.

It is a moot point whether the "cutting" should be done before or after intensification, but the most general practice, especially in using the copper intensifier, is to apply the iodo-cyanide after intensification, according to the following routine.

The negative is, after fixing and washing, bleached with the copper bromide solution, and then blackened with nitrate of silver. It can at this stage be determined by examination with a magnifier what amount of "cutting" is required. If the iodine is used separately, it is flowed over after the plate has been well washed. It is not necessary to allow the iodine to act until the whole of the image is converted into iodide of silver. As soon as there appears a greenish-blue tinge in the shadows, the treatment with iodine is stopped and the plate well rinsed, after which the cyanide solution is flowed on. The action on the light-coloured image can be watched by holding the negative over some dark object, the bottom of the washing tank being usually black enough for the purpose. A further good washing follows, and, if the negative seems nearly right in density, a solution of hydrosulphuret of ammonia of the strength one in twenty is flowed over. This gives intense blackness to the dots, and, though its use may be dispensed with, there can be no doubt the negatives are better after this treatment. There is, besides, the important advantage, that by treatment with the hydrosulphuret the image has not the tendency to set off on the printing plate as it does with the copper deposit alone, if the slightest trace of moisture is present.

Assuming that after the first application of the copper and silver and the cleaning with iodo-cyanide the negative does not look right, that is to say, the dots in the shadows seem rather weak and the high-light dots are not joined enough, the practice is to again apply the copper and silver and again "cut" with iodo-cyanide. It is, in fact, often necessary to make these applications a third time, finally applying the hydrosulphuret to complete the process.

This possibility of repeated intensification, or "building up," is one of the great advantages of the copper-silver intensifier. With mercury or lead it would not be possible to do this without blocking up or staining the transparent spaces.

So far, we have dealt with "cutting" and intensifying as applied to the wet-plate process, but the growing use of dry plates demands an analogous process. This cannot be entirely supplied, as the constitution of a gelatine film charged with silver bromide is so widely different to the collodion one. In the latter case the silver is deposited on the surface, and is therefore easily reduced or added to, so that it is more amenable to the methods we have described than is a dry plate, in which the silver is diffused throughout the film and is under the surface. The "cutting" solution must therefore penetrate the gelatine in order to attack the silver. The most satisfactory reducing solution for the purpose is by the ferridcyanide and hypo formula, but in practice we find it best to leave out the hypo, making up a sixty grains to the pint solution of ferridcyanide. We do not thoroughly wash the plate after the hypo fixing bath, leaving a sufficient trace of hypo in the film to bring about a mild reducing action, which is well under control and can be readily watched. In this way we are able to secure a very similar action to that in the wet-collodion process; but it will be found that the "cutting" cannot be carried quite so far, for, if the shadow dots are reduced to the same minuteness as in the wet plate, it will be found that the shadows are very liable to block up in printing, though the dot may look just as dense as in a wet-collodion plate. The explanation probably is that the dot has an apparent density because the silver is diffused through the film and has a sort of backing-up effect, but the dot is structurally weak to the sideways action of the light which gets under it just as the acid undercuts in etching. Thus it will be found best to leave the dot larger on the negative than it is intended to print, and so allow for the lateral action.

Lately I have been trying the iodo-cyanide reducer, as used in combined form for wet collodion in the way described above, and have found it yield very good results on gelatine plates.

The "cutting" must be followed by intensification, or the full effect will not be attained, in fact the negative may be quite unprintable by the enamel process if not intensified. Unfortunately we cannot use the copper intensifier on dry plates so well as on wet collodion, owing to the liability to leave a stain. A preferable intensifier, which is very similar in its action, is that by the cyanide of silver formula. I know there is a good deal of divergence of opinion as to its merits, but much depends on the way it is made up. In my own experience I have found the following formula answer very well:—

No. 1.

Bichloride of mercury	100 grains.
Bromide of potassium	100 ,,
Water	10 ounces.

No. 2.

Nitrate of silver	100 grains.
Cyanide of potassium, pure	100 ,,
Water	10 ounces.

In making up the No. 2 solution much depends on the strength of the cyanide. If not of full strength, it will not dissolve the precipitate of silver. The best way to make up the solution is to dissolve the silver in half the quantity of water and the cyanide in the other half, then adding the cyanide to the silver solution. If the first precipitate is not re-dissolved, add more cyanide until only a very slight precipitate remains and the solution is slightly grey. By the two latter signs it will be known that the cyanide is not in excess; if it were, the solution would act as a reducer rather than an intensifier. The image will be turned quite black, and on examination of the dots they will be sharply defined, dense, and well joined—that is, if all other conditions have been right. The want of sharpness of the dots in the dry plate is often ascribed to the gelatine dry plate itself, when it is really the operator, who does not know how to set the distance of the screen and determine the size and shape of the diaphragm.

WILLIAM GAMBLE.

PHOTOGRAPHIC CHEMISTS AND PHOTOGRAPHERS.

THE prosecution by the Pharceutical Society of two well-known Edinburgh dealers for selling "scheduled poisons," and using a restricted title, is the cause of a great deal of ill feeling. It will be a pity, indeed, if the result is not some action or agitation to restore an equilibrium, so that we may all have our rights in the matter. Personally, as a consistent reader of newspapers generally, and the drug and photographic journals in particular, I see no prospect of anything like "free trade" in poisons; judging by the frequently expressed remarks of sapient coroners and their juries, there is more chance in favour of further restriction—see the recent recommendation *re* pyrogallic acid.

I don't think myself that the chemist is quite fairly dealt with in this and other matters. Just consider for a moment. He passes a preliminary, serves an apprenticeship, and is then admitted to a pretty stiff (judging by the failures) examination, comprising botany, chemistry (organic and inorganic), including analysis, pharmacy, materia medica, and physics, and, on occasions anything else that happens to be of scientific interest at the moment to the examiner, as, for instance, isochromatic photography or Röntgen rays, and all for what purpose? To enable him legally to retail a few poisons, which, to put it plainly, are more bother than they are profit, while his position, and the fact that he has conformed to all regulations in selling, is no safeguard against possible ignorant abuse and bullying from certain coroners, who, as dozens of cases prove—in fact, they are of weekly occurrence—make a law unto themselves in this matter, and do not trouble to study or even refer to the Act which is supposed to be a safeguard to both seller and buyer.

Apart from this doubtful privilege, what remains? Pharmacy, *i.e.*, the compounding and dispensing of medicine, is, to the great majority, a merely pleasant fiction; for, the fact is, the doctors already do the bulk of their own dispensing, clubs and dispensaries do the rest. The chemist therefore, with an average of two or three prescriptions a day, fills up his time, and tries to get a living by the sale of all sorts of outside stuff:

perfumery and soaps, photographic apparatus, paints, hardware (I have seen the half of a chemist's shop lined with *chamber utensils!*), stationery, toys, and firelighters—anything, in fact, likely to sell and yield a little profit.

The main trouble, of course, arises from the fact that the man is not *sufficiently* protected. A writer once more compares the English with his foreign *confrère*, much to the disparagement of the former; but he artfully conceals the facts, that in France and Germany *the dispensing of prescriptions* is confined to the pharmacist, and that the *number of pharmacies* is restricted by law. *Per contra*, the man has to confine his operations to his own profession.

The rightful position of the pharmacist is midway between the doctor and patient. It is the business of the doctor to prescribe, that of the chemist or pharmacist to dispense; and, briefly, if this were done in all cases, the chemist would have enough to do without bothering with "outside shows."

It is contrary, in my opinion, to all ethical rules for the doctor to prescribe and dispense his own prescriptions. Many medical men relegate this work to their wives, sometimes to the page boy—very few keep a qualified dispenser. *It is not right, and it should be illegal, for the person who makes up the physic to sign the death certificate.* But this is done daily.

Suppose the doctor's dispenser—his wife maybe—makes a mistake, with fatal results, is it likely that the world knows of it? I have a great admiration of our medical men, a more honourable set of men does not exist; but they should be guarded against the remotest possibility of any such catastrophe; and he would be a bold man indeed who would assert that such mistakes have never occurred. D. D.

WOODFORD PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The Third Annual Exhibition of work of the members of the above Society was held on Saturday, November 21, at the Club-room, Coffee Tavern, George-lane. As last year, it was extremely well patronised, the room being for a long time uncomfortably packed, notwithstanding that the Exhibition was opened earlier and closed later than in former years. On entering the room, one was struck by the prevalence of darker tones. This was somewhat added to by the material that formed the background for the pictures, and which had a quiet, pleasing effect, and helped to bring all the pictures well into relief. The number of pictures shown was about the same as last year, and, as before, a few workers stand out conspicuously from the rest. Mr. Noble may be placed foremost, four of his batch being of very high merit. One picture, representing some children paddling in the sea, and another showing a lifeboat near the shore, with the surf very troubled, were exceptionally good. Two others, panels of flowers, enlargements on Alpha paper, about 15 × 9, were beautiful examples of careful work, rich in colour and delicate to a degree. Mr. Malby was well represented, as usual. His exhibits consisted of some nice specimens of portraiture and some enlargements in platinum, two of which deserve special notice; the first a view of Hastings beach, and the other Winchelsea Church.

Mr. H. Wilmer's contribution consisted of some seascapes. These were from sketches by Mr. W. L. Wyllie, A.R.A., and were very good examples of the photogravure process. He had also a small landscape, the name of which was not given, but it was one of the best in the Exhibition.

Mr. Marriage sent a somewhat mixed lot for him. Architecture and architectural details being his *forte*, it was here where his best work was to be found, the capitals of two pillars, the same as were shown at Pall Mall Exhibition, being the best. One or two smaller frames contained some nice landscapes which by no means detracted from Mr. Marriage's reputation as a clever and careful worker.

Mr. Emler, the Secretary, was a generous contributor, no less than fourteen frames being sent by him. All his exhibits but one were in platinotype, and comprised pretty bits in North Wales, Epping Forest, and Knighton. One photograph of some rhododendrons was very nice, while two or three of Bontddu, in North Wales, showed care both in selection of subject and the after-operations of production of print.

Mr. Caird was represented by a number of bromide enlargements, *A Scottish Glen* being the best; it is a nice piece of work. The others were mostly *genre* subjects. The Rev. N. R. Fitzpatrick contributed three enlargements on bromide paper, *Treib, Lake Lucerne*, being very good. Mr. Billings sent a few small things. These were mostly pretty scenes in the Isle of Wight. One, *The Smithy*, is a very creditable piece of work, more especially when we consider the great difficulty attending such work. The gradation of tone was all that could be wished for. Mr. Steriker had two or three nice things, the larger and perhaps best was a picture of *York Minster*. Mr. Hooper sent a few portraits, and one or two landscape scenes in the Lake country. Mr. Goodwin had a couple of frames, the *Retro choir at Chichester Cathedral*, and a small seascape, both being very creditable pieces of work.

One of the features of the Exhibition was an arrangement for the display of transparencies and lantern slides. These were much appreciated, and, for a greater part of the evening, attracted a good deal of attention. Transparencies of all sizes were shown, which came as a change to ordinary and almost too familiar lantern slides.

Looking at the Exhibition as a whole, the standard of the work was well up to the average of past years. It was fairly representative of the members as a body. The work of one prominent member was missed, but this was somewhat compensated for by the contributions of some younger members, who work on almost identical lines. The Council have every reason to congratulate themselves upon the display, which is the culmination of another year's good and successful work.

THE NORTH MIDDLESEX SOCIETY'S EXHIBITION.

The Eighth Annual Exhibition of this Society was opened on Monday, the 30th ult., with a *Soirée* for members and their friends, and remained open to the public on the two succeeding days. The North Middlesex Society, unlike the Hackney and most of the other large suburban societies, limits its annual show to the work of its own members, and offers to them even no medals, gold, silver, or bronze, but merely places at the disposal of the Judges a number of certificates of equal value. The Judges on this occasion (Colonel J Gale and Mr. F. P. Cembrano) made six awards, which were not characterised by more then the usual amount of eccentricity, although the reasons for some of them were hard to find. In their report these gentlemen say that they "are pleased to find so high an average in the Society's work. They would have been gratified to see greater attention paid to the lantern slides. The framing is, on the whole, harmonious; at the same time some meritorious work is marred by unsuitable mounts and frames." By way of emphasising this last remark, they select the only print out of Mr. S. E. Wall's four which contains an obvious technical defect for a certificate. The print in question (No. 152), *A Cool Retreat from Noontide Heat*, is mounted on a cut-out mount, which is painfully untrue in its lines. Mr. S. E. Wall's other work, especially (No. 2), *On Crymlyn Burrows*, is fully up to his usual high level of excellence.

Perhaps Mr. J. C. Mummery, the able and energetic President of the Society, has, as is only fitting but very uncommon, the finest exhibit of any one individual. He is particularly to be congratulated at having broken away from the lines of composition which at one time seemed to trammel him—a defect we pointed out in these columns only a few months ago; and, while his Pall Mall works with the old familiar figures are here also, he has in No. 53, *Misty October*, and in No. 181, *The Meadow Lane*, two charming examples of subjects which photography renders so well. *Misty October* is a clump of heather gradually shading off into a hazy background of trees. The various planes are well rendered, while the treatment of the *tout-ensemble* is broad and harmonious. (We have had this sentence specially written for us by an art contributor to a contemporary.)

No. 39, *Sunshine in the Woods*, by Charles Beadle; No. 58, *By Sea and Shore*, by W. B. Goodwin; No. 139, *The Yare, Early Morning*, by A. J. Golding; No. 144, *Home, Sweet Home*, by A. H. Lisett, and No. 24, *A Hamlet*, by J. C. S. Mummery, have also received certificates.

The North Middlesex Society is to be congratulated on having got together a really excellent show, one which is certainly the best it has ever held, and is, moreover, in all probability the best collection of the work of members of any one society ever got together, while it is well to note that this has been done without the offer of a medal. In addition to those we have already mentioned, Messrs. J. Addison, F. W. Cox, C. Dawkins, J. W. Marchant, E. R. Mattocks, J. McIntosh, W. J. Simpson, H. Smith, C. R. Steele, H. Stuart, W. Taylor (Hon. Secretary), and H. Walker exhibit works which attract attention, while other members of the Society show many excellent examples of their work.

The lantern slides are, as suggested by the Judges, poor, and this has always been a weak point with the Society. Those sent in for competition were exhibited in the lantern on Tuesday.

On Wednesday Colonel J. Gale delivered a lecture, *Under the Broad Skies*, illustrated by the lantern.

Our Editorial Table.

Bromide Paper.

By Dr. E. A. Just. London: Percy Lund, Humphries, & Co.

This is the fourth edition of Dr. Just's book. In what respects it differs from the editions that preceded it we are unable to say, but the work appears to be very exhaustive, every one of the manipulations demanded in contact printing or enlarging with bromide paper being very minutely entered into. But, from the fact that neither amidol nor metol as developers for bromide paper is alluded to, we conceive that Dr. Just's book, excellent though it be, requires bringing up to date. No doubt, a fifth edition, when called for, will supply the omission noticed.

THE PHOTO-AMERICAN (Vol. VII., Nov., 1895, to Oct., 1896).

New York: Charles H. Loeber.

THE seventh volume of our contemporary, neatly bound, well printed and illustrated, makes a book of excellent photographic reading. Most of the articles are from English sources, having originally appeared in our own pages and those of our contemporaries, and, as nice judgment has been exercised in their selection, it will be perceived that the *Photo-American* occupies a unique place among photographic periodicals, and possesses a distinctiveness by which none other is characterised.

THE SHAKESPEAREAN.

London: Dawbarn & Ward.

THE November copy of this little review apprises us that it is now issued by Messrs. Dawbarn & Ward. *The Shakespearean* is full of matter of interest to students and admirers of Shakespeare. Mr. A. H. Wall has the first of a series of articles on Shakespeare's portraits, and the frontispiece is a photograph of the Davenant bust, by Mrs. Weed Ward.

THE PAGEANT FOR 1897.

Edited by C. H. SHANNON & GLEESON WHITE.

London: Henry & Co., 93, St. Martin's-lane.

IN the way of typographical and pictorial excellence this refined and handsome annual would be difficult to surpass, while such details as binding and paper have been attended to with the most conscientious desire to produce an artistic result. *The Pageant*, however, is not one of those annuals that appeal to the multitude; it is obviously designed for persons whose preferences soar above the "usual thing" in the way of midwinter literature. Art "appreciations," stories, poems, a play, a note on wood engraving supply variety of contents, the chief authors being Edmund Gosse, Victor Plarr, D. McColl, the Editors, Maurice Maeterlinck, Max Beerbohm, Angus Evan Abbott, &c. Among the illustrations are reproductions by the Swan Engraving Company of pictures by Moreau, D. G. Rossetti, Burne Jones, C. H. Shannon, Puvis de Chavannes, Watts, and others. *The Pageant* makes a superb gift-book, to which persons of artistic sympathies may pleasurably return again and again.

THE INTERNATIONAL ANNUAL OF ANTHONY'S PHOTOGRAPHIC BULLETIN, 1897.

Edited by F. J. HARRISON.

New York: E. & H. T. Anthony & Co. London: Percy Lund & Co.

MR. HARRISON atones for the exiguity of the purely editorial portions of this well-printed annual by the good quality that distinguishes its many half-tone and other illustrations and the practical value of the contributed articles that he inserts. These articles are of unusual interest and emanate from American, English, and Continental photographers, among whom we note Bogardus, Bothamley, W. K. Burton, W. Gamble, M. J. Harding, Romyn Hitchcock, S. H. Horgan, Joé, F. P. Liesegang, Neuhauss, Rev. T. Perkins, Victor Schumann, Matthew Surface, Valenta, Waterhouse. The photographic tables and formulæ are of great utility. We must not omit to mention that a section is devoted to articles on process work, and, appropriately enough, the process blocks come out exceedingly well. It is altogether a capital book.

News and Notes.

ROYAL PHOTOGRAPHIC SOCIETY.—Ordinary Meeting, Tuesday, December 8, at 12, Hanover-square, at eight p.m. *Dr. Selle's Process for Natural-colour Photography*, illustrated, by Dr. Neuhaus.

AN INTENSIFIER.—Mr. W. T. F. M. Ingall writes and suggests the following plan of intensification:—In water, 20 ounces, dissolve potassium sulphite, 20 grains, then add mercuric chloride, 35 grains. Wash and redevelop. The results are brilliant and dense.

HASTINGS.—A short stay recently at this popular winter resort revealed to us the presence there of a large number of amateur photographers actively engaged in camera work. Coupled with this observation, our own experiences of photography in the bright, clear weather more than ever impressed us with the conviction that, in entirely abandoning camera work in the winter months, amateur photographers neglect many excellent opportunities of obtaining photographic pictures. We availed ourselves while at Hastings of the well-appointed photographic stores of Mr. Algernon Brooker, of Harold-place. Mr. Brooker is one of our best-known and most successful workers, and he not only keeps a well-selected stock of photographic requisites, but his practical knowledge and advice are freely placed at the disposal of those who seek them.

THE Aintree Photographic Society held their first Smoking Concert on Friday, November 27, from 130 to 150 members and their friends being present. Mr. J. Harvey Farmer, C.C., occupied the chair. Mr. A. J. Canfield and Mr. Manod Owen (both members of the Society) sang "The Village Blacksmith" and "Loch Lomond" respectively, each item being illustrated with appropriate views by aid of limelight, and which was the success of the evening. Other members, assisted by several gentlemen from Liverpool, contributed songs and recitations. Mr. George A. Ashley acted as lanternist.

"THE CHRONOPHOTOGRAPHE."—At the next weekly meeting of the Photographic Club, to be held at Anderton's Hotel, Fleet-street, E.C., on Wednesday, the 9th inst., M. L. Gaumont will exhibit, for the first time in London, his new apparatus for the projection of animated photographs. It is a Members' Open Night, and Mr. Charles Wallis will show slides from negatives taken on his holiday trip. Visitors are admitted to the meetings of the Club on the personal introduction of a member or by invitation cards, which the Hon. Secretary (Mr. F. A. Bridge, East Lodge, Dalston-lane, N.E.) will be pleased to forward on application.

LEICESTER AND LEICESTERSHIRE PHOTOGRAPHIC SOCIETY'S EXHIBITION.—After an interval of nearly two years this Society held an exhibition of its work on November 24, 25 & 26. The character of the exhibits was very gratifying, and showed a very decided advance upon that of previous years. Competitions were held in five classes, and the Judges (Mr. C. B. Keene and Mr. J. W. Wade) awarded the medals as follows:—Open Class (Landscape) silver, P. S. Lankester; bronze, G. Bankart. Quarter-plate Work.—Silver, W. J. Coates; bronze, W. E. Dunmore. Half-plate Work.—Silver, W. J. Coates; bronze, E. B. Miles. Instantaneous Work.—Silver, E. B. Miles; bronze, W. J. Coates. Lantern Slides.—Silver, G. Bankart; bronze, W. J. Coates. A large number of non-competitive prints were shewn, including work in carbon by the President (Mr. G. Bankart), platinum and carbon by Mr. Porritt, portraits in platinum and carbon by Mr. Frank Brown, and many others.

WRITING CHRISTMAS-CARD VERSES.—In the Christmas number of the *Windsor Magazine* Mr. Adolph Tuck gives his views on the style of verse most suited to Christmas cards: "It should not be too poetical. By that I mean it should not be involved or obscure in its allusions. We need verses that can be read at a glance and understood at the same time. They should read smoothly and rhyme correctly. Each should contain a simple appropriate sentiment of a friendly character; but the word 'friend' should be strictly tabooed. Then, it is essential that they should be quite general in character. As I have already said, any sentiment which would only apply to special circumstances or relationships would be fatal to the success of a card. The sentiment should not be especially Christmassy. We find practically no demand for the old-fashioned card, with a robin and a spray of holly. The favourite designs at the present day have no special reference to the season, and it goes without saying that the verse should agree with the design. You will be interested to know that about two years before Lord Tennyson's death I offered him a thousand guineas if he would write us eight Christmas-card verses. He sent me a polite refusal, though I have reason to know that he did not resent the proposal."

PLATINUM.—The following paragraph appeared in THE BRITISH JOURNAL OF PHOTOGRAPHY some months ago: "*New Source of Ptatinum.*—The precarious nature of the supply of platinum was well shown a year or two ago, when a small combination was able to 'bull' the price of this metal till, from a sum below 1*l.* 10*s.* an ounce, it rose by leaps and bounds almost to the value of gold. It will therefore be good news to photographers that a new source of supply has been discovered of such large area that it may fairly be expected to bring down the price to a level never before reached. We read that in New South Wales a bed of platiniferous lead over a mile long has been discovered. It has been known for some time past that the metal was to be found, but it had not been properly worked. It is stated that the platinum is to be present to the large extent of 75 per cent." Since this appeared, many other photographic and scientific journals have published similar information, and their writings have been recently copied by some intercolonial journals. From personal inquiries made at the Department of Mines of New South Wales, Sydney, we are in a position to state that no such extensive find of platinum has been made in the colony, and at the present time the value of this metal is nearly equal to gold.—*Australian Photographic Journal.*

Patent News.

THE following applications for Patents were made between November 18 and November 25, 1896:—

CAMERAS.—No. 25,730. "Improvements in Photographic Cameras." A. KERSHAW.

HANGING SCREENS.—No. 25,766. "A Mechanical Contrivance for Determining the Angle at which Optical Lantern Screens should be Hung." F. O. SCOTT and J. DAVENPORT.

COPYING APPARATUS.—No. 25,783. "Improvements in Apparatus for Copying or Transferring Photographs." Communicated by the "Neue Photographische Gesellschaft. Complete specification. G. A. DE KATOW.

PHOTOGRAPHS ON FABRICS.—No. 25,980. "Process of Printing Photographs on Textile Fabrics and Solutions connected therewith." Communicated by the International Photographic and Supply Company. Complete specification. J. LIDDLE.

CHANGING BOXES.—No. 26,160. "Improvements in Photographic Change Boxes." J. HOWSON.

PRINTING.—No. 26,234. "An Improvement in Producing Photographs and the Like." A. SCHWARZ.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK

December.	Name of Society.	Subject.
7	Bradford	*Conversazione* and Exhibition.
7	Camera Club	Smoking Concert.
7	Ealing	*Pictorial Photography.* Horsley Hinton.
7	North Middlesex	Informal Meeting.
7	Putney	*Holiday Rambles with a Camera.* John A. Hodges, F.R.P.S.
7	Richmond	Lantern Evening, Slides by E. Dockree.
7	South London	*Isochromatic Photography.* The President.
7	Stafford Y.M.C.A.	Open Lantern Meeting.
8	Birmingham Photo. Society	Exhibition of Photographs in Bromide, Platinotype, Carbon, &c. P. T. Deakin.
8	Royal Photographic Society	*Dr. Selle's Process for Natural-colour Photography.* Dr. Neuhaus.
9	Ashton-under-Lyne	Conversation on the Exhibition Pictures of 1896
9	Borough Polytechnic	Conversation Night.
9	Camera Club	Testing Lantern Slides.
9	Croydon Camera Club	Council Meeting.
9	Leeds Camera Club	Beginners' Lecture.—IV. *Squeegeeing and Mounting.* Mr. Swinden.
9	Leytonstone	*Bromide Enlarging.* F. W. Wates and M. D. Kerr.
9	Photographic Club	*My Holiday Trip.* C. Wallis.
9	Southport	*Negative-making.* Chapman Jones, F.I.C.
10	Liverpool Amateur	Annual Meeting.
10	West Surrey	*Bromide Printing.* Mr. Price.
11	Croydon Microscopical	*Stripping Films from Broken Negatives.* A. Roods.
11	Ireland	Demonstration in Platinum Printing. Alfred Werner. — Lantern Views J. H. Gane.
11	Plymouth	*Multiple Film Plates.* J. T. Sandell.

ROYAL PHOTOGRAPHIC SOCIETY.

NOVEMBER 24,—Ordinary Meeting,—Mr. E. J. Wall in the chair.

COLOURED LANTERN SLIDES.

Mr. CHAPMAN JONES (Hon. Secretary) showed specimens of lantern slides on gelatine plates, toned with the sulphocyanide bath, the point aimed at in toning being to get two colours. Most of the slides had been so treated that the foreground was of a warm tone, while the sky was tinted blue, the result, as was suggested, of "double toning." They had been lent to Mr. Chapman Jones for exhibition at the meeting, but he could give no details as to the manipulation, except that there had been no local treatment.

A PHOTOGRAPHIC MUSEUM.

Mr. R. CHILD BAYLEY (Assistant Secretary) read a paper with this title, in which he called attention to the various articles of which the Society's collection was at present composed, and indicated some directions in which it was desirable that it should be augmented. First in point of date was a curious work called *Giphantia; or, A View of What has Passed, What is now Passing, and, during the present century, What will Pass in the World.* The book was a translation from the French, and was printed in London "for Robert Horsfield," in Ludgate-street, 1761," and contained the following prophetic passage: "Thou knowest that the rays of light, reflected from different bodies, make a picture and paint the bodies upon all polished surfaces, on the retina of the eye for instance, on water, on glass. The elementary spirits have studied to fix these transient images; they have composed a most subtle matter, very viscous, and proper to harden and dry, by the help of which a picture is made in the twinkle of an eye. They do over with this matter a piece of canvas, and hold it up before the objects they have a mind to paint. The first effect of the canvas is that of a mirror; there are seen upon it all the bodies, far and near, whose image the light can transmit. But, what the glass cannot do, the canvas, by means of the viscous matter, retains the images. The mirror shows the objects exactly, but keeps none; our canvases show them with the same exactness, and retain them all. This impression of the images is made the first instant they are received on the canvas, which is immediately carried away into some dark place; an hour after, the substance dries, and you have a picture so much the more valuable as it cannot be imitated by art nor damaged by time." The Society's collection included a small collection of Daguerreotype apparatus, formerly the property of Mr. J. Werge; several calotype negatives, and an unmounted print, by Fox Talbot copies of the *Pencil of Nature* and *Sun Pictures in Scotland;* large volumes containing eighty-two calotypes, most, if not all, by Talbot, and a series of portraits and figure studies by D. O. Hill and Robert Adamson; calotype prints taken during the Crimean War by Mr. Maynard, and silver prints taken in the Crimea during the war by Mr. Roger Fenton, the first Hon. Secretary of the Society. The sole example of Daguerreotype in the collection was a stereoscopic view of the 1851 Exhibition. Mr. Child Bayley also summarised the books, apparatus, and lenses in the possession of the Society, forming the nucleus of a photographic museum; however rapidly it might grow, it was hardly likely to outgrow the power of the Society to provide accommodation for it, while many things of great interest to students of photography were lost every year through being left in private hands. He knew of two recent cases in which the deaths of persons connected with the early history of photography had led to the disposal and practical loss of many objects. It could not be too widely known that the Society offered to the possessors of such articles accommodation for their safe keeping and display, where they were likely to be readily seen by those most interested, and, if, for any reason, they could not be given to the Society, they would be welcomed on loan.

Mr. T. BOLAS suggested that a list of articles required for the museum should be printed and circulated.

Mr. T. R. DALLMEYER endorsed the suggestion, and referred to the advisability of a report being drawn up by the Technical Judges at the Exhibition with regard to the apparatus exhibited. Such a report would be valued by the exhibitors, and would be an inducement to them to come forward, and would also, no doubt, lead to specimens of many of the novelties introduced finding their way to the museum. He also alluded to the suggestion recently made with regard to the holding of a Technical Exhibition, and expressed a hope that it would be adopted and that a great deal more interest might be concentrated upon the technical aspect of photography.

Mr. BOLAS and others made some remarks upon this point, but the CHAIRMAN called attention to the fact that the discussion was not pertinent to the paper.

Mr. EDGAR CLIFTON advocated the collection of portraits of the pioneers of photography, and

Mr. CHAPMAN JONES said Mr. Hollyer had kindly undertaken to copy for the Society as many of such portraits as could be obtained, and was proceeding with the work.

Mr. W. THOMAS thought it would be well to include the museum in the Annual Exhibition together with the latest improvements; it would be very interesting to see how, and under what circumstances, the early photographers worked, and to compare their results with those attained in the present day; it would take the "bounce" out of a good many modern photographers.

Mr. W. E. DEBENHAM, Mr. DALLMEYER, and the CHAIRMAN also spoke, and promised to present various objects of interest to the Society, the last-mentioned referring favourably to the subject of the proposed Technical Exhibition.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

NOVEMBER 26,—Mr. R. Beckett in the chair.

Mr. F. Goddaer was elected a member.

Mr. P. Everitt exhibited a specimen of the Vergara film, developed before the Association some years ago by Mr. Wollaston, and which had been in his possession ever since.

The HON. SECRETARY read a communication from the late Recorder, Mr. G. W. Atkins, on the subject of the

DEVELOPMENT OF FILMS.

Having to make a stay in France, Mr Atkins, for the sake of something to do, bought an Eastman pocket Kodak, and took with him a quarter-plate dish, with some concentrated developer, and thought he was going ahead all right; but he found himself pulled up short on account of the extremely "rollable" proclivities of the film in the dish, which, with only the aid of one's natural number of fingers, was quite unmanageable. Being unable in Dieppe to obtain the special appliances for dealing with the films, in an inspired moment he thought of a test tube, and bought a couple and a rubber stopper. This was the whole outfit. He sent two sketches of the *modus operandi*, one showing the piece of film (three exposures) with its black-paper backing. If the former is pushed slightly in advance of the backing, and the two then inserted together in the test tube, slightly rolled at right angles to its original form, on the withdrawal of the paper the film remains behind in the tube. It only remains to pour in the developer, three-quarters of a fluid ounce being enough, and close the tube with the rubber stoper, rocking the solution from end to end. The development can be judged by transmitted light with great facility by holding up the tube between the eye and the lamp. The tubes were eight inches long by one inch in diameter, and Mr. Atkins advises that the diameter be no more than that given, as the film is liable to take up a spiral form, and collapse to its natural curl to the bottom of the tube. When development is complete, the tube is rinsed out with water, the film withdrawn, and inserted in the same position in the second tube containing the fixing solution. All these operations can be easily performed, and without any mess, and Mr. Atkins says these small films are more easily handled than a plate.

Mr. T. E. H. Bullen had a dodge for developing a long length of film very easily. By the aid of a deep quarter or half-plate dish, and a glass rod, over the ends of which a couple of elastic bands had been slipped, at the bottom, he was able to run the film round this from end to end, developing simultaneously the whole of the film in a minimum of space.

Mr. A. MACKIE mentioned a method for coping with great lengths of film, forty to seventy feet in length, by means of a tray fitted with a series of pegs, round which the film was wound. In this way transferring from bath to bath was greatly facilitated, the tray being simply taken from one to the other, and the film was not removed until it had been developed, fixed, washed, and dried.

Mr. EVERITT suggested the use of a roller and trough similar in effect to a stamp damper, but on a larger scale, the length of film being spirally wound on the roller. By turning a handle the film would be revolved in the trough containing the developer, and he pointed out that a good length of film of, say, one and a quarter inches in width, could be disposed of on a roller of twelve inches in diameter and about sixteen inches long.

Mr. MACKIE said this idea was abandoned in favour of the peg method. There were one or two advantages in the use of films—the possibility of printing from both sides, which was important, and their lightness, which was, however, but secondary.

CARBON PRINTING.

Mr. E. J. WALL described some peculiar markings on carbon tissue he had recently seen, and a discussion ensued on the working details of the process.

Mr. PAUL MARTIN said he used neutral bichromate solutions, varying in strength from one-quarter to four per cent., according to the effect aimed at. The temperature of his bath was 60°, and the immersion about three minutes, after which the tissue was transferred to a ferrotype plate and squeegeed down. The tissue was left on the plate, and dried in about two days, and was quite clean and free from fog.

Mr. MACKIE thought the value of varying strengths of solution was not so fully appreciated as the facts warranted. It would be found of great advantage.

Mr. EVERITT thought quick drying left the tissue in better condition. He contrived so that his tissue was dry in some thing like an hour and a half, and found no ill effect traceable to gas fumes. He had experienced difficulties in getting clean lights on sepia tissue until he reduced the percentage of bichromate in his bath, when he succeeded. The prints were previously so flat.

Mr. MARTIN said he found that the sepia tissue necessitated a weaker bath.

Mr. WALL, in reply to a remark by Mr. Everitt on the development of Artigue prints from the front, said it was on account of the extreme thinness of the vehicle containing the pigment on the tissue. There was far less vehicle than on a dry plate, and the true secret in its manufacture was to get a maximum of colouring matter with a minimum of the vehicle.

Mr. MACKIE added that the theory was that the gum holds the pigment more or less tenaciously, according to the degree of light action.

A discussion took place as to the preparation of the tissue, and Mr. WALL suggested the insertion of the gummed paper in a photogravure box, and dusting-on a suitable pigment by its means.

PHOTOGRAPHIC CLUB.

NOVEMBER 25,—Mr Frank Haes in the chair.

Major J. J. Thomas was proposed as a member.

Mr. Foxlee showed examples of work made by Mr. Witcomb, a photographer in Buenos Ayres.

Mr. H. L. N. NOEL-COX delivered his lecture entitled

POMPEII,

which was illustrated with a series of one hundred slides, mostly from his own negatives. The lecturer's descriptive matter was admirably lucid, and the slides of great excellence. Mr. Noel-Cox's contribution to the Club's series of Travellers' Nights was thoroughly appreciated by a considerable gathering of members and friends.

On December 16, Mr. Dallmeyer will give a paper entitled *A Chat about Lenses*.

Brixton and Clapham Camera Club.—November 17, Chairman Mr. W. Fraser (Vice-President). Mr. D. WALTER read a paper entitled

HOME-MADE APPARATUS AND HOW TO MAKE IT.

Accepting as undoubted facts that photography is an expensive hobby, and that much of this expense can be saved by knowing how to use a few tools and making one's own apparatus, he gave thorough instructions as to the making of cameras, dark slides, printing frames, shutters, and other articles, explaining mitreing, dovetailing, and other mysteries in woodworking, and showing many home-made tools and simple contrivances which greatly facilitate getting an accurate fit. As Mr. Walter's cameras and models were closely inspected and his paper aroused much interest, it is not improbable that attempts at camera construction will be made by some who were present, particularly as Mr. Walter promised his assistance to any one undertaking the task.

Croydon Microscopical and Natural History Club (Photographic Section).—The twenty-seventh annual *Soirée* of this Club was held on Wednesday evening, and was attended by some 520 of the members and their friends. In addition to the usual display of microscopes and numerous objects of natural history, &c., the Photographic Section was, as usual, well to the front, no less than ninety-two framed pictures and 363 lantern slides being shown. Space will not permit us to particularise all the pictures shown, but we may mention some very fine bromides by Mr. H. C. Collyer, illustrating some places of interest in the East. Mr. C. Moss sent six pictures illustrating his peculiar method, the colour and sky effects being very pleasing. Mr. E. Straker sent two frames of three pictures, each on gelatino-chloride paper. Mr. A. Roods (Hon. Librarian) showed some very good Welsh views, including two bromide enlargements of the Swallow Falls and Miner's Bridge. Mr. J. H. Baldock sent nine pictures, including some Welsh views and tree studies in gelatino-chloride, views in Kew Gardens on bromide paper, flower studies and views of the decorations at the Royal visit to Croydon in platinum, and a couple of bromide enlargements. Mr. East sent six pictures of rural and other scenes, and a very large bromide enlargement, representing a view of holiday life at the seaside. Mr. E. J. Platts showed some pretty views of places of interest taken in Surrey, some flower studies in platinum, and two bromide enlargements—one being of the Clayton Arms and pond on Godstone Green, and the other of a fine cedar-tree in Kew Gardens. Mr. C. H. B. Sparrow sent six pictures illustrative of the effects producible on Venus paper, the colours of which were much admired. Mr. J. Packham and Mr. S. H. Wratten showed some very pleasing portrait pictures, produced by processes peculiarly their own, the *modus operandi* not being stated, but the effect was somewhat similar to the carbon process. Mr. H. D. Gower (Hon. Secretary) showed a very good platinotype of a group of flowers, china, &c., painted by hand to represent the colours of the different objects, this being well done, and producing quite a novel and pleasing effect. Mr. J. T. Sandell showed eleven remarkably fine gelatino-chloride prints, 15×12, of his well-known series, taken for the City Companies. Other pictures were sent in by Messrs. Barber, Coldwells, Grundy, Hoole, Reeves, Page, Underhill, and Wild. Among the transparencies must be noticed a very fine set by Mr. Alfred Underhill, of Croydon, 8×5, representing a series of views taken on the occasion of the visit of T.R.H. the Prince and Princess of Wales to open the new municipal buildings. This gentleman also sent in eighty-eight lantern slides. Other slides were also sent in by Messrs. Baldock, Barber, East, Grundy, illustrating Alpine scenes; Hoole, views on the Norfolk Broads; Page, Platts, Roods, Sandell, and Wild. During the evening three exhibitions of selected slides from the above were given by the optical lantern, under the management of Messrs. Baldock and Underhill, to overflowing audiences. Messrs. W. Watson & Sons, of Holborn, gave a demonstration on a large scale of the Röntgen X rays, which, it is needless to say, was crowded the entire evening. Messrs. Thorne and Hoddle showed an acetylene generator and burner, together with the apparatus necessary to adapt this light, not only to ordinary illumination, but for microscopic and lantern work as well. A capital selection of music was discoursed by a local band, and at ten o'clock the Exhibition, which was in every way a success, was brought to a close.

Hackney Photographic Society.—November 24, Mr. R. Beckett presiding.—The report on the late Exhibition was given by the Hon. Secretary. It had been a success in every way, and thanks were given to those members who had specially helped to bring about the result. The discussion on Exhibition matters was postponed to the next Open Night. Members' work was shown by Messrs. Hudson and Carpenter.

Leytonstone Camera Club.—On the 18th inst., Mr. A. E. Bailey in the chair, Mr. G. E. Cox gave a lecture entitled

REMINISCENCES OF TRAVEL,

describing a recent tour to Morocco, the Canary Islands, and Madeira; the lecturer gave a graphic description of the many novel sights met with during his journey in these sunny climes, the first touched at being the renowned stronghold of Gibraltar, where a few hours were spent exploring the town and driving to Europa Point, from which coin of vantage a grand view over the Mediterranean is obtained; then across the Straits to Tangiers in the dominion of the Sultan of Morocco, where the first glimpse of Oriental life is obtained. This city is one of a most interesting character, the novel sights on every side being truly enchanting to the unaccustomed eye. The great mosque, the exterior only, however, to be looked upon by the "dog of a Christian," the Courts of Justice, the narrow eastern streets crowded with people in costumes of the most picturesque character combining to delight the visitor at every turn; but with all this charm of beauty and originality there is a great deal calculated to pain and disgust the senses of the fastidious English traveller who is accustomed to fairly clean streets, and the presence of some kind of sanitation, however imperfect it may be in some places; but in Tangiers, as in all Oriental towns, no one seems to think these matters are of any importance whatever, and the refuse of houses is thrown out into the streets, conducing to a result better imagined than described. Another point which strikes the visitor with feelings of sorrow and pain is the absolute cruelty of the people to their patient beasts, whose lives in Morocco must be constant torture. A visit was made to the prison where the unfortunate inmates are manacled and chained. The lecturer proceeded to describe at considerable length other Moorish towns on the coast, and the charming and grand scenery of the Canary Islands. The lecture, which was listened to throughout with sustained attention, was illustrated by a large number of lantern slides made from negatives obtained during the tour.

North Middlesex Photographic Society.—November 23, Mr. A. H. Lisett in the chair.—Mr. S. H. Schofield was elected a member of the Society. Mr. S. H. FRY gave his demonstration on the

HOME PREPARATION OF ROUGH BROMIDE PAPER.

He coated a sheet of Whatman's imitation Creswick paper with emulsion, first soaking the sheet in water and surface-drying it with a handful of cotton-wool, after laying it down in a glass-bottomed dish, with the edges turned up to form a dish of the paper itself, then pouring on the emulsion and allowing the surplus to run off at one of the corners. When set, it should be hung up to dry. He went very fully into the details of manipulation, and replied to the questions which the demonstration elicited. A hearty vote of thanks to the lecturer concluded the proceedings.

Polytechnic Photographic Society.—November 25.—Mr. T. E. FRESHWATER, F.R.M.S., F.R.P.S., read a paper on

PHOTO-MICROGRAPHY,

describing the necessary apparatus, fixing up, and exposure and working, also the best subjects for low-power work, finishing the lecture by showing lantern slides of all the objects upon which he had been speaking. The paper proved so interesting that the members, having heartily thanked Mr. Freshwater through the Chairman (Mr. Howard Farmer), asked him to be sure and favour them again at no distant date. On Wednesday, December 9, the Hon. Secretary will read a paper, with demonstration, on *Photography and Lantern Work* at 8.30 p.m.

Putney Photographic Society.—November 19, Mr. F. Chasemore in the chair.—Mr. H. W. BENNETT had kindly consented to read his Royal Photographic Society's lecture on

ARCHITECTURAL PHOTOGRAPHY,

and this attraction drew a large audience of members, who closely followed his most interesting and instructive paper. The paper is one that cannot fail to be of the greatest help to photographers who take up this branch of the subject, as it deals with it in a thoroughly practical way. The lecture was illustrated by some very beautiful slides of cathedral interiors, which were greatly admired. The next meeting takes place on Monday, December 7, when Mr. J. A. Hodges, F.R.P.S., will give a lecture on *Holiday Rambles with a Camera*.

Richmond Camera Club.—On the 23rd inst., Mr. Cembrano presided at a meeting at which Mr. J. T. SANDELL gave a highly interesting lecture on the subject of

MULTIPLE-COATED PLATES.

He explained the principle and structure of the well-known Sandell plates, claiming for them the three great advantages of latitude in exposure, fineness of gradation, and freedom from halation. The first point he illustrated by developing simultaneously in one dish four plates exposed on the same subject for one, four, sixteen, and sixty-four seconds respectively, all four yielding satisfactory negatives. The claim to delicacy of gradation and freedom from halation was convincingly upheld by the exhibition of a large number of photographs of subjects, and taken under conditions which were calculated to put those qualities to the severest possible test.

South London Photographic Society.—The Past Ordinary Meeting of this Society, held at Hanover Hall, Hanover-park, Peckham (Mr. W. F. Slater, Vice-President, in the chair), was devoted to a competition of prints and lantern slides from negatives taken at the Society's Excursions during 1896. Mr. F. W. Levett and Mr. Saville-Kent (Brixton Camera Club) officiated as Judges. Mr. George Brown was declared the winner of the silver medal offered for pictures. Mrs. Welford showed the best individual picture, *Marguerites*. In the lantern-slide competition, the Hon. Secretary was declared the winner of the bronze medal for the best set. Mrs. Welford and Mr. Sinclair were equal for the second place, Mr. Allen, the Excursion Secretary, was close behind them. At the next meeting, on Monday, December 7, the President will deliver a lecture on *Isochromatic Photography*.

Woolwich Photographic Society.—November 25, Mr. J. B. Panting in the chair.—The third of a series of lectures on *Art Photography*, by Rev. F. C. LAMBERT, M.A. The subjects treated on this occasion were: (1) Treatment of Figures and Groups, (2) Laws of Grouping, (3) Sentiment in Landscape Art. After the lecture several slides by the members were passed through the lantern for criticism by the lecturer.

Ashton-under-Lyne Photographic Society.—November 24.—Mr. THOMAS GLAZEBROOK is to be heartily congratulated on the success of his lecture and exhibition of photographic views on Tuesday evening. He makes no pretence to polished diction or neatly turned phrases, but he feels strongly and talks vigorously, and strikes the nail on the head with a forcible, unerring blow. He is an ardent lover of all that is beautiful in nature, and nobody can listen to him long without being fired with some portion of his enthusiasm. This is one of the greatest benefits conferred by photography. The devotee soon finds that he must go out into the country and study nature with the eye and inspiration of a poet if he has to make any great progress in his art. To reproduce with effect the beauties he beholds around him, he must become a master of his art and a keen observer of every process which contributes to the result. Mr. Glazebrook's series of slides, of remarkable variety and interest, kept the large audience entranced and delighted. The catholicity of subjects was one good feature. He is quite Shakespearean in the universality of his tastes. Nothing comes amiss. He revels among the delicate orchids of a gentleman's greenhouse at one time, and anon we find him at the farmer's pigstye, wondering at the gross animals there to be found. Then he is poking his camera among the hedgerows to secure a little bunch of wild flowers, and then a giant oak or spreading cedar takes his fancy. He follows the schoolboys to a pond, where they exercise the gentle piscatorial art at the expense of a few jacksharps, and sees them frolicking "like troutlets in a pool" in a state of artistic nudity. He revels among the mountains and the lochs, and "in darkness and in storm he takes delight." He is equally pleased with domestic pets, with the sheep of the hillsides and the cattle of the meadows. The birds of the air enchant him with their music, and no schoolboy was ever so fond of bird-nesting, not, however, to rob the eggs, but to photograph them. In short, there seems to be no department of the art into which he has not sought to penetrate, and the results, as seen on Tuesday evening, were very pleasing and instructive.

Bournemouth Photographic Society.—November 13.—Dr. HYLA GREVES gave an address on the science and art of photography. He prefaced his remarks on this subject by welcoming those assembled, and pointing those who were not yet members to the profitable and entertaining character of the Society's gatherings. He likewise took occasion to refer to the zeal and enterprise manifested by the Secretary, Mr. Greenleaves, in the interests of the Society. In the course of the evening there was some excellent vocal and instrumental music. Mr. Pardy presided at the pianoforte, and songs were given by Messrs. Twitchett, Gardner, Butler, and Britton. The photographs sent in for competition No. 2 were exhibited, and the awards made known as follows:—1st prize, 1*l.* 1*s.*, Miss Skirrow; 2nd, 10*s.* 6*d.*, Mr. R. W. Copeman; 3rd, 5*s.*, Mr. T. Lee Lloyd. The first of these had been sent in under the pseudonym "Hyacintha," and represented the Pillar under the Temple Platform, Jerusalem; the second, labelled "Kybosh," was a picture of the reredos, Christchurch Priory; and the third, labelled "The Baron," gave Salisbury Cathedral. A display of members' lantern slides took place, the lantern being operated by Mr. W. Jones.

Cardiff Photographic Society.—The Society opened the winter session at their rooms, in Working-street, on the 20th inst., with an interesting Social Evening. Most of the "powers" in local art circles were present, and a very varied programme was provided. The PRESIDENT and MRS. S. W. ALLEN gave a pleasing contribution, which was much appreciated, and the musical items were most ably contributed by Miss Nicholas, and Messrs. Stephenson, Pratt, and Wordsworth. A number of excellent prize slides were passed through the Allendale lantern, and only wanted perhaps a little more descriptive matter thrown in. One of the most interesting shows of the evening was the exhibition of the Vitograph, by Professor Kloss. In this form of apparatus the living pictures are projected by means of an attachment to the ordinary lantern, which certainly seems very portable and devoid of unnecessary mechanical complications. A good word must be said for those who have been responsible for the exceedingly attractive appearance of the rooms, and to whose efforts the entertainment was due. There are probably few societies which can boast of more artistic premises than those now occupied by the Cardiff Society.

MR. J. J. JENKINS gave an interesting paper on

ALPHA LANTERN PLATES,

illustrating his remarks with a large selection of slides. The great range of colours to be obtained from these plates, and the advantages they offered when the production of slides from poor negatives was required, showed them to be well worth the attention of amateurs whose stock of first-class negatives might not be of the largest. Mr. Jenkins pointed out that the use of a small quantity of metol in the hydroquinone developer of the maker's formula greatly reduced the time required for development which was otherwise rather a slow process, and also gave rather a better colour to the slide than that secured by hydroquinone alone. The annual meeting of the Society takes place on the 4th inst.

Liverpool Amateur Photographic Association.—November 26, the President (Mr. J. Sirett Brown) presiding.—Dr. C. THURSTAN HOLLAND gave a demonstration on the X rays. He explained the great strides that had already been made since Professor Röutgen discovered the new light, particularly as regards the length of exposure necessary to obtain a satisfactory result. He felt sure that it was only a question of time before an improved tube would be invented giving a larger quantity of rays, and so still further reducing the time of exposure, possibly making it instantaneous. Dr. Holland then "radiographed" the hand of one of the lady members, and afterwards exhibited in the lantern a number of examples taken by himself, including photographs of hands from that of an infant to that of an adult, showing the formation and growth of the bones, which he endeavoured to prove were not always uniform in children of the same age; also of coins which had been swallowed, and foreign substances imbedded in the flesh and bone; deformities, and perfectly and imperfectly set joints. He also showed how the rays could distinguish diamonds and paste.

Oxford Camera Club.—November 23.—Lecture on *Intensification and Reduction*, illustrated by lantern slides showing the effects produced by various processes. In the discussion of the paper surprise was generally expressed at the omission of the uranium process of intensification, many members having found that method much more satisfactory than any of the others. Notice was given that, at the next meeting, on December 14, a number of Captain Abney's slides of Swiss scenery would be shown, and members were asked to make the fact widely known.

Wakefield Photographic Society.—November 27.—Mr. H. M. BRIGGS read a paper on

EXPOSURES,

giving his experiences in England and in Norway, and illustrating his remarks with diagrams, negatives, and prints. Mr. STANSFIELD, in moving a vote of thanks to Mr. Briggs, dealt with several points of the lecture, especially with regard to the strength of light on bright and cloudy days. The Rev. C. J. JONES seconded, and, as a beginner in photography, much appreciated the paper and examples. Mr. MILES preferred a Wynne's meter to any other, as there was no guesswork, but an actual test of the light at the time. His method of counting is to hum the tune of "Yankee Doodle," there being four notes in each bar, and each bar represented a second. Sample boxes of Edwards's lantern plates were distributed.

Wolverhampton Photographic Society.—November 20.—Mr. J. GALE gave a demonstration of the

BROMIDE, SYLVIO, AND NEGATIVE PAPERS

of Messrs. Wellington & Ward. Mr. Gale had exposed several pieces of the bromide paper behind negatives for five seconds at a distance of eighteen inches from a gas burner, and proceeded to develop them before the members. He first soaked them in plain water, turning them over and over, to avoid air bubbles, and then immersed them in a developer of metol and glycin, with very satisfactory results, one piece of tinted paper having been used to copy an old engraving, for which it appeared to be admirably suited. Mr. H. HOLCROFT, who had tried the negative paper, spoke in favourable terms of its utility. In all respects the paper is treated as glass plates are, and, after development, the gelatine film may be kept upon the paper support or stripped off. Mr. Holcroft showed several paper negatives, and prints obtained from them, with and without stripping the film from the paper, the prints obtained from the unstripped negative being equally good, but required a little longer exposure, and showed no granularity; and the stripped films appeared to be everything that could be desired, being easy to strip, very flat, and exceedingly tough, and bearing any amount of rough usage in the operations without damage. Mr. Holcroft intimated his intention of discarding rollable films in favour of paper negatives. A number of specimen prints, which had been kindly forwarded by the manufacturers at the request of the Society, were handed round, and were much admired, and were allowed to remain the property of the Society. The meeting terminated with a cordial vote of thanks to Messrs. Gale and Holcroft for the trouble they had taken in the demonstration.

FORTHCOMING EXHIBITIONS.

1896.	
December 4.....	Aintree Photographic Society. E. P. Heron, 2 Tilney-street, Orrell Park, Aintree, Liverpool.
,, 29–Jan. 2.	Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.
Dec. 1896–Jan. 1897	Bristol International. Hon. Secretary, 20, Berkeley-square. Clifton, Bristol.

AMMONIA IN THE MANUFACTURE OF EMULSION.

To the EDITORS.

GENTLEMEN,—I note in your issue of the 20th a letter from Mr. York, in which he says that at an early date, I told him I was experimenting with ammonia in emulsion-making, &c. I cannot give the exact date of my first suggesting ammonia, but it came about in this way. Mr. J. Thompson was experimenting with gelatino-bromide emulsion. He gave

it as an opinion that certain failures arose from the action of the nitrate of silver on the gelatine. I immediately suggested double decomposition, so that another compound of silver should be employed (*i.e.* ammonia nitrate); this occurred at a date before I had any practical experience, and my later results, which were published, are well within the recollection of the early workers. When I suggested the ammonia, I had on my mind that all ammoniacal preparations were more sensitive. This recalls to my mind an episode that took place at one of the Photographic Club meetings. I made a statement that I was in the habit of mixing an ammonia-nitrate solution of silver with a plain solution without causing a precipitate. I was anything but politely informed "that it was an impossibility," and one of the members went so far as to say "he would not believe it if he saw it." Suffice it to say, that this member related at the next Club meeting, that I had called upon him, and made him do the so-called "chemical ledgerdemain trick. I had no idea that any three or four F. C. S.'s could be so ignorant in this matter. A few years ago I stated that "pita" in plates *did not* arise from grease in gelatine, and for a time I had emulsion-makers sending me batches of emulsion; to treat this was a very easy matter, I had only to melt it up and add a few grains of carbonate of ammonia. Subsequent to this, when I was at Monte Carlo, I was using French plates which had "pits" badly. I wrote to the maker, giving him the cure; he replied "that he would try, and if successful he would present me with some plates." He sent the plates and a letter to the effect "that the ammonia increased the rapidity and cured the pits."

In some respects it is a *pity* that there are such good uniform plates in the market, it prevents many from experimenting. It has been stated that ammonia-made plates do not keep well; that is not my experience. I have lately tested some I made in 1887, and, although they were very loosely packed, they were perfect in every way. Any emulsion made by the ammonia process is more rapid in the camera than a boiled one, *i.e.*, an ammonia emulsion giving fifteen per cent. Warnerke will be more sensitive than a boiled one, giving eighteen Warnerke (in the camera). One curious fact is that, the more carbonate of ammonia that is employed in converting the silver, the greater is the speed of the plate in the camera. I am quite well aware that an ammonia-made plate is more prone to give green fog when developed with pyro and ammonia; but, now that ammonia and pyro is seldom used, I can see no reason why all emulsions should not be made by the ammonia method. By the bye it may not be generally known that a small quantity of meta-gelatine added to the finished emulsion will soften the film and give a much finer and more rapid result.

In conclusion, I may mention that Dr. Monkhoven experimented at an early date with ammonia. Apologising for taking up so much of your valuable space,—I am, yours, &c. A. L. Henderson.

Hotel Finstermünz, Meran, Austria, November 23, 1896.

SCIENTIFIC INSTRUCTION AND THE PHOTOGRAPHIC PROFESSION.

To the Editors.

Gentlemen,—May I be permitted to say a few words in reply to Mr. Randall's letter in last week's Journal?

Although I do not pretend to have any technical or practical knowledge of the "rules and mysteries" of photography, it has always seemed to me a needful requirement, for those practising the art, that they should be well grounded in the scientific parts thereof.

On perusing the pages of your Journal, one cannot avoid wondering, and asking "how many of the professional photographers of this country understand the contents of your valuable weekly compilation?" For aught I know, *all* the 3000 professional photographers are well versed in the kindred sciences which have so much to do with the successful practice of the business—chemistry, optics, mechanical construction. No one can dispute that, if they possessed such knowledge as applied to their calling, they would, of necessity, produce more skilful results.

At the Edinburgh Convention I had the privilege of speaking upon the absolute necessity of such knowledge for the rising generation in the ranks of the professional photographer; not only for the daily duties of producing "portraits," but that the knowledge might be applied in all the various branches of the trade in photographic representations of articles of manufacture; of work for book illustrations, magazine, and newspaper work.

I am convinced that there is a wide field for active energy in the branches thus named, and which would bring profitable results to local and provincial, as well as to the metropolitan profession. I have taken a considerable part, for some forty years, in many of the works for Birmingham progress, and the development of its educational institutions.

Foreign competition has touched us nearly in this city, and the recent establishment of a Municipal Technical School has been the contribution of the citizens to supply the scientific teaching so needful to our youth, and all branches of trade and manufacture. We can now boast of a magnificent building erected at an outlay of 100,000*l.*, opened by the Lord President of the Council (the Duke of Devonshire). We are largely indebted to the continuous and indefatigable exertions of Councellor R. F. Martineau for piloting this noble institution to its present admirable condition.

The tenour of Mr. Randall's letter is not to give knowledge broadcast to our youth, but to restrict it, in fact, and, in the mean time, to go about, like the philosopher of old, with a lantern, seeking for a young man of genius. Mr. Randall completely perverts the intention of Huxley in the quotation made in his letter. Huxley, like all great thinkers of the time and all real educational experts, advocated the greatest possible spread of education, scientific and otherwise, whereby the "man of genius" can *discover himself*, and rise necessarily to the foremost place, which he merits by natural gifts and facilities afforded him for their practice and development. It is this practice and opportunity, afforded so widely to our German and French competitors, which gives them, in so many branches of science and trade, an immense advantage over the British youth.

However, we have entered upon the work of altering these defects and of supplying these deficiences, and not a day too soon for the interests, moral and material, of our people at large. There are many other considerations of this important question, suggested by Mr. Randall's letter, but I will not encroach further on your space.—I am, yours, &c.,

47, *Charlotte-road, Birmingham.* D. J. O'Neill,
Secretary, National Association of Professional Photographers.

THE PHOTOGRAPHIC SALON.

To the Editors.

Gentlemen,—When some few weeks ago a letter appeared in your columns making certain misstatements concerning the management of the Photographic Salon, I took the liberty of pointing out to you these inaccuracies, and from the nature of the circumstances I felt justified in referring to them as "fabrications." Now, it appears from another letter in yours of last week that this correspondent, having said what is inaccurate, complains of his being told of it.

If a person hazards a misstatement concerning an institution, or misrepresents it, he can hardly be surprised if some one, in attempting to set him right, waives for the time being such courtesy as is customary.

I cannot but regret, for your own sakes and for your readers, that your correspondent should last week have taken advantage of your desire to act fairly by all parties, and imposed upon you nearly two columns of matter dealing with the manner in which the Exhibitions are reviewed in the paper I have the honour to edit, and quoting what I at various times have said respecting them, all of which would seem to me so utterly unnecessary because other people read the *Amateur Photographer* besides your correspondent, and so can read *all* the text instead of disjointed, and therefore misleading, phrases.

My only object, in writing now, and asking you to publish this letter, is not to discuss, but to state some facts concerning the Exhibition of the Photographic Salon, because, doubtless, your paper reaches the hands of many whom last week's letter might mislead.

Firstly. The Salon prospectus and entry form is for all practical purposes identical with that of any other Exhibition, special mention, however, being made of the fact that all works will be submitted to a Selection Committee, and the particular kind of work desired is stated.

Secondly. Every picture sent in, whether by a member of the Linked Ring or by any one else, is judged on an *absolutely equal basis*.

Thirdly. No member of the Selection Committee is present whilst his own works are being judged, *nor has he any vote or voice respecting their acceptance.*

Fourthly, and by the way. The Linked Ring, so far as I am aware, is not a "magic" circle as your correspondent calls it!

Finally. Your correspondent's statement that "at the latter (*i.e.*, the Salon), members' works are accepted because of their membership" *is absolutely and entirely untrue.*

Now, Gentlemen, your correspondent may go on writing about me or may air his opinions or display his ignorance respecting the Salon and its Committee just as long as you think it desirable to print what he writes, and no one will be one little bit the worse, but do you not think we have had enough of it?—I am, yours, &c., A. Horsley Hinton.

Guildford, November 30, 1896.

PATENT-LAW REFORM.

To the Editors.

Gentlemen,—I am obliged to you for your commendatory remarks upon my address to the Society of Patent Agents; but, as it appears that my statement upon the subject of a Patent Court was not sufficiently explicit, permit me to correct a misconception which otherwise might cause unnecessary opposition to the proposed change.

The original suggestion was to try all Patent cases before a Judge, chosen for his knowledge of technical affairs, in a special division of the High Court. To this proposal in itself no objection can be raised, as it is obvious that, the more familiar the Judge is with the matter in dispute, the greater the probability of justice being done; but I pointed out that no one man can be thoroughly conversant with the technical principles involved in the various branches of industrial operations, and that the Judge must, therefore, rely upon expert evidence, the correctness of which he could not check. In addition, there was the danger of experts becoming advocates in giving evidence, and, with technically trained counsel, specially coached for the occasion, the system is most expensive and may lead to injustice.

My proposal was *not* to take the case out of the High Court, which would be an impracticable measure,* but, in cases of infringement and revocation, to empower the Comptroller-General to receive all expert evidence in the form of Statutory Declarations, under regulations, and to submit the points of law and evidence to the Judge for his guidance. This suggestion refers only to expert evidence taken, as it were, by commission under the trained staff of the Patent Office, and is not intended to affect the conduct of the case by solicitors and counsel in any way. Consequently, ordinary witnesses as to prior user, or other such matters, could be examined and cross-examined under the eyes of the Judge at the High Court, while the experts were directly opposing their written opinions at the Patent Office. This would expedite the case, reduce the cost, and employ all parties concerned in the work for which they are respectively best fitted.

Your regret at my omission to refer to the superior systems of the United States and Germany, in examination for novelty, would impel me to supply the deficiency now, were it not that I should be compelled to differ from you; and I have already taken up too much valuable space.—I am, yours, &c., J. SINCLAIR FAIRFAX.

433, *Strand, London, W.C., November* 24, 1896.

* The Incorporated Law Society would strongly oppose it.

A CORRECTION.

To the EDITORS.

GENTLEMEN,—Will you allow us to correct a slight error in your report of the meeting of the Croydon Camera Club of the 28th ult.?

We wish to state that the apparatus referred to by the President under the name of Grand Kinematograph was invented and perfected by my son, Mr. Gilbert Harrison, and myself; but the sole right to use and sell the same has been acquired by Messrs. Bender & Co., of Croydon.

Relying on your sense of justice for insertion of this, and thanking you in anticipation,—We are, etc., yours, T. J. & G. H. HARRISON.

Bowes Park, N., November 24, 1896.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2, *York-street. Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

Rev. J. H. Stanning, The Vicarage, Leigh, Lancashire.—*Series of four photographs interior of Leigh Parish Church, Leigh, Lancashire.*

RECEIVED.—H. S. C.; FADED PHOTOS; AND OTHERS. In our next.

J. BALLANTYNE.—We have forwarded your letter.

BOSCAWENT & CO.—H. GASCON, and others. See under Ex Cathedrâ.

S. H. ROBINSON (Charleville).—The ALMANAC is published at the beginning of each December.

E. B.—We have no practical experience of the camera. Better address your query to Mr. Friese Green, 39, King's-road, Chelsea.

BURNISHERS.—CAPTAIN X. Both forms are good. It is very much a matter of individual opinion as to which is really the better of the two.

H. L. MOREL.—We do not think you are either responsible or liable for the accident. If the lady threatens you, consult a respectable solicitor.

R. H. U. E.—We should call the colour of the mounts grey; but, as you are dissatisfied with the particular tint, the moral is, in future, only order by sample.

CHRISTMAS MOUNTS.—H. C. Surely you cannot be a reader of the JOURNAL, or you would see from the advertisement pages where Christmas and New-year's mounts are to be had.

STAINED NEGATIVE.—W. BOWER. The stains are due to the negative not being perfectly washed between the operations in intensifying, all the hyposulphites not being washed out before the bleaching operation.

F. W. BRITTAIN.—1. Yes. The process is well within the capabilities of a clever amateur. 2. Yes. 3. *The Half-tone Process*, by Julius Verfasser. It is published by Percy Lund & Co., Amen-corner, E.C., price 3*s.* 6*d.*

BURNISHING.—T. Wilson. The longitudinal lines on the prints enclosed are clearly due to scratches on the bar of the burnisher. The remedy is to work out the scratches on an oil stone or similar means. Grit would make the reverse kind of line.

CHRISTMAS CARDS.—W. HICKS. The print sent is a collotype. The reason why they are done so cheaply is that several negatives are printed on the same plate—indeed, as many as it will hold. Then the plate is printed from on a collotype machine. The prints are then severed and mounted as the one sent.

INSURANCE AGAINST FIRE.—DOUBTFUL (W. C.) There are at present some discrepancies between the ideas of the different fire offices as to the risks with acetylene. Therefore we should recommend you to communicate with the office in which you are insured before installing the light for night portraiture.

INCANDESCENT GASLIGHT FOR PORTRAITURE.—INCANDESCENT says: "I wish to try incandescent gaslight for portraiture. Will you oblige and give me the address of the Company that advertised in your paper some time ago having fitted up a trial studio somewhere in Oxford-street?"—In reply: The address is, O. Sichel & Co., 47, Oxford-street, W.

FALSE PLATINOTYPES.—W. W. C. We fear the case you quote is but too common, yet it is a fraud all the same. Any one can, of course, recover the money back, through the County Court, if it was paid for platinotypes and bromides were supplied. The photographer would only be too glad to pay the money into Court to avoid the exposure.

VARNISH FOR CAMERA BELLOWS.—T. ROGERS says: "Will you kindly give a recipe for varnish to coat bellows of camera (leather) in small quantity?"—In reply: As only a small quantity of the varnish is required, it will be more economical to buy it than to make it, which is not easy on a small scale. It may be had from any of the dealers in bookbinders' materials.

REMOVAL OF GREASE.—B. TYLER asks: "Can you help me as to how to get off some tallow-candle grease from a piano, walnut frame, which I use as an accessory in my studio? A candle was upset on it the other night. I am afraid to try anything, in case of hurting the polish."—If the wood is French polished the grease can be wiped off with a clean rag; if unpolished, possibly a little benzole on the rag will be necessary.

GELATINO-CHLORIDE PRINTS.—VERDES, to make prints (gelatino-chloride) readily come off plate glass after squeegeeing and backing, has lately not put them through the alum bath until they have been fixed and washed for ninety minutes, then twenty to thirty minutes' final wash. Is he doing right, or will the prints fade?—In reply: If in the ninety minutes the whole of the hypo salts are completely removed, the stability of the print will not be impaired by the treatment.

MOTOR-CAR INCIDENT.—(W. A.) We do not know of any illustrated paper that would be likely to buy the copyright of the photograph of the "Amusing motor-car incident on the way to Brighton;" indeed, we should say none would, however interesting, because the matter is too stale now. Such pictures are only of passing interest, and are of no value when even a few days old. Had you sent the picture to one or other of the "illustrateds" the day of the procession, they would doubtless have utilised it, and paid for it—promptitude is everything in such matters.

COPYING OIL PAINTING.—J. P. RIDDLE asks: "Would you kindly tell me what it is that is used for coating oil paintings that are to be copied, so that a matt surface is obtained, and which does away with the reflection and markings of the surface?"—Various things have from time to time been recommended. Wiping the surface of the picture over with stout will degrade the gloss. Practical copyists, who make a speciality of this class of work, use nothing at all. They rely upon the illumination of the picture to avoid reflections. No owner of a valuable painting would, of course, allow it to be tampered with by coating it with any foreign substance.

OBSTRUCTED LIGHT.—INJURED. As your studio has only been erected a few years, you cannot make your neighbour take down his building, although it obstructs your light and causes a "red reflection" in the studio. Try and get his sanction to whitewash the offending wall. Then you will get a reflected light that, with judgment, you can utilise to great advantage. That is the best way, in your case, to deal with a "bad job." We should certainly advise you not to spend any money on law, for, to use a familiar phrase, "you have not a leg to stand upon." If the studio had existed twenty years, you could claim "ancient lights;" then the case would be different.

AGREEMENT FOR SERVICES.—R. A. C. says: "I have applied for an appointment in the West End of London, but I am asked to sign an agreement not to enter the service of any other photographer, or carry on business for myself, within three miles of the place under a penalty of 250*l.* That would practically preclude me following photography at all in London. Could such an agreement be enforced if I signed it?"—We should say not, as it would come under the "unwritten law" of restriction of trade. The case might be different in a small country town. Any how, we should say that such an agreement should not be signed, whether it could be enforced or not.

OPTICAL LANTERN FOR ENLARGING.—H. DODD writes: "I have just gone in for a ——'s lantern, fitted with limelight, and it seems all right for slides on the screen. The other night I tried to make an enlargement with it on ——'s bromide paper, but failed entirely to get a sharp picture. The negative was perfectly sharp, and a slide from it projected on an eight-foot screen was also as sharp as could be wished; yet, although the enlargement desired was only 18×15, and was as sharp as could be when focussed, it was woefully unsharp in the enlargement. Four attempts were made, but all with the same result. But why?"—The explanation is easy. The objective of the lantern is not corrected for the chemical rays, nor should it be, for the best result, as a lantern objective. When the lantern is used for photographic purposes, substitute for the lens with which it is fitted a photographic lens.

FLASHLIGHT COMPOUNDS.—J. WALTON says: "Can you give me any information as to the safety or otherwise of explosive flashlights, and how far insurance policies cover their use? A serious accident is reported from America by the explosion of a flashlight mixture, the operator having his left hand blown off. I have heard that all explosive powders are not exploded by friction. There is no doubt that an explosive powder acts best for portraiture, but if the powder contains any chemical that can be exploded by friction, I think it should be so stated by the makers."—In reply: The use of all explosive flashlight compounds is attended with danger, and, therefore, for safety sake, should be avoided. If they are used at all, they should only be mixed, with care, in small quantities as required for use. In the case of accident, we expect the insurance company would repudiate any claim. But with regard to that, you had better communicate with the office in which you are insured.

JOURNAL OF PHOTOGRAPHY.

No. 1910. Vol. XLIII.—DECEMBER 11, 1896.

Contents.

EX CATHEDRÂ.

The suggestion that the Royal Photographic Society should hold a technical exhibition was discussed at the meeting of the Society, on November 24, and was favourably received by the members present. The photographic press is practically unanimous in recommending the Society to adopt the suggestion. Our own views with regard to the reasons that make the holding of such an exhibition desirable were fully set forth a few weeks ago, and do not need recapitulation, the more especially as there appears to us now to exist a strong general endorsement of our contention that technical photography has, in a great measure, been neglected by the Society of recent years, and that the holding of an exhibition devoted to illustrating the present position of the several branches of applied photography was urgently called for. We trust that the Council of the Society will take the matter into early consideration.

* * *

On the same occasion attention was drawn to the fact that the Society possessed the nucleus of a museum of photographic apparatus, examples of early processes, rare books, and other objects of interest to the student of progressive photography; and the hope was expressed that those in possession of such objects as were of historical or intrinsic interest in connexion with photography would select the Society as permanent custodians of them. We can bear testimony to the fact that the contents of the Society's museum are not permitted to grow dusty with neglect, and we are certain that, should any of our readers be disposed to make additions to the collection, they can do so with the feeling that opportunities will arise when the inspection and examination of such relics of bygone photographic times will give pleasure and profit to the members of the Society and others. Some further remarks on this subject will be found in our Leaderettes this week.

* * *

We learn that some of the fire insurance offices are modifying their ideas with regard to the "dangerous" nature of generated acetylene as an illuminant. In addition to the Westminster Office, which does not take an exaggerated view of the "risks" involved, we are told that the Royal and the Phœnix are not hesitating to grant policies on premises where acetylene is consumed, and it is also likely that other offices will adopt the same sensible course. The articles that we lately printed on this subject have been called alarmist by some of our friends, but we have so much faith in the future of the acetylene light that we considered it not imprudent to assist, thus early, in removing whatever obstacles stood in the way of its adoption. The English offices have been misled with regard to the "dangerous" nature of acetylene, but there is every sign that before long they will take up the common-sense attitude which the New York offices adopted many months ago, viz., that acetylene compressed in cylinders *may* be dangerous, but that the use of generated acetylene does not, *per se*, involve any more danger than the burning of house gas.

* * *

By the courtesy of Mr. Martin, photographer, of Wanganui, New Zealand, we give in another part of the Journal a copy of the Act which the New Zealand Legislature recently passed for the protection of photographs other than group or portrait photographs or those taken for a consideration. The substance of the enactment is, that by the simple inscription of the word "protected," with the date and the producer's name on the negative, the photograph has all the protection of the copyright law for a period of five years. Registration is apparently unnecessary. The simplicity of the means whereby even the

humblest amateur may, in New Zealand, protect his work against piracy will, we do not doubt, excite feelings of envy in the breasts of many of our readers, who look forward to the time when an amended Copyright Act, freed of ambiguities and absurdities, will be passed by Parliament.

* * *

Mr. J. B. Johnston, of Edinburgh, writes us: "Of all the curious places for photographing a group in, perhaps the top of a chimney 250 feet in height is as uncommon as any. In such a place, however, Mr. Moffat, of Edinburgh, photographed a number of gentlemen the other day. The occasion was the laying of the last brick (by the Lord Provost) to a new chimney for the gasworks at Edinburgh."

* * *

At the Camera Club, Charing Cross-road, W.C., there will be on view, from December 12, 1896, till February 2, 1897, an exhibition of photographs by Mr. J. Craig Annan, of Glasgow. The pictures include portraiture, landscape, and *genre*.

PROCESS PLATES AND THEIR USE.

To the few remaining users of the old wet-collodion process—a continually decreasing band—any kind of dry plate whatever is *anathema maranatha*. Yet that there is a demand, and an increasing demand, for process plates is shown by the greater prominence given to them by those makers who have added to their list of brands plates for use in process work. It is perhaps, in view of a desire to increase the sale of this particular class of plate, a little unfortunate that a different name had not been given to them, for the number of those photographers whose business is concerned in the manufacture of various kinds of metallic surfaces prepared by photographic agency for printing purposes must be very limited in comparison with those whose dry-plate consumption is mainly concerned with portrait and landscape work. We hope to show, however, that the field for the use of the specially prepared films we are discussing is by no means so restricted as the title given to them would suggest.

Throughout the various photographic establishments in the kingdom there is a quantity of work of no mean extent where, among those who were once familiar with but have now discarded wet collodion, many a regret is uttered that its merits and beauties are no longer practicable. Such workers should try process plates.

There is perhaps not a studio in the kingdom where there are not brought within a twelvemonth a large number of objects to be copied—photographs, old and faded, and sundry odd articles, ornaments, manufacturers' samples, old prints, manuscripts, and hundreds of other unconsidered trifles—for which the photographer would prefer to use wet collodion if everything were in order, but, as the necessary materials are no longer practically available, has to use ordinary dry plates. He is ignorant of the possible real usefulness of process plates, and is content to put up with the flat and grey results he is unable to get away from.

This avoidance of their use, is, in all probability, due to a misconception. Most photographers are aware that for such subjects as manuscripts, maps, plans, and pure line work generally, an almost opaque hard "black-and-white" negative, with perfectly clear glass, is desirable when a printing block, such as a photo-zincograph, is to be made from it. A kind of mental transference takes place, and it is thought that similar negatives are needed for half-tone process blocks, when the real truth is that the block-maker who makes the blocks that we see used in all the illustrated papers wants, it is true, utter absence of fog, but, at the same time, he certainly does not want black-and-white negatives.

If any one will purchase, for experimental purposes, a packet of these plates, he will find he can get portrait negatives of splendid printing qualities—plucky and full of half-tone. He will also discover that they are very slow—though not so slow as wet collodion—and that is their chief drawback. Their peculiarity, if worked as recommended, which is usually without ammonia in the developer, is that beautifully soft negatives may be obtained concurrently with any amount of density. The points in which they mainly differ from ordinary plates is their slowness, and their power of giving almost any density wished for. Let any one copy a faded albumenised print with an ordinary plate; it is most difficult to get a negative that will give a print devoid of a certain well-known flatness of effect; but with a process plate it is quite easy to get a negative with all gradations of shade that will give as good a print as if the most experienced wet-plate worker had taken it.

Very often an architect's plan has to be photographed on a reduced scale. To one not thoroughly at home with the work it is no easy matter to produce a negative that will give black lines in a pure white ground, even if the negative be intensified with mercury. If a process plate be used, such a negative will be obtained without any trouble with a very wide latitude of exposure.

Let us take the case of an old faded MS., the writing scarcely visible on the yellow paper, and ask what are the capabilities of the ordinary dry plate for securing even a fair printing negative? With a process plate it is possible to get a negative, not perhaps dense enough, but infinitely more so than even an isochromatic plate will give. If, then, a transparency by contact be obtained from this by a process plate, and in turn used for making a second negative, one that will give a brilliant print is easily produced, the chief point to note in this kind of work being to arrest the development before the blacks get clouded. We recently saw an excellent negative of a MS., which gave quite clear, pure whites that had been reproduced this way on account of stain in the original negative. Without any intensification, the portion of the film representing the white paper had been brought to such a depth of blackness that, though the stain was, no doubt, discernible, the writing printed out black before the stain had a chance to print. Again, in enlarging from a transparency in the camera, some workers find some difficulty in getting a plucky negative, such as they would easily have obtained years ago. If those who experience such difficulties will but change their ordinary for a process plate, all their troubles will shrink.

These few detailed examples give only a tithe of the cases where such plates may be used with ease and advantage, but they are sufficient for the purpose, and we may conclude by again repeating that process plates are slow, but are capable of giving a combination of softness with density that can only be likened to wet-plate effects, to which, moreover, are superior by reason of the readiness with which density may be obtained.

A Proposed Photographic Museum.—The paper read at the meeting, on November 24, of the Royal Photographic Society, by Mr. R. Child Bayley, once more raises the question of the formation

of an Historical Photographic Museum. It is really a matter for surprise that the leading Photographic Society of Great Britain has, for so long, allowed the matter to be in abeyance. "In abeyance,' we say, because the Society did, some years ago, get together a pretty complete collection of historical subjects in connexion with photography. There is no question that a museum of early photography and photographic appliances would be highly interesting, and at the same time instructive, even now as well as in the future, as showing what was accomplished in the early days of the art, and by what means. It would also often show that modern inventions were really old ones that had become forgotten. Mr. Bayley's paper shows that the Royal has at present a small, very small, nucleus of a collection in the form of early examples of photography. Some other societies have collections, though unfortunately they are seldom seen. The Photographic Club, for example, has some very early apparatus, and a very fine collection of ceramic photographs done by Lafon de Carmarsae, and, we believe, by Joubert, between thirty and forty years ago; also many fine Daguerreotypes and glass positives of about the same age and older.

A Museum Desirable.—There cannot be a divided opinion that a museum is desirable, and that no time should be lost in its formation. Photography has passed its jubilee, and the number of the earliest workers who can explain the old processes and apparatus is becoming fewer and fewer year by year. Even now some strange notions exist amongst modern writers as to the early photographic processes. For example, a writer in one of our contemporaries some time back glibly described the Daguerreotype as a picture developed on a silver plate, "and intensified with bichloride of mercury." The calotype and the wax-paper processes are frequently confounded by modern writers as being the same. So with the old compound toning and fixing bath and the sel-d'or bath. These and other perhaps more flagrant errors may, unless checked, be handed down to posterity, and accepted as facts. Again, how many of the present generation of photographers would know an iodising and bromising box, or a mercury box, if they saw it, to say nothing of its use? There is yet another reason why no time should be lost in the formation of a permanent museum. Early apparatus is getting scarcer and scarcer every day. It is too often treated as useless lumber, and for that reason is frequently destroyed or converted to other purposes. We know of an instance of a Johnson's pantoscopic camera being destroyed because some of its parts could be made useful for something else. That a permanent museum is desirable is incontestable; and where shall it be? Have the Royal accommodation for it in its present rooms? We put these questions for the following reasons.

Examples at South Kensington.—It may be new to the majority of our readers that an excellent and representative collection is, or was, in existence. The past tense is included because, as we shall presently explain, we are in doubt on the subject. At the Inventions Exhibition, 1885, the Photographic Society got together a very interesting loan collection, illustrating photography from the earliest period. From what we remember, it included bitumen pictures, by Niépce, on metal plates; Daguerreotypes and apparatus for their production; Talbotypes; the first book illustrated by photography; a model of Swan's original machine for making carbon tissue; the first photographic lens made by the late Andrew Ross, which antedated Petzval's calculations; Archer's fluid lens; Sutton's panoramic lens and camera, &c. At the close of the Exhibition the whole of this collection, with two or three exceptions, was transferred, presumably on loan, to the Science and Art Department of the South Kensington Museum. There it was—we had nearly written stowed away—deposited in a glass case in a corner of one of the topmost galleries of the buildings, which no one seemed to visit—but there it was for some years. Where the collection is now we cannot say, for on our last visit to the Museum we could not find it—evidently it had been removed. Although we made inquiries of several of the police attendants, we could not learn its whereabouts, or even if it were still in existence. This is a matter that the Royal, that got the collection together, might do well to inquire about. Perhaps, as it was not alluded to the other night, it has become quite forgotten. If the collection is still in existence—and we sincerely hope it is—it seems quite lost to photographers where it is; therefore, as it is, for the most part, on loan, the lenders would probably prefer it to be transferred to some more central place, where it can be the better seen and appreciated.

A Collection of Portraits.—Among the suggestions made at the Royal was that a collection of portraits of the pioneers of photography was also desirable. There used to be shown at the South Kensington Museum several dozen whole-plate portraits of scientific men, taken thirty years and upwards ago. Amongst them were a number of the chief pioneers of photography. On more than one occasion in the past we have called attention to this collection and its then state, though so old, and suggested their reproduction, as some few showed signs of decay. On our last visit the portraits had disappeared, and we could not learn what had become of them. It may be that we were not energetic enough in our search for them, as well as the other collection; but one thing was made evident to us, namely, that South Kensington is not the place for a photographic museum.

JOTTINGS.

ACETYLENE is the topic of the moment among practical photographers. Probably the generators that have so far made their appearance on the market are but the forerunners of more effective forms of apparatus which experience alone can suggest. It is, however, already clear that the generation of the gas within the gas-holder itself is not the best system to adopt, for, not to mention other though minor, disadvantages of using such forms of generators, it is impossible to recharge with the carbide while the acetylene is burning. I fully anticipate that, when the light becomes better known and understood, the presence of a quantity of acetylene in holders having the capacity of several hours' or nights' supply will be a feature of every photographic establishment. Acetylene is as simple and harmless in use as house gas; it is made as easily as was oxygen in the old gas-bag days, while, as an illuminant for optical lantern, enlarging, and portrait purposes, it perhaps in itself combines most of the good qualities of the electric arc, the oxyhydrogen, and the oil lights. I strongly recommend my professional readers not to be dissuaded by the timidity of the insurance companies from giving the light a trial.

The Photographic Salon and the Linked Ring have lately come in for some severe, but just, criticism, both with regard to the manner in which the Piccadilly Exhibition is conducted and the literary performances of some of the younger Links, by which, if they are wise, those most concerned will endeavour to profit. Mr. Henry W. Bennett goes to the very foundation of the reason why the Salon and the Ring are regarded with such extensive disfavour when he twits the members with an "assumed superiority over all photographic workers so frequently and so aggressively asserted." Photographic Podsnappery it might be termed, for Mr. Podsnap, you may remember, was a very superior person. I see that Mr. H. P. Robinson affectionately refers to the Salon as his own pet child,—an adopted one of dubious parentage, by the way—and is pleased to think that it is imitated in outward dress. I am confident Mr. Robinson will join me in the hope and the belief that in future the honesty and good sense of photographers generally will assure the Linked Ring and the Salon the unassailed possession of those features which have made both institutions what they appear to be in the eyes of observant outsiders.

Mr. Bennett's scathing indictment of the Linked Ring and the Salon has brought no official reply. It is a formidable letter to answer, and possibly therefore Mr. Maskell is wise in keeping silence. You see, it is so easy not to write letters to the papers when, metaphorically speaking, your critics have left you without a leg to stand on. However, during the bad time that he has been

having lately, Mr. Maskell has, doubtless, consoled himself by the thought that ridicule, hard knocks, and unappreciatedness fall to the lot of most pioneers. I conclude my references to the Salon for the year 1896 by quoting the following passage from the London correspondence of the *Indian Photographic Society's Journal*. The writer's contributions are invariably marked by knowledge, discrimination, and thoughtfulness: "If only the Linked Ring will give up its rather undignified appeals for flattery and commendation, all biassed critical feeling must very soon disappear in the presence of such broad and masterly art-work as it has this year brought together for public appreciation and guidance." Very good advice. Take it, gentlemen of the Ring!

The publication in these pages, a week or two back, of the conditions under which the Council of the Royal Photographic Society makes an award of the Society's Progress Medal is a reminder of the circumstance that this more or less coveted distinction will shortly come before the Council for disposal. I am not about to discuss its probable destination, though I may say that I should not at all grudge its bestowal on Mr. H. P. Robinson in recognition of the progress he has been instrumental in imparting to the Society during the last five years. This, however, by the way. In glancing down the list of recipients, it appears that Abney (twice), Willis, Warnerke, Woodbury, Eder, Waterhouse, Emerson, and Dallmeyer figure upon it. I remark that the Society appears entirely to have overlooked the valuable optical work of Rudolph, Von Hoegh, Schroeder, Dennis Taylor, and others during the last seven or eight years. Surely the solitary award made for photographic optics is an under-estimate of the advances recently achieved in this branch of photographic science?

Some of the new movements in photography, or rather the photographic world, have a progressive character not always found associated with undertakings promoted by bodies of photographers, whose reputation for conservatism is only too well deserved. The Convention Council has created a noteworthy precedent in resolving to endow research work. I have little doubt that, carried out with care and deliberation, the scheme is one calculated to be of benefit to photography. Certainly, the Council do not lack admonition and advice from persons who, while themselves incapable of initiating ideas of a progressive nature, are ready and eager to pour cold water on the suggestions of others. The research scheme of the Convention has been subjected to a great deal of uncalled-for carping. I see no reason for supposing that the Convention money is more likely to find its way into the wrong channels than are the guineas of the Affiliation Committee, which just now appear to be lavishly expended on lectures that can scarcely be admitted to have more than a very restricted beneficial scope.

With regard to the proposed technical Exhibition no hostile criticisms or objections appear to be forthcoming. The field awaiting occupation by the Royal Photographic Society has been lying fallow for years, for, since the Crystal Palace display of (I think) 1890, no representative Exhibition devoted to apparatus, or to the illustration of processes, &c., has been held in London. To be successful, the proposed Exhibition must be organized on broad and comprehensive lines, and the participation of those engaged in the various industries and sciences upon which photography relies for its well-being frankly sought for. The suggestion thrown out in these columns that the collection should be retrospective to the extent of, say, five years, is an excellent one, in view of the fact that, during that period, no adequate opportunity has been provided for completely showing the actual position of photography in its industrial, scientific, and commercial aspects. I hope that, when the Society has got over its internecine troubles, the subject will be taken in hand.

It is seldom that a number of this JOURNAL does not appear without it contains the expression of a professional photographer's grievance against such irritating forms of competition as free or excessively cheap portrait schemes—the coupon system in one of its many disguises; attempts to induce photographers to take photographs for nothing, and so forth. I am aware that some prosperous members of the profession affect to doubt the wisdom of photographers seeking publicity in these and similar matters, and are sceptical that any good result ensues; but I am very much mistaken if a careful perusal of these pages for the last six months would not reveal instances where the publicity given to some of these doubtful schemes has not prevented many photographers availing themselves of them, and deprived their originators of much of the illicit profit they were striving for. Affluent persons who sneer at their less fortunate brethren for "writing to the papers" do not realise that to many a struggling little man the friendly columns of a representative paper are the only means he can find for making his voice heard against attempted injustice, swindles, and knavish tricks of trade.

By the time my next batch of "Jottings" appears in these pages a new year will have opened. It is rarely that an anonymous writer in a journal can say that among its readers in all parts of the world he has, despite his anonymity, accumulated innumerable friends; yet this is the pleasant experience of the author of these lines. To those friends—and, indeed, to all—I beg to be allowed to wish every prosperity in the year 1897.

COSMOS.

FOREIGN NEWS AND NOTES.

Mechanical Intensification.—It was recently pointed out before the Société Française de Photographie that, if a film be treated with formaline after development, and then washed and placed in alcohol, it will contract more or less according to the strength of the alcohol and the duration of the immersion, and that by this contraction the negative is intensified. It is suggested that ninety-five per cent. of alcohol be used, to which forty per cent. of glycerine has been added. If the contracted film be placed in water, it will absorb the same, and extend to its original size and intensity. It has, of course, long been known that a film which has been allowed to expand in stripping with hydrofluoric acid gets thinner, but this is the first time that a contraction and intensification has been observed.

Mercury Toning.—Mercier pointed out in, in his well-known work, *Virages et Fixages*, that gelatine and collodio-chloride prints can be partially toned with mercuric chloride with success. A writer in the *Bulletin de la Société de Bourgogne* now points out that such a toning process is extremely useful when the lights are slightly yellowed. If the prints have been toned with gold to a purple, they turn to a fine carmine. The procedure is merely to immerse the print, well washed after toning and fixing, in a bath composed of—

Mercuric chloride	1 grain.
Salt	20 grains.
Water	8 ounces.

It is stated that the results thus attained are quite stable after washing without any fixing.

Artigue's Paper.—Herr Watzek points out in the *Wiener Photographische Blätter* that, instead of using gum arabic in the Artigue process, gelatine may be employed, if it is used in a liquid state. The image can be obtained of a finer grain and adheres more firmly. As a suitable formula is recommended:—

Gelatine	40 grains.
Chloral hydrate	25 ,,
Water	100 minims.

By using this, the developer may be employed cold, and hastened by the addition of a little carbonate of potash, and it is only necessary to use sawdust to clear up the whites should they show at all dirty. The surface of the paper, seems to have no effect when gelatine is used, and the paper is more sensitive and keeps better than that prepared with gum. It might be possible to replace chloral hydrate with glacial acetic acid or some other solvent of gelatine.

Aluminium as a Support for Collotype Plates.—In the current number of the *Photographische Correspondenz*, A

Albert suggests the following method of working:—New sheets of aluminium should be cleaned with a mixture of ammonia, 1 part; water, 3 parts; and then well dried with a cloth. If they have been previously used for collotype, they should be freed from the gelatine film by treatment with dilute sulphuric acid 1:30, well washed with water, and then treated with ammonia and water, as suggested above. The best substratum is waterglass and beer, without any caustic potash. To coat the plates with gelatine, the aluminium should be laid on plate glass and then coated. It is much easier to print on aluminium plates than with glass, as the metal can be turned back like paper, and it requires less printing. For damping these plates in printing, a mixture of glycerine and water only must be used; no ammonia or hypo should be used, as these attack the metal. Printing from these plates is much easier than from glass, as the ink shows up much better, particularly by artificial light, than on glass.

Toning of Bromide Prints.—According to Valenta the following procedure will give any desired colour on bromide paper, developed with any of the alkaline developers. Ferrous oxalate must not be used. The print should be soaked in water in a flat dish till soft, then drain off the water and apply the following solutions as directed.

Solution A.

Uranium nitrate	5 grains.
Water	1 ounce.

Solution B.

Potassium ferridcyanide	4 grains.
Water	1 ounce.

Solution C.

Ferric chloride	4 grains.
Water	1 ounce.

For sepia brown tones, mix 9 parts of *A* with 1 part of *B*, and the toning should be allowed to continue for from six to ten minutes. The tones range through black to sepia, bistre, dark sepia, and vandyke brown. For brownish red tones mix *A* and *B* in equal parts and tone for six to eight minutes. For orange red tones, mix 35 parts *A* and 75 parts *B*.

For bluish-green mix *A* and *B* in equal parts, and tone till one image is a dark sepia brown, and then wash well, and then treat with a mixture of the part of *C* with 5 parts of water. Toning will take from two to four minutes and the print should then be washed and dried.

For blue tones the print should be treated with equal quantities of *A* and *B* till a brownish-red colour is obtained, and then washed and treated with *C*, when in about three minutes the desired tone will be reached.

Blue Tones on Celloidin Paper.—Lainer describes the following method of preparing a bath to give blue tones on celloidin paper, which would, doubtless, also answer for gelatine and collodio-chloride paper. Two grains of ammonium sulphocyanide are dissolved in 10 c. c. of water, and heated almost to boiling point, and then 30 c. c. of a one per cent. solution of neutral gold chloride should be added, in quantities of 3 or 4 c. c. at a time, and, after each addition, the solution heated till the red colour first formed disappears. The solution should be allowed to cool and filtered, and kept for stock. To every 100 parts of a five per cent. solution of ammonium sulphocyanide five parts of this solution should be added. In this bath a print will assume a pure, soft blue tone in four or five minutes, and this can be seen on examining the print by transmitted light as usual. The use of a fixing bath with some sulphite in it will tend to give pure whites.

THE THEORY OF DEVELOPMENT.

III.

So much for what goes on during and after exposure. On the application of the developer, the first result is the decomposition of the nitrate of silver adhering to that contained in the film, and, whether the developer be pyro, or iron, or gallic acid, this involves oxidation of the developing agent, reduction of the silver to the metallic state, and possibly, as suggested by Brande and Taylor, liberation of hydrogen. When this process commences, the liberated hydrogen commences its reducing action in different directions; it combines with the remaining atom of iodine or bromine in the sub-salt which is reduced; also probably attacks the newly formed iodide or bromide of silver on the surface of the film, which, being comparatively unprotected, suffers easy reduction, and it will also reduce the silver nitrate, with which the developer now becomes mixed. The process is not an instantaneous, but a continuous one, and, as the different substances—the iodide, sub-iodide, and nitrate of silver—are respectively reduced, the liberated iodine combines with the fresh silver from the developer so long as any remains unreduced.

Then, as fast as the sub-haloid is reduced, the halogen recombines with fresh silver before it can escape out of the film, or, if it reach the surface, it is reformed into iodide or bromide, to be again reduced, and so *ad infinitum*. What becomes of the nitric acid I will not venture to say with certainty; but, as the action of the developer gets weaker as it proceeds even though fresh silver be added, it is set free to act as a gradually increasing restrainer.

If we imagine some such interchange of elements to proceed, it is not difficult to see how the reduced silver is found in the exposed part of the film without the necessity for supposing it to be attracted there by electrical means. On the contrary, my hypothesis is, that it is not deposited from the developing solution in the metallic state, as usually supposed, but is attracted to the surface of the film *in the form of iodide or bromide* by the hydrodic or hydrobromic acid derived from the decomposed haloids, and is then, in consequence of its unprotected condition, reduced by another portion of the developer. Meanwhile, the exposed and reduced haloids undergo reformation, and so the film retains its original formation.

The upholders of the molecule theory will, no doubt, argue on the basis of Carey Lea's experiments quoted a few weeks ago by Mr. A. D. Pretzl, that this chemical explanation does not fit in with observed facts, notably with the persistence of the latent or developable image; but I shall try and show that the two are by no means antagonistic. The experiments referred to have to do with the removal of the developed image by acid nitrate of mercury or nitric acid when the film is found to be entirely unaltered in constitution, and, what is more, is capable of having the image reproduced by a second, and third, and fourth application of the developer. This is held to prove the physical character of the action of light; in other words, that the latent image consists only of particles of silver in a state of molecular excitement.

My own view of these successive redevelopments is that they are not due to any action of light at all, but simply and purely to chemical causes. For instance, take a plate developed with alkaline pyro and treat it with nitric acid to remove the image. The result will be, not a restoration of the film to its primitive condition, but a reverse of the original image in which the picture is formed in bromide of silver. Now wash this well, and apply a developer of acid pyro and silver, and *the image will be restored in all its original gradations*. In other words, the more complete the absence of silver, the more transparent the film, the greater the quantity of silver deposited there. Can this be considered the result of particles of silver in a state of molecular excitement?

Has any one—I do not recollect to have seen such an experiment recorded—tried the experiment of treating an exposed and undeveloped plate with nitric acid and *then* developing an image? I think in such a case the result would be entirely negative. I see on p. 726 (November 13) an experiment of Dr. Reissig's is quoted by Mr. Pretzl, which bears out this view. An exposed plate treated with iodine prior to development gives no image. Captain Abney, twenty years ago, showed that oxidising agents, generally nitric acid among the number, destroy the latent image and prevent development. How, then, does it happen that in Carey Lea's experiment the image is reproducible? Can it be that there is a physical as well as a chemical action, and that the physical image is not so removable? I do not think so.

Let any one try the following experiment, and I think it will throw a little light on the cause. Take a wet-bath plate and wash it well, not too thoroughly, but sufficiently to remove the free silver; or, better still, take a collodion-emulsion film which has no free silver in it, and drop two or three drops of solution of silver nitrate on different parts of the surface, and then wash again, this, of course, in the dark room. Now apply a developer of acid pyro with or without silver, and it will be found that wherever the silver has been dropped, a deposit will be produced, weak if no silver be added to the developer, but reaching any strength if silver be employed.

The bearing of this upon the question is just this: In Carey Lea's experiments, and in the one I quoted of the removal and reproduction of a chemically developed image, the development is, I believe, entirely due to what I may term silver stain. The portions of the film where the image has been removed are, in the very act of removal, submitted to the

action of free silver; the collodion is, in fact, partly impregnated with it, and this suffices to set up development with acid pyro and silver in just the same way that a dirty plate will reproduce all the streaks and smears it bears. But, surely, no one would set down that result to molecules of silver in a state of excitement. In the case of the reproduction of the chemically developed image, the denser proportion of the original image will, of course, be subjected to the action of stronger solution of silver when the image is dissolved out, and, indeed, the same holds goods of the physical image; and this accounts for the reproduction of a stronger image or deposit on those parts.

If, instead of simple nitric acid, a mixture of that acid with a soluble bromide be used, or hydrobromice acid, chromic acid, and a soluble bromide, or, indeed, any reagent or combination that will destroy the organic compound of silver and convert it into bromide, then no reproduction of the image can occur. Is this treatment to be supposed to allay the "molecular excitement?" If so, why?

Over a quarter of a century ago I upheld the electrical theory, but during that period there is plenty of time to think things over, and possibly to recant. I have done so, and this must be my explanation.

W. B. Bolton.

PHOTOGRAPHIC WORKERS AT WORK.

XII.—Messrs. G. W. Wilson & Co. at Aberdeen.

The good ship, *Ban Righ*, landed us recently in the granite city of the North, after thirty-eight hours of delightful separation from the turmoil of London life. Passing through the city on our way to St. Swithin-street, where Messrs. Wilson's works are situate, we could not but admire the magnificent pile of municipal buildings with its graceful spire and the long vista of Union-street flanked with massive granite structures, broken in its severity by the beautiful public gardens in Denburn Dell.

Upon arrival at the works, we were received most cordially by Mr. Louis Wilson, the managing director, and, seated in his office, he gave some account and many interesting particulars of the growth of this business, which now enjoys a world-wide reputation for its photographs and lantern slides. The firm originated early in the fifties, when Mr. G. W. Wilson, a portrait photographer, turned his attention to landscape work. His first publications were stereoscopic slides. These were followed by *carte-de-visite* views, which for a time enjoyed great popularity, but in turn they have had to make way for the more attractive unmounted print. Still more recently opalines have been first favourites, but fashion in photographs, as supplied by the publishing firms, is now transferred to goods mounted in plush. Two or three years ago there was a temporary revival of stereoscopic pictures. The demand came from America, and the boom was of short duration.

In answer to our question, Mr. Wilson remarked: "Our business grows more complex year by year. It may seem incredible, but we can supply a photograph in two hundred different styles. Such variety would, of course, necessitate an unmanageable stock. Our customers are sometimes unwittingly exacting, and think we should have stock of anything they may require, but with over forty thousand subjects it is an impossibility. This is our catalogue for 1871, a small volume, $5\frac{1}{2} \times 5\frac{1}{2}$ inches, containing forty-six pages. Our present catalogue comprises twelve octave volumes of 120 pages each. The landscapes are mostly English and Scotch, but we have sent operators to Australia, and one has just returned from South Africa. In addition to photographic prints, we do a fair volume of business in lantern slides. We do not publish religious, temperance, or comic series, although these command the largest sale. Our subjects comprise landscape and educational series, such as geology, trees, and historical portraits. This letter is an acknowledgment from the Birmingham School Board, for whom we have just completed an order.

"You inquire about prices. Of course they have fallen, as there are now so many competitors. I should estimate prices now at about one-third of what they were in the early years of the business. Reverting to those times reminds me that the first medal taken by my father was for improvements in calotype."

We then passed into the store-rooms, and found a most varied stock of mounted and unmounted photographs, and tiers of drawers filled with lantern slides. We inquired if the public had shown any desire to be supplied with pictures of the art type seen in these latter days at our Exhibitions.

"No, none whatever. I must say we are simply photographers, and my experience is that most dealers care little or nothing for the merits of a photograph. They look at size and price, and, if one picture is a little larger than another, no matter what its quality as a photograph, the larger picture will secure the order. We once tried to introduce a series of pictures of a much higher order, but the venture was an absolute failure."

Returning to the business aspect, we inquired if subjects had frequently to be renewed.

"Some pictures soon get out of date owing to changes in landmarks and alterations in buildings. Look at this photograph of a seaside resort. In the distance you will see a small wreck, of no moment as a factor in the picture; but the wreck is gone, and we have had to send an operator a long distance to make a fresh negative, because that wreck in the old photograph makes it out of date. You will think it incredible, but we have had to take fresh negatives, for no other reason than the change of a shop sign or other trivial alteration."

Leaving the store-rooms, we entered the works, and were introduced to Mr. Belton, the able manager of the printing department.

The works are divided into two sections, separated by a lane, one side being reserved for the Scotch views. We first entered a building of considerable length and some breadth. This provides accommodation for the storage of negatives and apparatus, the filling of printing frames, and rooms for washing, toning, fixing, and drying prints, and the sensitising and drying of albumenised paper. In front of this building is a glass structure for printing, when the weather is unfavourable, and beyond this glass lean-to is a large space fitted with frame stands, where most of the printing is done. We were especially impressed with the systematic arrangements for the control of waste.

Each printer is kept in touch with his work until it reaches the stock-rooms, and in this way an interest is created in the production of good work. To obtain an idea of the organization of the work, we selected a subject in the catalogue at random. Within two minutes the negative was brought to us from its place on the grooved shelves at the back of the building. It is then sent to the printer with an order form. The printer keeps a daily record of his work, the quantity of paper received, the number of prints made, and the number rejected. The prints then pass into other hands for toning, fixing, washing, and drying. Each printer's work is kept separate, and the number rejected at each stage is recorded. The figures are tabulated, and a monthly abstract of the waste at each step is made. This system permits of the loss being localised with ease and certainty. As a testimony of its efficiency, we may say that the percentage of waste from all causes is low down in the units.

The arrangements for washing after fixing are also very interesting. A frame resembling an inverted Chinese umbrella, of exceptionally large size, forms the support for the prints, the ribs being interlaced with twine. A pipe, perforated with numerous holes, traverses the diameter of the frame at some distance above the prints, and throws a continual spray of water upon them. The frame is kept in rotation mechanically, and the time of washing for each batch of prints is fifteen minutes. The prints are thus subjected to a constant stream of running water, and we were struck by the harmony of the practical experience of a large firm like Messrs. Wilson's, with the experiments recently made by Messrs. Haddon and Grundy concerning the washing of prints. At the end of fifteen minutes no trace of hyposulphite of soda is discoverable in the washing water.

The greater part of Messrs. Wilson's prints are on albumenised paper, but platinotypes and carbon prints are also produced. Outside the building are eight large tubs, into which all waste solutions are run for recovery of the precious metals. These are a valuable asset, and the return from the refiners is about fifty-five per cent. of the residues.

In the drying-rooms on the first floor provision is made for the supply of artificial heat when required. The mounting-rooms also are on this floor, and we see tanks of gelatine in solution, at which workers are deftly mounting prints in optical contact with glass, this being now an important feature in the Company's business. The rooms for the production of lantern slides adjoin. Only the wet-collodion process is used, and all the slides are toned with gold to the peacock-blue characteristic of the firm's work. Some beautiful specimens were exposed and developed in our presence, and revived lingering regrets for the days of old, when wet collodion reigned supreme. This department is under the supervision of Mr. Charles Wilson. The firm still continues the old-established portrait business in Crown-street, where Mr. John Wilson has charge of the management.

PRODUCING PHOTOGRAPHS IN RELIEF.

Mr. T. C. Marceau has patented certain improvements in the art of finishing and mounting photographs after they have been taken, and the

invention is especially designed to throw certain parts of the picture up into relief above the plain surface.

It consists in certain details of construction which are more fully explained by reference to the accompanying drawings upon, which

Fig. 1 is a view showing the manner of outlining the picture upon the surface in which the corresponding intaglio is to be produced.

Fig. 2 is a view showing the means for registering the pictures which are to be afterwards thrown up into relief.

Fig. 3 is a vertical section through the mould.

The object of the invention is to simplify the methods of making relief pictures, so that any number of such pictures may be made to accurately coincide and correspond with each other.

"In carrying out my process," says Mr. Marceau, "I first prepare a photographic negative in the usual manner. The pictures are then taken from the negative upon films of sensitised paper, and the outline of those portions which it is designed to show in relief is cut out from one of these sheets, and pasted upon a surface of glass as shown at A.

"The paper upon which the pictures are taken is all cut of a certain size, and the negative is marked, so that this paper is always laid in the same position upon the negative for printing each picture. The pictures are therefore all in identically the same relative position upon the paper, and they all correspond with the one from which the outline was cut for the purpose of making the intaglio block.

"The exterior portion of the paper from which the outline has been cut now serves as a pattern for the exact registry of each of the pictures

Fig 1.

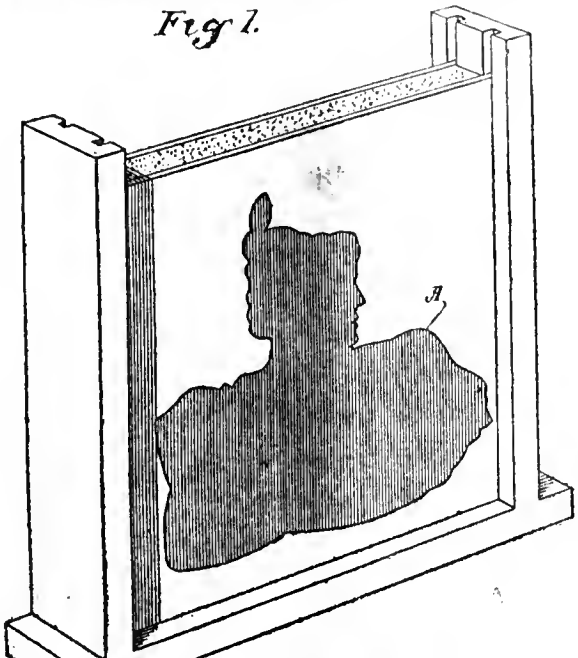

Fig. 2.

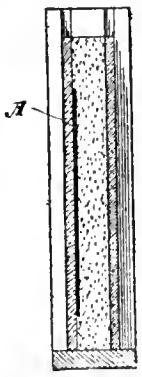
Fig. 3.



which are to be thrown up into relief, and is afterwards used for this purpose as will be hereafter more fully explained.

"The surface, A, upon which the figure is pasted, as previously described, forms one side of a mould, the space between the two sides being sufficient to provide a necessary thickness, and the sides being also connected by edge strips so as to form an enclosure, as shown in fig. 1.

"Into this enclosure I pour plaster of Paris or other plastic material which will afterwards set and become hard, filling the space within the mould.

"The plastic material flows around the figure which has been pasted upon the glass, and this figure, projecting the thickness of the paper above the surface of the glass, will form a corresponding indentation in the material with which the mould is filled, and which indentation remains after it has set.

"The mould is then opened, and the hardened material is taken out, the outline or figure is removed from the face of the plaster, if it has adhered thereto, and the perfect outline remains upon the surface.

"The surface of the block is now excavated or engraved out in the usual manner for producing intaglios, so as to form the various features of the picture to greater or less depth, as the shade or contour of the picture demands and the taste of the artist shows to be proper.

"When this is completed, it is in readiness to receive the pictures which are to be thrown up into a relief corresponding with the depth of the intaglio which has thus been formed.

"The part, B, from which the figure was cut to form the outline upon the block, is now pasted, or otherwise attached, to the block, forming an accurate peripheral outline around the intaglio, and, as all the pictures are in exactly the same relative position upon the printed sheets, it is only necessary to register the edges of each sheet with that upon the block, to register each picture with the intaglio. The picture is wetted, and then pressed into the block by any of the usual or well-known means for producing raised surfaces, and those parts of the picture which are designed to be thrown up into relief will be correspondingly forced into the various depressions of the intaglio in the block, remaining there under pressure until dried, after which they can be removed, and the pictures mounted in any usual or well-known style for mounting such pictures.

"If preferred, any suitably prepared block may be used, and the outline within which the engraving or intaglio is to be made may be marked upon the surface of the block, by laying the cut-out figure thereon and outlining it, and afterwards engraving the block.

"A convenient method for effecting this is to lay the picture to be produced in relief upon a supplemental sheet, which is properly proportioned to the block, and then to cut the outline of the picture, and at the same time cut through the supplemental sheet beneath, the two sheets being secured together so as to remain in the same relative position until the cut has been completed.

"The supplemental sheet may be made of any suitable material. I have found that collodion in thin sheets makes a very satisfactory substance for the purpose, but it will be manifest that other materials may be used without departing from my invention. This supplemental sheet is then laid upon the block, to which it is temporarily fixed by pins or clamps, and the outline which is to be engraved in the block is marked by following the outline of the cut. The sheet may then be removed and the engraving of the block completed. The pictures to be thrown into relief are then fitted to the opening in the supplemental sheet, and the picture and sheet are placed upon the block, the face of the picture coinciding with the intaglio which has been cut in the block, as in fig. 2.

"This registration is ensured by passing pins through the holes already made in the supplemental sheet and through the picture, these pins entering the holes previously made in the block, and after this is effected the pressure is applied to throw the picture up into relief by pressing the parts of it into the intaglio in the block.

"The claims are for:—

"1. The method of forming photographic pictures in relief, consisting in cutting out one of a set of pictures and outlining it upon a block formed by hardening a plastic mass within a mould, engraving an intaglio upon the block to correspond with said outline, then registering the other pictures upon the block, and pressing the portions coincident with the engraved surface thereinto.

"2. The method of forming pictures in relief, consisting in cutting the outline of one of the pictures and a supplemental sheet upon which it is overlaid, indicating said outline upon a block, and engraving an intaglio in said block corresponding with the outline, fitting the pictures successively to the opening in the supplemental sheet, inverting them and the sheet over the engraved surface, and retaining the pictures in register with said surface, while they are pressed thereinto by uniting the pictures and the supplemental sheet and entering corresponding holes in the block.

PHOTOGRAPHIC CHEMISTS AND PHOTOGRAPHERS.*

As things are at present, it is by no means a fancy picture to say that, so busy is a modern pharmacist with goods foreign to his actual profession that, when, by chance a prescription does come in, it is looked upon as an unqualified nuisance, I have felt that way myself scores of times; while as to *poisons* the less said the better; for my part, I run no risks; and, therefore, considering this state of things, what possible action can the Pharmaceutical Society take against the "Company Pharmacy?" So much is written by devoted adherents of the Pharmaceutical Society against the "Company" Pharmacy of a totally misleading character that it is really a kindness to put things

* Concluded from page 778.

sometimes in a clearer light. They judge these matters from an outside view and by hearsay only. It is quite a mistake to say that the founders of these big companies know nothing whatever of pharmacy; my experience is, they know everything that is to be known, their business aptitude is marvellous. I refer, of course, to those who have initiated their own gigantic systems, and, with their own and other people's money, established these big concerns. I can speak personally of one of the largest. I know that every shop has its own qualified manager, that there is a "relief" staff of qualified men in case of illness or holidays, that all *dispensing* is done by qualified men, that all the shops are most completely equipped, that the drugs sold, selected, and prepared by and under the immediate direction of specially qualified men are in many cases greatly superior to those sold by ordinary chemists. I know one firm of chemists whose tinctures are mostly under proof, and whose "faking" is simply monstrous. I know one town where the "Society" could get convictions in shoals; but it is plain that is not what the "Society" cares to do against their own adherents. It does not *pay* (to put it on a low ground) the "Company Pharmacy" to "fake" and do contrary to law; it would be impossible, there are too many people about, too many "spies" on the watch; but no one watches the ordinary chemist, *he* may keep his "spirits of nitre" until the ethyl nitrite is almost a vanished quantity; but woe betide the store or company! The ordinary chemist may "improve" his "spermaceti or *simple* ointment" until it becomes "lard," but not so the Company.

Of course, what is said of "covering" is mostly nonsense. In *one* large shop may be *twenty* employees; I know three such, in different towns. There are two qualified men at the drug counter and two juniors; there is another qualified man in the dispensary; the remainder are lads, cashiers, and ladies at the various toilet and fancy counters; this is in a Company Pharmacy. Where is the "covering?" Does it require a qualified man to sell a comb or hair brush? What about the ordinary chemist's *apprentice*, who sells daily for his master "white precipitate" in penny packets and suchlike scheduled pennyworths? The ordinary chemist often "covers" a round dozen of juniors and apprentices, and breaks the law hourly.

As regards payment, your readers interested in their boys' future need pay little attention to the 90*l.* statement. The three qualified men above referred to share between them 600*l.* a year. I don't know one who makes less than 120*l.*, and commissions will often make this 140*l.*; the man is an idiot who takes less.

The drug trade is, no doubt, from a series of mischances, in a parlous state; there has been legislation, and examinations stiffer year by year, as if ours was a high-class profession, and we were all to be—well, dispensing chemists; the adjective is, for the most part, a farce.

The "poor chemist," it will be seen, has a lot to put up with, take it all round. It is as if a lad pays a premium and at great cost serves a long series of years with a firm of photographers, passes a stiff examination in chemistry, anatomy, and the higher branches of photography, then finds his work mostly confined to the *framing of pictures!*

But, after all, there is money in the drug trade yet. I mean, of course that branch of industry which is called the drug trade. As times go, the qualified chemist can get as good, or better, living as any one else; it is quite his own fault if he does not. But naturally, if he seldom has a chance of exercising his profession, it is only to be expected that he will forget things and get rusty: his botany and chemistry will, for the most part, "go by the board." All "medicos" are not clever by a very long way, and only a few know anything of pharmacy, although they think they do.

It must be easily understood why it is difficulties are often put in the way of sales of certain photographic chemicals. We are, for the most part, in dread of the bullying coroner, and when it comes to the point, and you are asked by a stranger for a little "bichloride," you don't care to risk it, although you may be pretty certain that his application is quite *bonâ fide*. It might suffice for the touring amateur to show a membership badge or card of his favourite society. It is a well-known fact that purchasers are often obstinately reticent when asking for these goods; they forget or do not know that the chemist must be certain of his customer, and then the "stranger" clause is difficult to get over. The purchaser *must be known* to the seller. It is a troublesome thing all round. My own rule is to stick closely to the Act, but make an offer of my dark room and chemicals, and very often this cuts the knot and leads to better business. Undoubtedly the *seller* ought to be protected; having done his duty laid down for him by law, any fatal result, by no means *his* fault, should not render him liable to abuse in open court. It is only fair to say coroners are not all alike in this matter, and I know for a fact that some of them, having ascertained by private inquiry that the sale has been in form and legal, do not trouble to call the vendor; they understand perfectly well that poisons *can* be procured in small quantities if not in large, not from one, but twenty different chemists.

One is almost forced to conclude that some remedy must be found for a state of things which threatens to become intolerable. Would a revival of the old "Assistants" examination and qualification do any good (providing larger numbers of trained men for the retailing of certain scheduled goods)? But really the assimilation of an assortment of scientific subjects does not give a man the most important acquirement in the vending of poisons—*discretion*. D. D.

PHOTOGRAPHIC COPYRIGHT IN NEW ZEALAND.

Mr. A. Martin, photographer, of Wanganui, New Zealand, kindly forwards us a copy of the Photographic Copyright Act, 1896, of New Zealand, which we append. It is entitled "An Act to Protect Certain Photographs."

"1. The short title of this Act is 'The Photographic Copyright Act, 1896.'

"2. The protection of the copyright law shall, in respect of photographs other than portraits of persons or of groups of persons, or photographs of any subject, for the taking of which valuable consideration has been given, apply in all respects as if such photographs had been duly registered and protected under such law in favour of the person or firm taking and producing such photographs, for a period of five years from the date of the first taking the same, if the word 'Protected,' followed by the name of the person or firm taking such photographs, and the true date of such taking, are made part of the original plate, and clearly appear in each reproduction thereof.

"3. Any person publishing any copy of such photograph without the authority of the person or firm protected under this Act shall be liable, on conviction, to a penalty, in respect of each copy so published without authority, not exceeding 20*s.*, and all copies so published without authority may be ordered to be destroyed. Proceedings under this section may be by way of summary procedure before any two Justices of the Peace.

"4. Any person who shall inscribe on the original plate, or publish on any reproduction thereof, the particulars intended to confer protection under the second section of this Act in respect of any portrait or photograph excepted from the protection conferred by that section, and also any person who shall in any way reproduce or publish the portrait of an individual or individuals, or a photograph for the taking of which valuable consideration has been given, without the authority in writing of the individual or individuals whose portrait or portraits have been taken, or from whom valuable consideration for photographs has been received, shall, on conviction, be liable to a penalty not exceeding 5*l.* for each offence."

SOME RECENT PHOTOGRAPHIC INVENTIONS.

[Croydon Camera Club.]

I propose taking three subjects this evening, in the following order: (1) Moving pictures upon a screen; (2) Printing by photography on both sides of the paper; (3) Röntgen rays. I shall first of all get through the demonstrations as briefly as possible, for, as you all know, there is enough in a part of any of the subjects to occupy months instead of an evening; but it is not my aim this evening to go very deeply into any of the subjects. I do not want to weary you with minute detail of what would be uninteresting at the present time; I want you to look at the three demonstrations in a very broad light, to let them suggest by themselves the possibilities of our very fascinating and instructive art—Photography; but, should we have time after the three subjects are finished to do some more demonstrations, it shall be from that one which most of you desire. If you prefer moving pictures upon a screen, I will run some more films through the lantern. If printing by photography on both sides of the paper, we can easily run another long band through the machine, and perhaps some of you could supply fresh negatives, so that you can see your own pictures printing and developed at a rapid rate. If it should be the Röntgen rays, then we can have a few more bands done, or any articles you may wish to try. I may say each subject is deeply interesting to me, and I shall be pleased to answer any question you might ask to the best of my ability.

We must remember that not one of us can have the absolute knowledge of any one subject; for instance, how could one explain a straight line if he had not a crooked one for contrast? The same with imagination. If we were to imagine all the world in this room, or, still further, all the suns, planets, stars, systems, there will be still something beyond, which imagination cannot grasp. This brings me to what I want to impress upon you. While the moving picture is upon the screen, and the printing of both sides of the paper is going on, also the shadows taken by the Röntgen rays, I want you just to have a wide hemisphere of thought and try to imagine the marvels of light, chemistry, and electricity going on between, that is to say, the light-impression upon the retina of the eye, conducted by the optic nerve to the brain, thereby leading to imagination and contrast; and, while the pictures are being developed, the latent image, the electrical energy of the developer, and a host of other chemical problems, also the marvels of electricity connected with the Röntgen rays; think of the vibrations of light of various kinds, ranging from 400 millions of millions per second, the rods and cones of the retina of the eye with half a million points within a square whose sides are only a tenth of an inch in length. There are various other matters connected with the perception of light which are of great importance to our well-being and to our enjoyment, which, of course, I will not venture to touch upon, especially the two eyes, which enable us to obtain a single vision notwithstanding that the two eyes are at work. I shall have a lot to say about this at some future demonstration, also that we can distinguish one light from another light by its colour, not by its intensity only; and we must not forget that present knowledge is only built on past experience,

therefore we must always recognise what is due to our worthy predecessors, and to others who are working at the present time to advance knowledge of any kind.

Very few know the difficulty and expense in perfecting new inventions, for what one throws away is enormous; it is like many who take photographs, they show us splendid negatives, but never say how many they have spoilt to obtain them. I think I can safely say that those who have, and those who are (and there are many in this room to-night) experimenting with apparatus for showing moving objects upon a screen, are not an exception to this rule; indeed, one would hardly think a simple apparatus like this would require the patience that it does, and yet, when you go into it and think, we can imagine why it does. First, to make the celluloid free from blemishes, that is no easy task, I can assure you, then coat it with rapid emulsion, also free from blemishes, perforating with extreme accuracy; then, to make the apparatus for taking the pictures at a rapid rate, say, twenty or thirty a second, to move the film intermittently forward exactly the same space each time, the stop for exposure, to move it on again, all this is necessary for a good set of negatives; then the developing the whole band (seventy to eighty feet) with more than 1000 pictures upon it, this must be done in one operation, for you want all the pictures to be equally good; then the printing the transpareney and developing, then adjusting the same to the projecting apparatus, and see that each picture pauses in front of the lantern aperture just sufficiently long to appear momentarily on the screen and in its proper place. As each picture differs slightly from the one preceding, you obtain the lifelike effects; usually, a shutter is used to cut off the light while the film is moving, because the film usually moves half and half during each intermittent motion; but, if you make the apparatus so that the film moves one-seventh and is stationary seven-eighths during the intermittent motion, no shutter is required, therefore you have *more light and no flicker*. Here is a point where theory helps practice to obtain the desired end, for we are aware that an impression depends on the rate of excitation propagated along the optic nerve. Taking advantage of this short period, we obtain the impression of continuous motion. Instantaneous photography gives us something akin to this; yet, if we look at one picture, the movement does not seem natural, but put a lot of them through the apparatus at a rapid rate and they appear true to nature, because it is the impression which is made up of different views rapidly presented during several minute intervals of time, whereas the ordinary snap-shot photograph gives only what takes place during one of these small intervals.

I may add that sight is eminently far in advance of all our senses, and now the unaided eye sees but little compared to the hidden world which lenses and photography have brought before us, one feels he would like to shake hands with Baptiste Porta, the inventor of the camera obscura, and others who have helped our knowledge in this direction since his time. No doubt, those who were ignorant as to how the camera obscura pictures was formed, thought it was formed by some magic art—hence the name of magic lanterns—and those who worked it magicians, who were supposed to have intercourse with evil spirits. Then there is the man who invented the zoetrope, or wheel of life; then there is Muybridge, and now we have Anschutz, Edison, Birt Acres, Lumière, Paul, and a host of others, and we must give all due praise for helping (not only those in our country, but those in other countries as well) to enhance pleasure to the community, and increase their liking for science.

Printing by Photography on both sides of the Paper.

The construction and operation of the machine is based upon the proper timing, relatively to each other, of the three movements; that is to say, the intermittent movement of the sensitised paper, the up-and-down movement of the pressing plates, and the movements of the shutters. The speed depends upon your light, your negatives, your sensitised paper, and of developer; of course, you can print by reflected light or direct light.

Röntgen Rays.

No doubt, this is one of the most important discoveries of the century. It is a new form of energy, and to discover that is no small matter. Could Wedgewood, Nicéphore Niépce, or Daguerre ever have imagined that the present-day development of photography was possible?

The probability is that all Röntgen rays are not alike, and whether the wave forms are transverse, longitudinal, or resemble the circular polarisation of light, there is, doubtless, among them a considerable range of frequency. We have much to learn yet, and still have to find a tube to give us perfect definition and intensity, and by that time some other marvel connected with it will be discovered.

W. Friese-Greene.

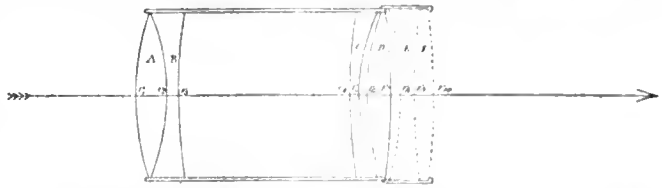
DALLMEYER'S IMPROVEMENTS IN PHOTOGRAPHIC LENSES: AN "ASTIGMATIC CORRECTOR."

Mr. T. R. Dallmeyer says:—

"In older types of lenses, especially portrait lenses, in which the character of the glasses employed necessitated a higher dispersive power to accompany a higher refractive index (a condition no longer necessarily existing since the invention of the Jena glasses), flatness of field always involved astigmatic aberration; or, if the astigmatic error was practically eliminated, the curvature of field was considerable. The construction of the best forms of the older types has been the most skilful compromise between these errors.

"The object of this invention is to remedy this defect by an astigmatic corrector, which eliminates the residual errors (of astigmatism and curvature of field) of the older forms of positive lenses, largely increasing their covering power at the expense of an inconsiderable lengthening of the focus.

"For this purpose I place behind any particular form of the old types of lenses, after having determined the residual errors referred to, my astigmatic corrector, which is calculated to eliminate these errors. The



form necessary to do this in the case of Petzval's construction consists of a negative combination consisting of a double concave lens, cemented to a double convex lens of greater dispersive material and higher refractive index.

"This reversal of material applies in every case, but the shapes of the lenses may be varied for some of the older types of lenses.

"The drawing shows my invention applied to the well-known Petzval lens made up of four lenses—A, B, C, and D.

"The lenses, E and F, shown in dotted lines, form my astigmatic corrector.

"The radii of curvature of the lenses are as follows:—

$r^1 = 4{\cdot}725$ inches $r^2 = 3{\cdot}735$,, $r^3 = 31{\cdot}5$,,	A and B
$r^4 = 9{\cdot}85$,, $r^5 = 3{\cdot}405$,,	C
$r^6 = 4{\cdot}25$,, $r^7 = 13{\cdot}155$,,	D
$r^8 = 6{\cdot}95$,, $r^9 = 8{\cdot}85$,, $r^{10} = 27{\cdot}5$,,	E and F

"The indices of refraction are:—

	μ for D line	μ for H γ line
A	1·5151	1·5267
B	1·5738	1·5919
C	1 5738	1·5919
D	1·5179	1·5288
E	1·5179	1·5288
F	1·5738	1·5919

"The claims are:—

"1. The combination with the older forms of positive lenses of a negative compound lens, consisting of a negative lens and a positive lens of greater dispersive material and higher refractive index.

"2. The combination with the older forms of positive lenses of a negative compound lens consisting of a double-concave lens, and a lens of greater dispersive material and higher refractive index."

THE "AUTO" ACETYLENE GAS-GENERATOR.

The Scottish Acetylene Gas Co., Glasgow.

The chief advantages claimed for this, the latest form of apparatus for generating acetylene for photographic illumination purposes, are that the gas is cooled in the generator itself, and is therefore delivered into the gas-holder *quite dry* and ready for use; there is thus no trouble by the pipes choking with condensed moisture. There is ample storage capacity, and no gas is lost. The supply of gas is regulated to a *nicety* by the automatic regulator, exactly in proportion to the quantity of gas consumed. The supply of gas and light can be kept up continuously, as the generator can be recharged while the lights are burning. There is no danger, as the pressure in no part of the machine ever exceeds four inches of water. The method of using the Auto generator may be understood from the following directions:—

The generator is packed inside the gas-holder. Fix the generator on to the cocks on the bottom of the container by the screwed couplings, and see that the catch at the bottom of generator faces out. Place the gas-holder in the container and ship the guide rods into their sockets. The regulating rod must be pushed up through the eye on regulating lever and secured to the bracket on top of gas-holder by the nut. Fill the container with water till it is just level with the top of gas-holder when

quite down. Fill the water jacket. Fill seal can up to the inside with water. Shut all cocks. Place the charge of carbide, broken to about the size of a hazel nut, in the carbide box, and push it up into generator, securing it by a turn to the right. Lift up seal can and hook it on. Open the middle cock. Unhook the regulating lever and press it down. The machine will now make gas and regulate itself. When the charge of carbide is exhausted, the machine may be recharged as at first, taking care to shut the middle cock, and hook up the regulating lever. Should the machine be left set up at any time, hook up the lever till it is again wanted for use. To adjust the regulator, should the machine not be making gas fast enough, bend the spring on end of regulating lever inwards a little; if too much gas is being made, bend the spring outwards a little.

We have inspected the Auto generator, and it appears to us well adapted for projection and illuminating purposes in photography. The separation of the generator from the gas-holder, and the advantage of being able to recharge while the gas is being consumed are two of the strongest points in its favour. The Auto has been well thought out, is simple to use, and should be appreciated by those adopting the new illuminant.

THE LATE R. KENNETT.

One of the band of workers to whom modern gelatine dry-plate photography is so much indebted has passed away in the person of Mr. R. Kennett, who died on Friday, December 4, aged 79. For many years past Mr. Kennett had not taken any active part in photographic matters, and latterly had been in failing health, but at one time, through the medium of Kennett's pellicle and plates, his was a prominent personality in the photographic world.

It was in the year 1874, when the gelatino-bromide process was in the experimental stage, that Mr. Kennett, on June 9, read a paper before the London Photographic Society, in which he fully described his mode of preparing gelatino-bromide pellicle, from which we make the following abstract:—

"One pound of Nelson's gelatine is placed in a porcelain dish with one hundred ounces of distilled water, and after soaking for three hours is dissolved by heat. While still hot, eight and a quarter ounces of bromide of potassium are thoroughly incorporated with the gelatine, and afterwards eleven and a quarter ounces of silver nitrate (dissolved in a small quantity of water) are added and well mixed. Directions were then given for the subsequent treatment of the emulsion for the removal of the excess of bromide and the decomposition salts. This Mr. Kennett effected by pouring the emulsion into a dish to the depth of about a quarter of an inch, and, after allowing it to set, washing it in several changes of water or in a continuous stream. The emulsion was then ready to be redissolved and used at once for coating plates, if only a small quantity had been prepared. If, however, a large quantity had been made for stock, the emulsion was placed in dishes and evaporated to the consistency of thick paste, and, after being allowed to cool, the drying was completed on suitable frames. When dry, it could be cut up into convenient pieces for storage."

This latter operation was the portion of the process which formed the subject of Mr. Kennett's patent, now lapsed. There can be very little doubt that to Mr. Kennett's energy in thus bringing gelatino-bromide pellicle before the public in a practical and easily obtainable form, much of the subsequent success of the process was due; for, up to this period (1874), the number of those who had ventured into original research in this direction might be numbered easily upon the fingers.

Mr. Kennett leaves two sons and a widow, but it will, we are sure, be known with regret that the deceased gentleman did not die in affluent circumstances.

The Inquirer.

Action of Salt.—Cum Grano writes: "A friend of mine makes a practice of placing his negatives in a bath of common salt between development, and fixing for the purpose, as he says, of removing stain and preventing frilling. In fact, he claims that this bath plays the same part as alum without the disadvantages of the latter. Is this correct?"

Sulphite of Soda.—J. B. asks: "Is there any advantage in the use of sulphite of soda in the developer for collodion emulsion beyond that of preserving the pyro solutions? I have been told that it has an effect upon the colour of the image, but, so far as I can ascertain, such is not the case to any extent. Have the bisulphites or metabisulphite of potash any different action?"

Quicklime.—J. Hastings writes: "I have some quicklime that has been kept for two or three years in a stoppered bottle, and presents the appearance of powdery cubes that are easily crumbled to dust, whereas originally they were firm and hard. also, when moistened, they give off very little heat and undergo little or no change. Am I right in assuming that such a sample is useless for purposes where lime or its hydrate are required; as for instance, in rendering carbonate of soda caustic? I have great difficulty in obtaining small quantities of out-of-the-way chemicals, of which quicklime appears to be one. Is there any reliable way of keeping it in the 'quick' condition?"

News and Notes.

Vevers' Second-hand List.—Mr. C. C. Vevers, of 163, Briggate, Leeds, forwards us his price-list of second-hand photographic and lantern apparatus, shop-soiled stock, &c. It contains numerous bargains. Seekers after such should obtain the list.

Royal Photographic Society.—Photo-mechanical Meeting, Tuesday, December 15, at eight p.m., at 12, Hanover-square, W. *Some Probable Causes of Trouble in Photo-engraving*, with demonstration of methods for their detection, by Mr. Andrew Wybrandt-Penrose.

A correspondent writes: "It may interest you to learn that acetylene, or rather carbide of calcium, has been tried as an agricultural insecticide with alleged success. A vine-grower near Lerida, in Spain, has experimented with this substance against the *phylloxera*, which has proved such a scourge to wine-growing lands. He states that the vines so treated now show no signs of the pest, and are in a specially flourishing and healthy state."

Glasgow "Evening Times" Camera Club.—The winter Exhibition of this Club will be held in the rooms at 46, Gordon-street, Glasgow. The Exhibition will open on Monday, February 1, and remain open until Saturday, February 27, 1897. The Judges are Messrs. William Crooke, George Mason, and Francis H. Newbery. Communications respecting the Exhibition should be addressed to the Secretaries, *Evening Times* Camera Club, 46, Gordon-street, Glasgow.

"The Practical Photographer."—Commencing with its January issue, our contemporary will introduce several new features. A list of well-known contributors, pictorial and literary, is published, and it is proposed month by month to give examples of the various printing processes. "Peeps at Professional Photographers," "The Critic in the Studio and in the Field," "Lantern Lectures," and subject numbers, devoted mainly to special subjects, are among the new departures contemplated. By adopting this policy, the Editor hopes to clash with no existing publications.

South London Photographic Society.—The Eighth Annual Exhibition of this Society will be held at the Public Baths, Church-street, Camberwell, S.E., on Saturday, Monday, Tuesday, Wednesday, Thursday, Friday, and Saturday, March 6, 8, 9, 10, 11, 12, and 13, 1897. The following are the Open Classes:—J, Pictures which have previously received an award; K, Pictures not previously medalled; L, Lantern slides which have previously received an award (sets of six); M, Lantern slides not previously medalled (sets of six); N, Photo-micrographs and other scientific subjects; O, Stereoscopic slides not previously medalled (sets of four). The Society's medals will also be awarded for the best trade exhibit, and for the most useful novelty in photographic apparatus. Entry forms and further information respecting the Exhibition can be obtained from Mr. Charles H. Oakden (Hon. Secretary), 30, Henslowe-road, East Dulwich, S.E.

An Acetylene Explosion.—A young man named Ernest Munro Field, eighteen years of age, son of Mr. A. Field, High-street, Olney, met with his death on Wednesday, December 2, under painful circumstances. The young man had always evinced a great interest in mechanics and engineering, and has of late been experimenting with the manufacture of acetylene gas in a generator of his own manufacture, to which a pipe and burner were attached. He attended a drawing class on Wednesday evening, returning home about 8.30. There was no one at home when he returned, his father and mother being at a meeting. It is supposed that on entering the house he immediately proceeded to the cellar where the generator was, and struck a match, an explosion following, which threw him to the ground and rendered him unconscious, and, no aid being at hand, he was suffocated by the gas. On the return of his parents, no notice was taken of his non-appearance, as he often sat up till late, either at home or with some friends in the pursuit of their hobbies. Mr. and Mrs. Field went to bed, but, as he did not hear his son return, Mr. Field arose about twelve o'clock and went round the house, when he was shocked by finding his son lying dead in the cellar. The doctor was at once sent for, but pronounced life extinct.

ROYAL INSTITUTION.—The following are the lecture arrangements before Easter:—Professor Silvanus P. Thompson, six lectures (adapted to a juvenile auditory) on *Light, Visible and Invisible;* Professor Augustus D. Waller, twelve lectures on *Animal Electricity;* Professor Henry A. Miers, three lectures on *Some Secrets of Crystals;* Dr. J. W. Gregory, three lectures on *The Problems of Arctic Geology;* Professor Percy Gardner, three lectures on *Greek History and Extant Monuments;* Professor W. Boyd Dawkins, three lectures on *The Relation of Geology to History;* Mr. Carl Armbruster, three lectures on *Neglected Italian and French Composers;* Mr. Walter Frewen Lord, three lectures on *The Growth of the Mediterranean Route to the East;* and the Right Hon. Lord Rayleigh, six lectures on *Electricity and Electrical Vibrations.* The Friday evening meeting will begin on January 22, when a discourse will be given by Professor Dewar. Succeeding discourses will probably be given by the Right Rev. the Lord Bishop of London, Professor Jagadis Chunder Bose, Professor John Milne, Dr. G. Johnstone Stoney, Lieut.-Colonel C. R. Conder, R.E., Mr. Shelford Bidwell, Professor Arthur Smithells, Sir Edward Maunde Thompson, Sir William Turner, Mr. Charles T. Heycock, the Right Hon. Lord Rayleigh, and other gentlemen.

EXAMINATION OF CATHODE AND RÖNTGEN X RAYS THROUGH COLOURED SCREENS BY THE FLUOROSCOPE.—Mr. J. Carbutt, the well-known plate maker of Wayne Junction, Philadelphia, sends us the following notes on this subject:—I. The cathode rays in an excited Crookes' tube, viewed through a pale yellow screen, show increased brightness of the yellow rays. 2. Viewed through a dark violet screen, the cathode rays present a phosphorescent glow, similar to that in a low-volt lamp when held in the field of an induction coil. 3. Viewed through a green screen, the cathode rays present to the eye a light emerald-green. 4. Viewed through a dark red screen, the cathode rays present a pale red on the carmine tint. The screens are of thin, polished plate glass, 1½ mm. thick, coated with gelatine, coloured with aniline dyes such as I use in making my photochromic screens. Examination of Röntgen rays through plain glass and the afore-mentioned screens shows that both cut off or absorb fully fifty per cent. of the Röntgen rays from reaching the screen of the fluoroscope. Screens of the following colours were placed side by side with the clear glass, viz., dark violet, green, light yellow, and dark red, and when in juxtaposition it was impossible to recognise which was clear glass and which was coloured, and the eye was unable to detect any colour sensation when looking through the fluoroscope with the coloured screens in close contact. These experiments confirm me in the opinion I have held from my first dealing with the Röntgen X rays, that they are of the ultra-violet, because I find they absorb the entire spectrum, while a deep violet screen absorbs all but the red. It was early determined by Professor Röntgen that the X rays could neither be deflected nor refracted, and I am not aware of any experiments having been made to determine the absorptive powers by the X rays of the colours of the spectrum.

KEEPING PROPERTIES OF NEGATIVE BROMIDE PAPER.—Colonel Waterhouse, in the *Journal of the Photographic Society of India*, says: "When going to Europe, in March, 1886, I took with me supplies of negative paper for use in a roll-holder, and in the dark slides. A few pieces of the latter were exposed a Aden, and developed some few weeks afterward at Venice, giving very good negatives. A fresh supply of the paper was received at Suez, and a large number of negatives were taken in Egypt on it, and the paper in rolls. At Venice also a large number of exposures were made on paper, and a few developed, which turned out quite well. Further exposures were made in Austria and Switzerland, but, as I had no time to develop them in England, I brought them all back to Calcutta in November, and began developing shortly afterwards. It was then found almost impossible to bring out the images on any of the papers even with strong developers; they all seemed very much under-exposed, and on some there were only traces of an image. Thus a large number of very interesting negatives were lost, though, fortunately, many of these latter in Egypt and Venice were more or less duplicates of glass negatives which were developed in Venice satisfactorily. There is no doubt that the keeping of the paper and the action of the air on both sides of the sensitive surface had destroyed the image. I believe that Colonel St. G. Gore, R.E., had a similar experience with paper negatives which had been kept for some time before being developed. The bromide negative paper was also tried in the Surveyor-General's Office for half-tone negatives, and successfully, but it was found that, in printing on ordinary albumenised paper, the negatives soon became very badly stained and useless. This could be easily avoided by the use of bromide paper, or any kind of printing paper prepared without an excess of silver nitrate or other salt likely to deliquesce and cause stains. At the same time, I do not recollect this staining being a marked feature of working with the old wax paper and calotype paper negatives, though my experiences with them were always in the dry climate of the N.W. Provinces and Central India. Paper is certainly very convenient and cheap in comparison with celluloid films or glass plates, and has its own advantages over both. If care be taken to develop soon after exposure, excellent results can be obtained, and if the emulsion be spread upon a suitable paper, and the negative properly waxed after finishing, the grain shows very little. Nevertheless, it would seem as if paper negatives must have some radical defect (no doubt the grain) which prevents them making their way in practice, and it is doubtful whether they will ever supersede celluloid or glass."

PHOTOGRAPHIC EXHIBITION AT AINTREE.—Since their first Annual Exhibition, three years ago, in the Walton Institute, the Aintree Photographic Society, like the district, has increased and developed remarkably. The new Aintree Institute has provided the members of the Society with most convenient headquarters, and the organization, under the direction of experienced gentlemen, promises to grow still further in popularity. The Third Annual Exhibition, opened last Friday, December 4, in the Institute, showed a wonderful advance on its predecessors from all points of view. There was a much bigger display of photographic work, and an admirable collection of paintings and specimens of brass work, wood-carving, embroidery, and other things comprised under the general head of home arts and industries. The total number of exhibits was between 600 and 700, being about three times more numerous than that of last year. The competition open to professional photographers was a feature of the Exhibition, and comprised specimens of the work of men of high reputation in the country. Indeed, the quality was of such a class that the Judges were impelled to award an extra silver medal. The open amateur classes also drew competitors from all over the country, and it is pleasing to note that the first-prize winner in one class is a member of the Aintree Society. The Exhibition was formally opened by Mr. Charles Dyall (Curator, Walker Art Gallery), who congratulated the Society upon their success, and referred particularly to the merit of the *repoussé* work and wood-carving specimens exhibited. During Friday evening a string orchestra from the Walton Musical Society gave a performance, and the prize lantern slides were displayed by the Lanternist (Mr. George A. Ashley). The honorary officials of the Society, particularly Mr. C. H. Adkins (President) and Mr. D. J. Neill (Secretary), deserve credit for the commendable manner in which the Exhibition has been arranged. The Judges in the Photographic Section were Messrs. T. F. Lloyd and F. Anyon, and their awards were as follows:—Six prints under half-plate (members): silver medal, William Lockier, Aintree; certificate, C. H. Adkins, Aintree. Six lantern slides (members): silver medal, William Lockier, Aintree; bronze, G. H. Jacksons Walton; certificate, C. H. Adkins, Aintree. Landscapes, four prints (amateur): silver medal, Hugo Meynell, Cheadle; bronze, W. Smedley Aston, Birmingham; certificate, Llew. Morgan, M.D., Liverpool. Hand camera, six prints (amateurs): silver medal, C. F. Inston, Liverpool; bronze, J. Kearney, jun., Liverpool; certificate, E. E. Barron, London. Enlargements (two prints (amateurs): silver medal, W. Smedley Aston, Birmingham; bronze, E. Sinnett, Liverpool. Lantern slides (amateurs): silver medal, Edgar R. Bull, London; bronze, Harry Holt, Liverpool; certificate, William Harvey, Egremont. Figure studies and portraiture (professional): silver medal, G. Layfayette, Glasgow; extra silver medal, W. J. Auckorn, Arbroath; bronze, W. M. Harrison, Falmouth; certificate, W. H. Pugh, Liverpool.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK

December.	Name of Society.	Subject.
14	Bradford	*The Composition of a Picture.* H. J. Dobson, R.S.W.
14	Ealing	*Development.* H. W. Peal.
14	North Middlesex	*Pictorial Photography.* Horsley Hinton.
14	Richmond	*Making a Lantern Slide.* C. H. Davis.
15	Birmingham Photo. Society	*The Intensification and Reduction of Negatives, with Practical Hints in the After-treatment of Negatives.* Thomas Bolas, F.C.S., F.I.C.
15	Brixton and Clapham	Lantern Evening.
15	Gospel Oak	Copying and Isochromatic Work.
15	Hackney	*Practical Pictorial Photography.* A. Horsley Hinton.
15	Isle of Thanet	*Development.* A. D. Sackett.
15	Leeds Photo. Society	*Lantern Slides.* Godfrey Bingley.
15	Lewisham	Lantern-slide Making.
15	Munster	Demonstration on Acetylene Gas. K. B. Williams.—Members' Lantern Slides.
15	Newcastle-on-Tyne	*Enlarged Negatives.* J. Brown and W. Thompson.
15	Royal Photographic Society	*Some Probable Causes of Trouble in Photo-engraving.* Andrew Wybrandt-Penrose.
16	Borough Polytechnic	*At Home Subjects.* W. Thomas, F.R.P.S.
16	Croydon Camera Club	Lantern Night.
16	Halifax Camera Club	Members' Lantern Evening.
16	Leeds Camera Club	*Collotype Printing.* W. J. Wilkinson.
16	Leytonstone	*Photography as Applied to Mediæval Architecture.* F. Clarke.
16	Photographic Club	*A Chat about Lenses.* T. R. Dallmeyer.
17	Darwen	*Lantern-slide Making and Toning.* S. Mitchell.
17	Leigh	Competition: City Scenes.
17	Liverpool Amateur	*The Optical Lantern, and How to Use it.* P. H. Phillips and Walter Archer.
17	London and Provincial	T. Bedding.
17	Oldham	*How to Make a Dry Plate.* J. Hall.
17	Putney	*Enlarging by Artificial Light.* C. H. Davis.
17	West Surrey	Designs Competition decided.
17	Woodford	Travellers' Night. F. G. Emler.
18	Croydon Microscopical	Lantern Evening, Members' Slides.
18	Nottingham	*Intensification and Reduction of Negatives.* Thomas Bolas, F.C.S., F.I.C.
18	Oldham	Annual Dinner.
18	West London	Members' Lantern Night.
18	Wolverhampton	Prize Slides.
19	Ashton-under-Lyne	*Flower Photography at Home.* Samuel A. Platt.

ROYAL PHOTOGRAPHIC SOCIETY.

DECEMBER 8,—Ordinary Meeting,—Mr. John Spiller in the chair.

AFFILIATION.

The HON. SECRETARY announced that the Chiswick Camera Club and the Gainsborough District Camera Club had been admitted to affiliation.

RESIGNATION OF THE PRESIDENT AND HON. SECRETARY.

The CHAIRMAN announced that Captain W. de W. Abney, the President, and Mr. H. Chapman Jones, the Hon. Secretary, had tendered their resignations of their respective offices, and that the Council had, with regret, accepted the resignations. It was also stated that, in order to fill the

vacancies thus created, the Council had elected the Right Hon. the Earl of Crawford, K.T., as President of the Society, and Mr. F. P. Cembrano as Hon. Secretary, subject to those gentlemen consenting to act, and that Mr. Chapman Jones had been elected a member of the Council, in the place of the late Mr. William England.

A hearty vote of thanks was accorded to the retiring President and Hon. Secretary for their valuable services to the Society during their period of office.

ELECTION OF AUDITORS.

Mr. Leslie E. Clift and Mr. Peal were unanimously elected Auditors of the accounts of the Society for the current year.

DR. SELLE'S COLOUR PHOTOGRAPHY.

The HON. SECRETARY read a paper, adapted by Mr. R. B. Roxby from a communication by Dr. Neuhaus, on *Dr. Selle's Process of Photography in Natural Colours*. The paper commenced by summarising the methods of Becquerel and Lippmann, both of which were regarded by the author as unsatisfactory, the latter being said to bear the same relation to colour photography as the Daguerreotype bore to photography proper. A practical solution of the problem of photography in colours by direct means might not be an impossible ideal; but, for some time to come at any rate, indirect or positive processes must be looked to for a solution of the problem, and all endeavours in this direction had been founded on the Young-Helmholtz theory. Amongst the various abortive systems founded on this theory, the most notable was that of Ducos du Hauron, who, in 1878, prepared papers covered respectively with yellow, blue, and red sensitive gelatine, and, when such papers were exposed, the gelatine was rendered more or less insoluble, according to the greater or lesser degree of transpareucy of the negative, and, the soluble parts being washed out by water, the three "stencils" thus obtained were superposed and produced a picture in colours. This method, however was of no practical value, and the difficulties encountered led to the developments of Vogel, Ullrich, Albert, Joly, Macdonough, Anderson, &c., but neither of these systems could truly be called "photography in natural colours." Dr. Selle, like his predecessors—with the solitary exception of M. Lippman—took his departure from the theory of Young-Helmholtz, and argued that an exact reproduction of any given object must be obtained if from a white surface, absorbing no light, there were extracted equal quantities of red, blue, and green in the manner in which the object *in naturâ* extracted them from daylight. Therefore, if impressions of a subject were taken by means of three plates, each sensitive to one of the three primary colours, three images would result, which when coloured with their complementary colours and superposed, would produce a picture in natural colours. Dr. Selle used a blue-violet, a green, and a red filter for taking the negatives, from which he made positives on chromated gelatine, each being developed in a bath containing a solution of a colour complementary to that represented by the negatives; the positives were superposed when dry, and a picture in colours was produced. The exposure for the negatives was under ten seconds, and it was hoped that within a few weeks it would be possible to give instantaneous exposures. The method had been very successfully applied to colour-printing, either by heliography, lithography, or letterpress, and excellent results in these directions had been obtained by Mr. Feisch, a Berlin lithographer. Hypercritics might say that Dr. Selle's invention was not new; but, admitting that he had not discovered a new principle, that he had levied tribute on previous researches, and that he had profited by the experience of predecessors, Dr. Neuhaus thought it could not be denied that the process was in the main original, that what had hitherto been only a possibility had been turned into an accomplished fact, and that the problem had been solved in a manner so simple as to render colour photography as easy as ordinary photography.

Several specimens of work by Dr. Selle's method were shown, including lantern slides, positives on paper, and prints by three-colour photo-mechanical processes.

A very brief discussion followed the reading of the paper, a few remarks being made by Mr. H. Snowden Ward, Mr. W. E. Debenham, and Mr. J. J. Vesey, and

Mr. E. J. WALL remarked that the author of the paper had "muzzled" everyhody by declaring that any one who differed from the views put forward in the paper must be hypercritical. So far as he could see, Dr. Selle had discovered nothing new; and, in some instances at least, he could not regard the colours of the specimens as in any way true to uature.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

DECEMBER 3,—Mr. H. Snowden Ward in the chair.

Mr. R. Beckett showed some examples of an application of the collotype process to the photographic decoration of Christmas and other presentation cards, produced by his son, Mr. S. J. Beckett. He also passed round some plates coated with a backing made after Mr. Haddon's process. He described it as a backing that will dry and not become tacky, and spoke very highly of it.

Mr. Bayston showed the result of an attempt at making his own carbon tissue, with the idea of developing from the front. The paper was coated with a preparation of gelatine, some water-colour paint as pigment, and bichromate, and printed by gaslight. Development was effected from the front, yielding a very presentable picture.

Mr. W. J. MACKENZIE exhibited and described a new acetylene gas generator, made by the Scottish Acetylene Gas Company, of Glasgow. It was constructed with the principal view of being able to recharge without the necessity of extinguishing the light; next with a provision for the purity of the gas from the first; and, thirdly, to supply a machine which would not become heated by use; and the apparatus, it was stated, fulfilled all these conditions. The generation of the gas was brought about by water being allowed to drip upon the carbide of calcium, an automatic connexion controlling the water supply and thereby the generation, according to the quantity in the reservoir.

A discussion ensued as to the relative proportions of acetylene and air, and other conditions requisite to cause an explosion.

Mr. E. J. WALL then addressed the meeting on

COLOUR SCREENS.

Mr. Wall commenced by throwing upon the screen a beam of white light from the lantern, which by means of a prism he split up into the spectrum. He proceeded to show the action of a number of coloured screens, or filters, upon this spectrum, taking first those of commerce. Having pointed out the range of the spectrum, he said the sensitiveness of an ordinary plate lay principally in the blue and violet, but by dyeing the plate or staining the bromide of silver with some chemical we can increase the sensitiveness of the bromide of silver to the less refrangible rays; but at the same time the sensitiveness of the silver salt to the blue and violet was so great, that it was necessary to use one of the numerous colour screens to get a proper rendering of the colours of which the object is composed. He placed the lightest tint of one of the commercial screens in the path of the rays, when the violet practically disappeared; the second tint exercised the same effect, but in a stronger degree; and the third, again, cut it out still more; while the darkest of all cut out more than any of the others. The next screen, a light one, cut out very little, but at the same time was used with very good effect. All these were of a yellow colour. The next screen, which was green, curtailed the spectrum at both ends. He mentioned a screen prepared with aurantia and collodion, which cuts down the violet fairly strongly, and was much recommended, and also passed round some made in a hurry from lantern plates, fixed and washed, and then dyed, of various grades of tint. For three-colour work he used filters of different depths, and showed the part played by these upon the spectrum. A red filter was shown to cut out the whole of the spectrum but the red; a green, to cut out the majority of the red and some of the violet and blue; and a violet, which should cut out green and yellow, leaving blue and violet unaffected, and a little of the red. The sole action, then, of these screens in this work was to cut out certain colours which were not required to act. The commercial yellow screens are probably made by taking glass and stirring it with a piece of wood. The glass in a liquid state dissolves or chars some of the wood, and probably some chemical compound of carbon was formed, resulting in a dark colour in the glass, which had no other effect than that of increasing the exposure, and, if one could get pure yellow, it was quite as effective as the ordinary commercial screen, and did not appreciably increase the exposure on the other hand. In orthochromatising a plate, the sensitiveness of the plate to yellow may be increased, leaving it normal to the blue and violet. There is a difficulty with green, which is that there are very few dyes which will sensitise for this colour. Yellow, orange, and red are not so difficult to manage, but for green there are but one or two suitable agents. He mentioned a series of negatives of varying exposures on orthochromatic plates, with and without a screen, which he had shown some time ago, and it was in the longer exposures only that the greens acted anything like properly, being represented very badly in the shorter ones. Screens were not difficult to prepare. He preferred collodion, with sufficient of the dye to make a saturated solution, or rather one that just fell short of the crystallising-out stage. It was very difficult to state exactly the proportions which would fulfil this condition, it depended greatly on the dye itself and the maker of the dye. Dyes varied considerably, and he had found many foreign substances in them which, no doubt, might have their use if the dye were used for what it was intended, but they were not wanted in screen-making. Brilliant yellow was good, and naphthol yellow was one he used for pale screens, which, however, had quite as much action as the deep orange ones. Orange in a screen was a mistake, as this colour cut out the green. With reference to green screens, if it were desired to photograph the red, a green screen was a mistake. It was very difficult to sensitise for red, and, if green were used, some of it was cut out, and things made worse than before; and therefore it was false that, by using green screens in connexion with orthochromatic plates, a correct colour rendering could be obtained. Ives recommends multiple yellow for colour screens, as it cuts out the ultra-violet, but he (Mr. Wall) had found that no yellow cut out the ultra-violet completely, and in his opinion it did not matter if one did have ultra-violet coming through the screen. With orthochromatic plates a very pale screen is advisable for ordinary work, and it will not greatly increase the exposure. When you come to special work, the depth of screen can be increased, and any effect obtained you want. In photographing flowers, it was very rarely necessary to use a screen. In the case of yellow and blue flowers, you would over-correct; the blues would be made too dark and the yellows too light. With pictures, however, it was almost essential to use screens. A pastel required a lighter screen than a water colour, and this a lighter one than an oil colour, and with some of the old masters, where you get blue and deep browns (which are simply reds with a lot of black in them), a very deep screen indeed must be used. The best way to copy an oil painting was to use two screens—a very deep yellow, with which a fairly long exposure is given, and a lighter one to finish with. He would say that it was absurd to state that with a yellow screen and an ordinary plate one could get a correct colour rendering. Matters were made worse by using a yellow screen on an ordinary plate unless one were prepared to give an exposure which was practically out of the question.

Mr. PAUL MARTIN asked if optically worked glass should be used for screens.

Mr. WALL replied that it all depended on the work to be done. For general landscape work, where diffusion of focus was an advantage, it did not matter, but there were cases where it was undesirable. Of course, the glass may not be parallel in its sides; and, again, curved glass would act as a lens. It was best to focus with the screen in position. In three-colour work, if the lens were imperfectly achromatised, the focus with the different colour screens would be quite at variance one with another. For landscape work the screen should be either behind the lens or between the combinations, but must not be placed in front.

Borough Polytechnic Photographic Society.—December 2, Mr. W. C. CORNFORD, the Hon. Secretary, read a paper on

PAPER NEGATIVES,

describing an almost new negative paper placed on the market by Messrs. Wellington & Ward, Elstree. In the course of his remarks he explained that the only difference between it and the ordinary dry plate was, that the gelatine film was supported on paper, in the place of glass, and that it was practically unbreakable, a very great advantage, thereby obviating the trouble and annoyance of broken negatives, that has perhaps been very difficult to procure. A great benefit is also gained by lightness as compared to glass. He also explained what a great advantage it was to carbon printers, as it can be printed from either side, thereby saving a double transfer; it is also far superior to glass negatives for enlarging, &c., as it can be affixed to the enlarging board much easier. There was also another advantage that proved it to be a long way ahead of glass plates, and that was that it was absolutely halation proof, and thus the trouble and inconvenience of backing plates was overcome. Mr. Cornford then went on to explain how it was possible to greatly improve faulty negatives by working with a pencil on the back of the paper. By this method it was by no means a difficult matter for even a novice to tone down those parts of a negative that have a tendency to print too quickly. The paper is only made in one speed at present, *i.e.*, rapid, and the best results are obtained by a full exposure and full development. Some specimen negatives and prints therefrom were then passed round for inspection, and, after ably answering a few questions that were put to him, Mr. Cornford distributed among the members samples of the paper which had been sent by Messrs. Wellington & Ward; and, judging from the favourable manner in which Mr. Cornford's remarks were received, negative papers should have a big future before it.

Brixton and Clapham Camera Club.—December 1, Mr. J. W. Coade in the chair.—A lecture on *Enlarging*, by Mr. J. A. Hodges, F.R.P.S., was read by Mr. F. W. LEVATT, and very well received, the after-discussion being also of an interesting nature. Sample packets of B. J. Edwards & Company's lantern plates were given to such members as promised to use them and show results at next meeting. Prints intended for members' quarterly competition must be to hand by the 15th inst. The subject is optional, but the work must be done on bromide paper, a bronze medal being given for the best results.

Croydon Camera Club.—December 2.—Mr. FRIESE-GREENE, assisted by Professor Braham and Messrs. Johnston and Nichols, gave a series of demonstrations, accompanied by a display of apparatus invented by himself. Begining with animated photographs, he described and showed various models of cameras which he had successively invented, and similarly treated of the lantern apparatus used for projecting the moving image upon the screen. A striking point was made by displaying on the lantern screen two views of the Lord Mayor's Show. The first was projected from an ancient and primitive magic lantern over a hundred years old. The pictures or slides, which were hand drawn and coloured, and which were most quaint and curious, were, it was stated, about a hundred and fifty years old. Immediately after the above, a moving photographic presentment was, by means of a new lantern, thrown on to the screen, depicting the 1896 Lord Mayor's Show, with all the figures, &c., moving in a wonderfully lifelike manner. The waiting flunkeys, the soldiery and police, the seething and expectant crowd, all were there. Then was seen the Lord Mayor's coach approaching. It drew up, the flunkeys formed up in two lines, the mace-bearer and sword-bearer alight, and pass by; finally the Lord Mayor himself is beheld striding along in his weighty robes. At this point the prolonged applause testified to the audience's deep delight. The above, it should be said, was taken by Messrs. Wrench & Sons, following which was a captivating scene depicting Van Biene in *The Broken Melody*, by Esmé Collins. An Edison film, *Buffalo Bill*, was also put through. Perhaps the finest and most perfect effects were the sea views. The one showing rough waves breaking against a sea wall was singularly lifelike, flicker and false register being notably insignificant. *A Tub Race* (in the sea) was also technically good, and also had the further merit of causing roars of laughter. The lecturer proceeded to explain how, under the auspices of Sir George Newnes, he had brought to a high state of perfection machinery for setting up and photographing type, and for printing illustrations upon both sides of photo-sensitive paper at a high rate of speed and a low rate of cost. The sensitised paper could be produced, by the lecturer's method, at as low as threepence per pound, cabinet-size prints costing, for sensitised paper, twenty-four for one penny. Mr. Friese-Greene proceeded to print, develop, and fix, by means of a small model of his full-sized machine, a long band of bromide prints, with a picture upon each side. In response to a query of one of the members, Mr. Greene also printed a similar band of paper, using two negatives which Mr. G. W. Jenkins, a member of the Club, provided. Although Mr. Greene had never, until the moment of putting them into his machine, seen the above, he had no difficulty in running a long series of prints from Mr. Jenkins's negatives, probably of better technical quality than nineteen people out of twenty can get using the greatest individual care with each print. Mr. Friese-Greene next took up the Röntgen-ray subject. He began by intimating his intention of attempting a snap-shot, which he proceeded to accomplish, developing the plate before the audience, and passing it round, the exposure having been a fraction of a second. A shadowgraph of the President's hand was similarly developed and shown round, following which a considerable proportion of the company had their hands done, others meanwhile being indulged with a look at their bones, which were rendered visible to the eye by means of the vacuum tube and fluorescent screen.

Hackney Photographic Society.—December 5, the President (Mr. T. Bedding) in the chair.—On completion of the ordinary business, a lecture on

THE EVOLUTION OF THE GELATINE PROCESS

was given by Mr. A. MACKIE, in which, starting with an account of the labours of Nicéphore de Niépce and Daguerre, he detailed the work of the different experimenters from the early times to the present, and traced in detail the stages which ended in the modern gelatine process. Amongst those mentioned special importance was given to the following:—Niépce was the first to produce permanent photographs; Daguerre discovered development of iodide of silver with mercury vapour; the Rev. J. B. Reade discovered the use of gallic acid; Fox Talbot invented the calotype; Sir John Herschel introduced the use of glass; Niépce de St. Victor used albumen to hold the silver salts; Scott Archer brought out the wet-collodion process; Sayce and Bolton prepared a collodion emulsion; then followed gelatine and methods of ripening the emulsion. In concluding the lecture, and remarking on the fact that some of the earlier experimenters seemed often to have approached the discovery of facts which were yet not found out until years afterwards, Mr. Mackie said that, although one might at first be surprised at the non-success of the early workers in these instances, yet, when the imperfect materials and data with which they had to deal were fully taken into account, the wonder then was not at their having done so little, but of their achieving so much. The lecturer showed some fine examples of Daguerreotype portraits and calotype negatives and positives. Mr. H. BECKETT said that modern photographers owed a debt of gratitude to past workers, who had, in spite of great difficulties, laboured so well for the advancement of photography. Consider the benefits of being able to get one's plates ready-made; but, in the present race after rapidity, there was danger of losing sight of the advantages in the use of slow or landscape plates.

North Middlesex Photographic Society.—December 7, Mr. Mattocks in the chair.—Mr. H. STUART showed an ounce bottle of benzole, in which he had dissolved thirty grains of white wax. Shortly afterwards, on going to use it, he found a white crystalline precipitate, which occupied apparently more space than the wax originally put in, and he wanted to know the cause. No other reason than that the cold had caused it to precipitate was forthcoming. Mr. MacIntosh showed a quarter-plate changing box and dark slide to hold twelve plates in sheaths, which was admired for its simplicity. Mr. MATTOCKS asked how stale platinotype paper could be renovated. One member said that it had been recommended to dry it in an oven for some time; also a few drops of hypochlorite of lime in the developer helped to clear away fog. Mr. MACINTOSH suggested that monthly competitions for lantern slides should be introduced in order to encourage that department of work in the Society. After a long discussion, he was asked to bring it before the Council for consideration.

Bath Photographic Society.—November 25, the President in the chair.—Dr. Coppinger and Mr. H. M. Scott were elected members of the Society. The CHAIRMAN said it was decided to hold the annual dinner on December 21, at Fertt's, tickets 7*s.* 6*d.* as last year, and the usual *Conversazione* in conjunction with the Literary and Philosophical Association had been fixed for New-year's Day. Colonel H. H. SEALY then gave his promised lecture on

SOUTH DEVON,

which was illustrated by upwards of forty slides, both negatives and transparencies having been made by Colonel Sealy during the past season. He contended that one of the chief charms of photography was the bringing back of reminiscences of scenes and places visited. Incidents were thus made lasting. South Devon offered much attraction to photographers. There are large towns and pretty villages, also moors adjacent, so that, if one failed in finding subjects, he must be hard to please. The route illustrated started at West Buckland near, Kingsbridge, with some quaint views; going thence to Builth and Averton Gifford; views of and around Borough Island followed, and then Thurleston; and each view proved to be a theme for some interesting anecdote of the locality. In due course Plymouth and Torquay were dealt with, and, at the close of the lecture, the CHAIRMAN complimented the lecturer on the high quality of his photographs, and expressed the appreciation of the audience.

Cardiff Photographic Society.—The report and accounts for the year just ending were presented at the Eleventh Annual General Meeting of the Society on the 4th inst. The treasurer announced that the financial position was very sound. After matters of minor importance had been disposed of, the election of officers for next year was proceeded with. The President (Mr. S. W. Allen) was unanimously re-elected, although he expressed a strong desire to vacate the office. Mr. Faulkes, who has for so long undertaken the duties of Hon. Secretary, also asked to be allowed to retire, but the members succeeded in persuading him to retain the post. Mr. E. B. Howard, who had acted as Treasurer during the year, said, in reply to a proposal for his re-election, that he would be quite prevented from devoting the necessary time to the work. Mr. C. E. Hancock was elected to the post. The officers were heartily thanked for the assistance they had rendered to the Society during the year. The following were elected on the Council for next year:—Messrs. W. J. Jenkins, Kitchin, Harris, Booth, McCall, Dighton, McKinnon, J. J. Jenkins, and F. W. Kendall.

Leigh Photographic Society.—December 3.—The PRESIDENT (Mr. M. F. Burrows) read a paper on the

HAND CAMERA,

treating the different forms of cameras, shutters, plates, films, the advantages and disadvantages over the ordinary camera, and his experiences. A discussion followed, in which Messrs. Syms, Hampson, Wragg, and others took part. The best negative with print competition was decided in favour of Mr. Robert Leigh, for the first prize for a negative of Peel Castle, and Messrs. S. J. Green and P. Seddon tied for the second place.

Sheffield Photographic Society.—December 1.—The President (Mr. Tomlinson) occupied the chair. Two new members were elected. The medals gained in the recent annual competition were then presented to Messrs. Smith and Lygo, and the negatives from which the successful pictures were made handed round for inspection. An instructive and interesting paper on

PICTORIAL PHOTOGRAPHY,

prepared by Mr. A Horsley Hinton, was read by the PRESIDENT. Some of the author's Salon pictures were exhibited and greatly admired; and lantern slides were thrown on the screen, to show more clearly the author's meaning.

Wolverhampton Photographic Society.—December 1.—A lecture was delivered by Mr. T. H. Cox, entitled,

IN THE WILDS OF NORWAY,

illustrated by a large number of lantern slides of the towns, villages, rocks, and waterfalls of a portion of Norway recently visited by him. The lecturer described the various places visited, and the manners, dress, and customs of the people, speaking highly of their simplicity and kindly disposition as experienced by himself and others. He described their communal mills, which are maintained at the public expense, by the sides of the river torrents, for the free use of the people, and the enormous water power running to waste, which is now beginning to be utilised for electric lighting. Several striking slides were exhibited showing the peculiar dresses of the people, the female dresses embroidered with beads and their starched headgear, the interior and domestic arrangements of their houses. Some remarkable houses and churches were shown, the buildings being entirely of wood without nails.

Edinburgh Photographic Society.—December 2, Mr. F. P. Moffat in the chair.—Mr. J. C. OLIPHANT, M.A., read a paper on

LONG-FOCUS AND TELEPHOTO LENSES.

Mr. Oliphant advocated the use of lenses of longer focus, in proportion to the size of plate, than were generally used. Mountain scenery especially (it was pointed out and illustrated by several slides) lost a great deal of its grandeur if lenses of even the ordinary length of focus were used. In photographing buildings, too, the lecturer showed, long-focus lenses should always be used where practicable, as in this way the roofs, which are among the most characteristic features of a building, could be shown. A lens of eight or nine-inch focus for a quarter-plate was about right. Mr. Oliphant then went on to describe the telephoto lens. He considered that the results given by these lenses were, from an artistic point of view, unsatisfactory, although very interesting from a scientific point. Mr. Haddow then, on behalf of Mr. J. Lizars, exhibited and demonstrated the Vitagraph. The Exhibition was much enjoyed.

FORTHCOMING EXHIBITIONS.

1896.

December 29–Jan. 2. Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.

Dec. 1896–Jan. 1897 Bristol International. Hon. Secretary, 20, Berkeley-square Clifton, Bristol.

1897.

January 14, 15 ..... Weymouth and District Camera Club. E. C. Bennett, 10, Newberry-terrace, Weymouth.

February 1–27 ..... Glasgow *Evening Times* Camera Club. The Secretaries, *Evening Times* Camera Club, 46, Gordon-street, Glasgow.

March 6–13 ..... South London Photographic Society. Charles H. Oakden, 30, Henslowe-road, East Dulwich, S.E.

Patent News.

THE following applications for Patents were made between November 25 and December 2, 1896:—

MAGAZINE HAND CAMERA. — No. 26,551. "An Improved Photographic Magazine Hand Camera." W. BULLOCH.

CAMERAS.—No. 26,604. "Improvements in Photographic Cameras." Complete specification. P. K. STERN.

BURNISHING PHOTOGRAPHS.—No. 26,626. "Improvements in Burnishing Devices for Photographs." Communicated by G. Meyer & Co. W. P. THOMPSON.

STEREOSCOPIC PROJECTION.—No. 26,682. "An Improvement on the Action of Movements of Projectors, Stereoscopic Magic Lanterns," &c. V. DE L'ISOOY.

SCREEN KINETOSCOPY. — No. 26,765. "Improvements in Apparatus for Taking and Projecting Animated Photographic Views." Complete specification. A. LAPIPE.

PHOTOGRAPHIC APPARATUS.—No. 26,857. "Improvements in Photographic Apparatus." A. C. SMITH.

EMULSION.—No. 26,891. "A New or Improved Emulsion for Photographic Printing Purposes." A. HILL and THE CRESCO-FYLMA COMPANY, LIMITED.

CINEMATOGRAPHIC CAMERAS.—No. 27,007. "Improvements in Cinematographic cameras." J. W. HOLST.

CAMERAS.—No. 27,102. "Improvements in Photographic Cameras." A. C. JACKSON

Correspondence.

SUGGESTED EXHIBITION OF PRETSCH'S WORK.

To the EDITORS.

GENTLEMEN,—I was rather interested in your remarks in last week's JOURNAL about Paul Pretsch's work, as I have some eight or nine specimens of it, given me by Pretsch in 1858, and, as far as I know, it would not be easy to show anything much superior to-day. The company you refer to had, if I remember rightly, several prominent photographers as leading men in it, and it was rumoured that it was never intended to succeed.

It would be of some interest if a small exhibition of Pretsch's work could be held, say, at the rooms of the Royal Photographic Society, where they could be carefully examined by process workers, and with them could be shown permanent reproductions done by other workers at his time; there were several then well known.

I think the method of steel facing of copper-plate engraving was either not known or practised at the period referred to, and without this the number of good impressions from a copper plate was very limited.—I am, yours, &c., FRANK HAES.

28, *Bassett-road, W., December* 7, 1896.

[We commend Mr. Haes' excellent suggestion to the attention of the Royal Photographic Society. EDS.]

THE PHOTOGRAPHIC SALON.

To the EDITORS.

GENTLEMEN,—I should have preferred not to continue the discussion of the peculiarities of the Salon management, but Mr. A. Horsley Hinton's reply to my last letter renders a short comment necessary. In his previous letter he alluded to certain statements of mine as "fabrications," and, although I have been able to quote Mr. Horsley Hinton's writings as my authority for these statements, he still considers that he was "*justified in referring to them as fabrications.*" After such an expression of opinion, of what value is any attempt to answer or refute his views?

In concluding this correspondence, I would call your attention to Mr. Horsley Hinton's change of position from that taken in his first letter. The first contention in his last contribution relative to the Salon prospectus is identical with the statement in my first letter to you (*vide* THE BRITISH JOURNAL OF PHOTOGRAPHY, November 6, 1896). His second and fifth, I have endeavoured to show, are practical impossibilities, for reasons already stated. His final remark, that any views I may have expressed would have no influence, and are of no importance to any one but myself, is rather inconsistent with the trouble that he has taken to combat them.—I am, yours, &c., HENRY W. BENNETT.

December 8, 1806.

[This correspondence here terminates.—EDS.]

PHOTOGRAPHERS AND COPYRIGHTS.

To the EDITORS.

GENTLEMEN,—My attention has been drawn to the article on the above subject by Mr. G. Watmough Webster, F.C.S., F.R.P.S., in your paper of yesterday's date.

Mr. Webster admits that he "has received many scores of copyright fees," and that, "in nearly all cases, editors treat photographers with the utmost courtesy, liberality, and honesty."

Now, let me ask Mr. Webster, who is a member of the Photographic Copyright Union, and which he seems to consider it his duty to slate so unmercifully, whether he would have received all these scores of nice little fees and sweet amenities from the press had the Union never existed?

No, sir. Were it not for the Union, Mr. Webster, in common with the rest of the photographic profession, would at this moment be looked down upon, defied, and have his work filched by the press, as was the case before the formation of the Union. Of course, it is easy to pick holes in, and hurl cheap contumely on, the best of institutions.—I am, yours, &c.,

A GRATEFUL MEMBER OF THE PHOTOGRAPHIC COPYRIGHT UNION.

December 5, 1896.

To the EDITORS.

GENTLEMEN,—I am directed by the Committee of the Photographic Copyright Union to reply to Mr. Webster's article, which appears in your issue of December 4, and to answer the various statements therein *seriatim*.

In reference to the case of the Autotype Company, the infringement referred to was that of a valuable picture, and was carried through by them before the Union was fully organized, and since this action the Autotype Company have become members. As to Mr. Whitlock's case, Mr. Webster has made several blunders. In the first place, it was not a case of Mr. Whitlock's, but of Messrs. Guggenhim & Whitlock, of Wolverhampton; secondly, they did not offer the case to the Union, nor are they members of the Union; and, thirdly, Mr. Whitlock, jun., personally assured the President that they just managed to escape a loss.

Mr. Webster makes a grievance that the Union transmitted to him the offer as received from the *Christian Herald*, and that they made no further suggestion that any larger sum should be obtained. Our answer to this is, that we always transmit to the Union's members the offers made, as a matter of routine, in the form in which they are received. Mr. Webster wired his dissatisfaction at this offer. The Solicitors of the Union pressed further, and, after considerable difficulty, got the *Christian Herald* to pay 10*l.* and costs. This offer the Committee recommended Mr. Webster to accept, and the reasons which induced them to come to this conclusion were: first, Mr. Webster had, in his letter to the *Christian Herald* dated November 10, 1894, given himself completely away by stating, "I shall be pleased to permit the use of *any* of my copyright photographs for the following fees . . . . one guinea and two guineas," which letter he never recalled; and, secondly, that the *Christian Herald* has been found by the Committee to be a straightforward firm, who honestly paid for subjects when used. Mr. Webster seems to think that, because he had signed the document authorising proceedings, he had no further discretion in the matter. Now, it must be clear that, before the Union takes up a case, they must have written authorisation from the members. However, in the course of proceedings, everything is submitted to the approbation and consent of the member before any decisive action is taken. With regard to Mr. Webster's insinuation that the London members only are the recipients of large compensations, and also his desire to get answers to Nos. 1 and 2 questions, we have to say that the business matters between the Union and its members are private, but we are willing, in confidence, to submit the whole transactions of the Union from its inception to Mr. Bedding, of THE BRITISH JOURNAL OF PHOTOGRAPHY, and another Editor of a photographic publication, in order that they may judge whether country members do not get full proportionate compensation for the use of the copyright publications which they produce.

As to Mr. Webster's allusion to the President's remarks at the general meeting of the Photographic Copyright Union, here, again, he blunders. He says that the President stated that seventy-five per cent. of the compensations was obtained for provincial members. What the President really did say [see THE BRITISH JOURNAL OF PHOTOGRAPHY, October 16, 1896] was: "Perhaps many here will be surprised to learn that at present four-fifths of the the business done by the Union is for provincial members."

We must remind photographers that the object of the Photographic Copyright Union is to obtain payment for all reproductions of photographers' copyrights, and to prevent infringements of their rights, and to help those of the profession who, through ignorance of the law or other causes, are unable to get just payment for the use of their productions, but not to claim or to obtain excessive or vindictive damages.

Mr. Webster has been careful to point out to your readers that the Union take twenty-five per cent. of the compensation recovered, but carefully omits to point out that, when the case fails in a court of law, the Union pays *half* the expense. Can any member find a solicitor who will undertake a case on such liberal terms? Certainly they do not feel justified in expending their funds upon any very doubtful or exorbitant claim, which they feel could never be recovered in Court.—I am, yours, &c., HENRY GOWER, *Secretary*.

GERMAN RECIPROCITY.

To the EDITORS.

GENTLEMEN,—Dr. Kaempfer, of Voigtlander & Sohn, recently borrowed a series of slides which were in my possession, and which he has shown before a few German photographic and Shakespearean societies. The doctor says that there is a strong wish amongst many of the best workers and societies for more direct touch with British workers, and suggests that, if any of the British societies would be interested in them, he will send over here a fine set of slides of English and Spanish architecture, which can be regarded as a good representative set of best German work. As Dr. Kaempfer will wish these slides to be returned to him within reasonable time, I have suggested that they should not be sent before the end of January, in order that such societies as might wish to see them may have a chance of making arrangements. I shall be glad if any secretaries who are interested in this matter will send me, as early as possible, lists of what dates they have available in February. —I am, yours, &c., H. SNOWDEN WARD.

6, *Farringdon-avenue, London, E.C., December 5*, 1896.

SCIENTIFIC INSTRUCTION AND THE PHOTOGRAPHIC PROFESSION.

To the EDITORS.

GENTLEMEN,—It is unfortunate that Mr. D. J. O'Neill, in challenging my remarks on polytechnics and photography, should be compelled to admit his ignorance of the technical and practical side of the "rules and mysteries" of photography. The convictions I expressed have been wrought out of a lifetime of bitter experiences of commercial competitive photography, a lengthy course of polytechnic instruction, and an acquaintance with numbers of photographic workers. Obviously, then, it cannot be expected that Mr. O'Neill should be in a position to weigh the truth or falsity of my opinions. Furthermore, as a photographer, I repudiate Mr. O'Neill's claim to formulate out of his inner consciousness what scientific instruction is or is not beneficial to photographers at large. His position approaches the ridiculous when his close connexion with a National Association of Professional Photographers is observed. Could anything illustrate more completely my original contention that there exists the idea that mere knowledge of photography is thought sufficient, not only to enable a man to produce good work, but, as in this case, to dictate a policy to the photographic world? This claim I do not admit, but, on the contrary, would draw a strict line between photographers and those who possess but a knowledge of photography.

Mr. O'Neill is no less unhappy in his reference to the Birmingham technical schools. According to the Committee: "The main object is to obtain students who are already occupied in work during the day, and, in order that this class may have precedence, registration is specially kept open for them three weeks at the beginning of each session."

Again: "The objects of the tuition is to give the students a knowledge of machinery and processes outside the work in which they may be engaged during the day."

Clearly, then, if these objects are carried out, they in no way conflict with my contention that polytechnic teaching should be practical, and confined to those actually engaged in the industry. If these are the main objects, what becomes of Mr. O'Neill's scientific principles? The practical object is also the most prominent in the Photo Process School, lately established by the London County Council. This being so, perhaps Mr. O'Neill will explain the value of a knowledge of the law of error and photography, logarithms, and exposure, or Lord Ryleigh on pinholes to the ordinary photographer. To begin with, it is said, that only Lord Rayleigh and one other man can understand his abstruse studies. Yet all such subjects come within the scope of the City and Guilds Examinations.

But such limitation in teaching remote scientific principles in no way implies that they are to be neglected, nor do I think that, in quoting Huxley as attaching extreme importance to the man of genius, I perverted his meaning. Huxley had a dread of over-education, and said we do not want "exhausted book-worms," but "shrewd, handy men." He also said: "I weigh my words when I say that if the nation could purchase a potential Watt, or Davy, or Faraday at the cost of 100,000*l.* down, he would be dirt cheap at the price." Again: "Now, the most important object of all educational schemes is to catch these exceptional people, and turn them to account for the good of society." We are to "catch," and even "buy," our men of genius. What, then, becomes of Mr. O'Neill's doctrine of "discovering himself?" My experience of the present system of science teaching is that it more often enables a good man to lose himself in some immense labyrinthine polytechnic, and to be never heard of or seen again. Several that I am aware of have already perished, and are buried in these gigantic buildings.

What is or what is not technical education was not my original inquiry, but the effect of polytechnic teaching upon the economic condition of photographers, my answer being that it had been injurious because, (1) it was too theoretical; (2) it had not been confined to *bonâ-fide* workers; (3) it had sought to displace workshop training by a class system. This economic question I consider the more important, and, if polytechnic teaching of scientific principles has proved so exceedingly beneficial, perhaps Mr. O'Neill will show how it has improved wages, profits, or prices.—I am, yours, &c., JOHN A. RANDALL.

42, *Tonsley-hill, East-hill, Wandsworth, S.W., December 5*, 1896.

THE GRAND KINEMATOGRAPH.

To the EDITORS.

GENTLEMEN,—In reply to the letter in your last, from Messrs. T. J. & G. H. Harrison, calling in question an announcement made by me at the Croydon Camera Club, on October 28, I can only say that our

members, Messrs, Victor Bender and Adolphe Langfier, have always referred to the grand kinematograph as an instrument originally conceived by them at the beginning of March, and since completed under their directions and at their cost.—I am, yours, &c.,

Croydon, December 5, 1896. HECTOR MACLEAN.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post. Questions are not answered unless the names and addresses of the writers are given.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2, *York-street. Covent Garden, London.*

H. R. HOLMAN; A. LEVY; PERPLEXED. In our next.

HERBERT W. LEWIS.—Please send us your address.

PHOTOGRAPHIC CLUB.—Report received too late for this week's issue.

NOTICE OF DISMISSAL.—NEMO. We believe you can claim a clear week's notice.

GELATINO-CHLORIDE PAPER.—C. WARDELL. If the prints are alumed before they are fixed, the alum should be thoroughly washed out before they are put into the hyposulphite bath—that is, if permanence be a consideration.

H. H. B.—We should say that the arrangement you propose would work well; the exposure would be comparatively long. If, however, you could use two lights, and employ a large white cardboard reflector, you would probably get a more even illumination.

COLLODIO-BROMIDE.—WM. MITCHELL. A bad example of halation. Collodiobromide plates should not be used without backing, even when making transparencies from negatives, if they have such strong contrasts as those from which the examples were produced.

PERMANENCE OF ALBUMEN PRINTS.—T. A. C. asks: "What is the life of an albumenised paper print?"—This is a query that it is impossible to answer. We have seen prints that have got into a woful plight in a few months, and we have seen others that have endured for thirty or forty years without apparent change.

REDUCING RESIDUES.—T. ERWIN writes: "Will you kindly inform me if I could use a metal pot for reducing silver ashes in? If I were using a crucible, how could I get the reduced silver out without breaking the crucible?" In reply: A metal pot will not do. The reduced silver can only be got out by breaking the crucible. This will be no loss, as they will only do for one operation. Crucibles cost only a few pence each.

LEAKY ROOF.—C. A. W. The roof may not have been made perfectly watertight by the builder, but that will not account for water dropping on to the furniture when it is not raining or wet outside. The trouble is from moisture in the studio, with the heat from the stove condensing on the cold glass and then dropping off. If the roof of the studio had a higher pitch, the condensed moisture would drain down the glass to the eaves, and cause no trouble.

GELATINE.—W. BLOTT. As you say, the term gelatine is very vague. There are scores of gelatines in the market, and no two of them are identical in character; but in Continental formulæ "gelatine" is too often treated as if it were a definite and constant article. However, we should recommend you to try one of medium hardness and solubility, such, for example, as Nelson's No. 1 Flake. If that prove too hard, mix with it some of the same maker's No. 2 Soluble.

COPYING FADED PRINTS.—G. R. says: "I have a photograph sent in to copy, a silver print in a very yellow and faded condition. Is there any means of restoring the picture a little for the time being for copying purposes?"—Not temporarily. If the print be immersed in a solution of bichloride of mercury, the yellowness will be removed, but no missing detail will be restored. However, yellow prints, as they are, often copy better than might be surmised, and very much better if plates orthochromatised with eosine be employed.

FACTORY ACTS.—F. E. G. asks: "Would you kindly inform me if I am liable to prosecution inasmuch as I employ five young women and three young men (ages from sixteen to twenty-one) from nine a.m. till six p.m., or, when pressed with work, from half-past eight a.m. till seven p.m. every day of the week, of course excluding Sundays?"—No; not if the conditions of the Factory Acts are complied with as regards meal times, work-rooms, &c. These you will get, in the form of an abstract of the Acts, from the Inspector of Factories for your district.

ALBUMEN TRANSPARENCIES.—MEW writes: "I shall be much obliged if you will say whether the beautiful albumen lantern slides of the French makers are printed by contact or whether by reduction in the camera, and if it is possible to reduce by this process from large-size negatives, supposing that the more usual method is to print by contact?"—Generally they are made by contact printing, but they can as well be made in the camera, and, of course, reduced from larger negatives. The albumen is a slow process, consequently camera printing requires a long exposure.

FERROUS OXALATE.—T. R. says: "When developing negatives with the above, is it necessary to use the clearing solution as for bromide prints, or wash in plain water before fixing? Also, should I use bisulphite of soda in fixing solution? I want soft negatives—copies of photographs?"—In reply: A clearing solution is not absolutely necessary. Better use plain hypo for fixing.

POSITION OF STOPS.—T. O'CONNELL says: "I have just had given me an old portrait lens, and the stops (two) are made to slide in the front, or hood, of the lens. Is this the best position for them, as with all the portrait lenses I have hitherto seen they have been fitted between the glasses? Is the position in this case due to something different in the construction of the lens from modern ones?"—No. In the oldest portrait lenses the stops were put in front; but that was not the best position, hence it was abandoned for the present arrangement—between the lenses.

THE LATE D. O. HILL.—F. GUTEKUNST says: "In the latest issue of THE BRITISH JOURNAL OF PHOTOGRAPHY favourable mention was made of the portraits exhibited by Mr. D. O. Hill at the recent Exhibition of the Camera Club of your city. Being desirous of communicating with the gentlemen in reference to the same, we beg your indulgence in the request that you kindly furnish us with his address. By doing so at your earliest convenience you will greatly oblige."—In reply: D. O. Hill has been dead some years. The Royal Photographic Society, 12, Hanover-square, London, possess some examples of his work, we believe.

MEDALS.—H. S. C. says: "Can you give me information upon the ownership of medals obtained at photographic exhibitions? If my employer is the recipient of medals gained by exhibiting work executed solely by me in my capacity as operator, &c., is he entitled to those medals, whether gold or bronze, considering he has the honour of his name in conjunction with them? What is the usual arrangement between employers and employed under the circumstances, and are there any laws recognised by the exhibiting fraternity of photographic societies?"—In reply: The medals belong to your employer. Why should they not? Presumably you are paid for your work? We know of no "usual arrangement" between employers and employed on this subject.

DAMAGED WATER-COLOUR PICTURE.—W. H. W. says: "A friend of mine has a water-colour picture which he values very much. Some years ago he sent it to be mounted and framed. The man mounted the picture on a show-card or something of the kind, and now the printed matter is beginning te show through the water colour. Can you suggest a remedy for this? By show-card I mean that the card was covered all over with printing."—In reply: It is doubtful if there is any remedy if the printed matter has affected the colours. A restorer of paintings may, however, be able to unmount the picture and remove the stains, if they proceed from the greasy matter from the ink. As the work is valued, it should not be tampered with by amateurs.

A HARDSHIP.—HARD LINES writes: "In the spring I made a verbal agreement with —— & Co. for a year certain as assistant operator. Last week I received a week's notice, politely worded, that I should not be required any longer as business was always very bad in the winter, but they would be very pleased to take me on again in the spring, if I were disengaged, as they were perfectly satisfied with me and my work. Can I compel them to keep me on till the end of the time agreed upon, or make them pay me up till then, or, at least, give me some recompense? I am told that this is a usual custom with this house."—We fear our correspondent has no remedy, as the arrangement was only verbal. If the agreement had been in writing and properly stamped, the firm would have to hold to it, instead of behaving as they are.

ELECTRIC LIGHT FOR CINEMATOGRAPH.—PHOTOGORGOS asks: "1. Would you kindly tell me how many cells, and of what kind of battery, I might work a cinematograph ordinary-sized film, up to, say, a yard long projection, sufficiently illuminated? 2. Also, approximate cost of working? 3. Prime cost? 4. Would there be risk of grave accident in case of misadventure in handling the wires? 5. Would ordinary porous unvarnished jars—such are easily made at any tile-yard—suit for inner jars or what would be cheapest and most effective class of battery?"—1. and 3. About forty cells of either Groves or Bunsen batteries will give a good light. Forty cells of the former (if our correspondent buys the parts and puts them together himself) of suitable size will cost from about 15*l.* to 20*l.* The latter from about half that sum. 2. If economically managed, two to three shillings per hour. 4. No. 5. Get the porous jars specially made for the purpose; they are very inexpensive. In our volume for 1879 is a series of articles on batteries, and their construction, &c., for electric light for photographic purposes; their prime cost, and cost in working.

SALE OF GOODWILL.—REMBRANDT writes: "I have recently bought a business at the above address, and, in the usual way, paid a certain sum for the 'goodwill.' Knowing at the time of purchase that the photographer had branches not far from here, I asked if his name, which I will call X, went with the business? He replied by letter, 'Yes, certainly.' Now, however, I find he has filled up the usual form directing that all letters addressed to X shall be sent on to him. I think this hardly fair, and have somereason to believe that it is an infringement of 'goodwill,' because, as you will perceive, orders for groups from the country, &c., would be sent on to him. I therefore am writing for your valuable opinion on the matter."—This, if the facts be as stated, seems to be a case of sharp practice, to say the least of it. But, whether our correspondent has any legal remedy, we cannot say, as all depends upon the conditions of purchase and the wording of the agreement. If that was properly drawn up or approved of by the purchaser's solicitor, a court of law will, doubtless, give redress.

*** Several answers to correspondents, &c., unavoidably held over.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1911. Vol. XLIII.—DECEMBER 18, 1896.

Contents.

EX CATHEDRÂ.

The resignations of Captain Abney and Mr. Chapman Jones of their respective offices of President and Hon. Secretary of the Royal Photographic Society, which we announced last week, have doubtless provoked almost general surprise. Captain Abney was a member of Council and a Vice-President of the Society for many years, and had nearly completed a second term of office as President. Mr. Chapman Jones has held the responsible office of Hon. Secretary for a period of four or five years. Both gentlemen occupy scientific positions of high standing—Captain Abney's admitted eminence being far from solely dependent upon his photographic work—and their administrative abilities have been well demonstrated in the management of the Royal Photographic Society. On those grounds the resignation of two such men is to be deplored by all friends of the Society.

* * *

The reason for Captain Abney's and Mr. Chapman Jones's resignation lies in the fact that there is a desire on the part of many of the members to revise the rules relating to the election of the Council. With the object of assuring a constant stream of "new blood" into that body, it is sought to provide that at each annual election a certain number of the outgoing Councillors shall be ineligible for re-election until a year has passed. At present there is no restriction on what is called freedom of election. Captain Abney and Mr. Chapman Jones found themselves unable to agree to the proposed alteration, and therefore resigned.

* * *

That the grounds upon which Captain Abney and Mr. Chapman Jones took the grave step of throwing up their offices are slight and insufficient, will, it is probable, be generally admitted. Nevertheless, we, at any rate, were not at all astonished at, or unprepared for, their action. Writing on this very subject of the attempt to force "new blood" into the Council, we, on January 24 last (page 49), remarked: "There are many members of the Royal Photographic Society, who are of opinion that in very recent years the enormous amount of time which the Society has passed in discussing questions of internal policy has been, if not altogether unnecessary, at any rate largely in excess of the requirements of the case." We have good grounds for believing that Captain Abney and Mr. Chapman Jones were among those to whom we referred, and that, to put the matter plainly and in words that have been used in connexion with it, their resignations are, in part, a protest against "the constant tinkering of the rules" of the Society.

* * *

The Earl of Crawford has been elected President, and Mr. F. P. Cembrano Hon. Secretary of the Society. Two men better fitted for those posts could not have been chosen, and there need be no apprehension, if they consent to serve, that the Society will deviate from the path of prosperity it struck a few years ago. We hope that no time will be lost by the members in making such alterations in the rules of the Society as may be agreed on. The interest this Journal has long and consistently taken in the affairs of the Society, is our justification for the expression of a hope that the patience of very many of its members will be no longer tried by the idle and wasteful discussions upon trivialities of detail and procedure, which have been such unfortunate features of the

Society for many years past, and which it is high time were stopped, once and for all.

* * *

Mr. J. Craig Annan's collection of photographs now on view at the Camera Club, consists of about fifty works, which, with few exceptions, have been shown at the four exhibitions of the Photographic Salon. It is, therefore, not necessary for us to make detailed references to the exhibits, among which are such works as *S. R. Crockett, Esq.; A Utrecht Pastoral; A Lady in White; James Guthrie, Esq., R.S.A.; The Church or the World; Zandvoort Beach; Sibylla; Sisters; A Veronese Vineyard*, &c., with all of which the exhibition goer and the reader of illustrated photographic literature is familiar. It is hard to say whether Mr. Craig Annan excels in portraiture, in landscape, or in narrative work with the camera. He is, perhaps, the finest exponent of all three branches of photography that we have. There is a breadth, richness, and masterliness of conception and treatment about his one-man exhibition at the Camera Club that make it well worth visiting by all students of pictorial photography.

* * *

The Selle process of stained gelatine colour photography, which formed the subject of a paper at the Royal Photographic Society on December 8, is not new, and the claims made for it by the author cannot for a moment be allowed. It has frequently been described in these pages—so recently as October last, and before that about two years ago. Mr. F. E. Ives has worked the process, and has produced excellent results with it. Dr. Selle has taken a patent for the process in this country, which in all probability is valueless. There is room for surprise that a man having so much knowledge of what has been done in experimental photography as Dr. Neuhaus, should not also have known that the process he was describing was, figuratively speaking, as old as the hills. But why was the paper read at all? Papers to be brought before the Society are supposed to be submitted to the Council. Was that done in this case? It is not the first time that a meeting of the Royal Photographic Society has been utilised for the presentation of an unsuitable paper.

* * *

Our presence in Bristol last week recalled to us an incident that took place after our visit to the Exhibition there in 1893. By one of the routes to the station from Clifton Bridge, you get a very striking and comprehensive view of Bristol city, the Cathedral making a prominent object in the foreground. At the time we mention, we were shown a print that came from America, which bore a very mystical title. It depicted a large and apparently ancient town, and had a certain amount of atmospheric effect. We were asked to believe that this photograph had been taken in America—the continent of wonders—and that the city had no actual existence there, but was simply an aerial, reflected, or mirage-like image, which the photographer was fortunate enough to see and clever enough to photograph. The alleged cloud picture, however, was simply a copy of a well-known photograph of Bristol, by, if we remember rightly, Mr. W. Harvey Barton, that had been passed off by an American photographer as the photograph of a city in the clouds, and the circumstance of our being able to recognise it as a view of Bristol was the means of arresting the further spread of the imposture in this country.

THE SEPARATION OF THE LENSES IN STEREOSCOPIC WORK.

It is generally accepted that the separation of the lenses of a stereoscopic camera should be three inches. The purpose of stereoscopic photography is to reproduce, true to nature, the relief and solidity of objects; therefore it would seem essential that we should separate the lenses by a distance equal to that separating the eyes, and this varies in most people from two and a half to two and three-quarter inches. In children, the separation of the eyes is, of course, considerably less; till about the age of sixteen it becomes just over two inches, and in old people even increases to rather more than the normal.

If we assume that, from the centre of each eye, a single line is drawn till the lines meet, we shall find that we have a triangle with the distance of separation of the eyes as the base, and it will be easy to see how much we can see round an object placed within this triangle; that is to say, we can determine exactly how much more of the left side the left eye will see, and how much more of the right side the right eye will see. If we now increase the distance of separation, or, in other words, increase the base line, we shall find, keeping the distance of vision normal, that we shall see more on each side, and, therefore, we exaggerate the roundness of the object. This is what we do in increasing the distance of separation of our lenses in the camera. If we increase the base line of our triangle, or, in other words, shift our head some inches, using only one eye, and then shift it a like amount on the other side of a given point, using the other eye, we shall, in cases of small objects, actually be able to see right round them.

It is impossible, or, at least, not practicable, to alter the separation of the lenses to suit the separation of each individual worker's eyes, and, therefore, a mean separation of three inches has been chosen, which gives a slightly exaggerated relief, which, in practice, is not found disadvantageous.

When the eyes are directed to a distant object, practically infinity, it is obvious that the axes are practically parallel, but when directed to a near object, the axes are convergent. This has led many to assume that the axes of the camera lenses should be altered in precisely the same way, but the falsity of this reasoning at once becomes evident on applying it to a building. For, if we follow out the laws of perspective, we shall find that there will be two vanishing points, and, therefore, that the two images cannot be made to correctly coincide in the stereoscope. This was pointed out by Mr. W. I. Chadwick in a lecture before the Stereoscopic Club in Manchester seven or eight years ago, in which he shows by diagrams the falsity of this reasoning, for, as he points out, if we place the lenses with convergent axes, the left lens will see the parallel lines of the house converging to the right, and the right-hand lens will see the lines convergent to the left.

In choosing three inches as the distance of separation, there is one point which has been overlooked, and that is the position of the axes of the lenses as regards the centres of the plates. Assuming that the size of the stereoscopic plate most used to be $6\frac{1}{2} \times 4\frac{1}{4}$ inches, it is obvious that the centres of the two halves will be exactly three and a quarter inches, and therefore the axes will be in each case one-eighth of an inch out of the centre, a distance which, in such small plates, will, of course, be negligeable as regards the covering power of the lenses; but, assuming that we use a whole-plate, with its longer base horizontal, it is obvious that then the axes of the lenses will be five-eighths of an inch out of centre. With most of the modern lenses this is not of very great moment as regards

covering power, as most have sufficiently extended a field to cover a circle with a diameter considerably longer than the diagonal of the plate they are advertised for, and sharpness of definition may be obtained by stopping down; but there is yet another consideration which ought to be taken into account, and that is the difference in size of objects represented on the edges of the plates, which, whilst it may be neglected for pictorial purposes, cannot be neglected in scientific work.

Whilst for all stereoscopic work with plates of six and a half inches in length, we may determine on a separation of the lenses of three inches, for larger plates the axes of the lenses should be coincident with the centres of the plates.

There is one point in connexion with stereoscopic work which is frequently overlooked by young workers, and that is the distance of objects which should be included in the picture. It is well known that the smallest difference which can be detected by the human eye is a minute of arc, and if we draw a triangle with the normal separation of the eyes as the base line, and the angle at the apex as equal to a minute of arc, it is easy to calculate that all the points which lie beyond 240 yards may be considered as infinity, as the eyes will not be able to see them in relief. But when we come to consider the making of negatives, we shall find that this distance is considerably reduced. If we assume the greatest disc of confusion to be one two-hundred-and-fiftieth of an inch, we shall find that with a lens of two-inch focus, the depth of vision—for we know no better term to employ—will be only eighty feet; with a four-inch focus lens it will be 160 feet; with an eight-inch focus lens, 320 feet. It is therefore obvious that to choose subjects for stereoscopic work, which may be described as open landscapes or panoramas, is absurd, and even should these be chosen, unless near objects are included, the results will be more or less on one plane than standing in relief. It may, in fact, be taken as an axiom in stereoscopic work, that the nearest objects should never be more than thirty feet distant, and far better results will be obtained if this is reduced by one half or even more.

Beeswax in Solution.—At a recent meeting of one of the London photographic societies, a bottle of benzol was shown in which thirty grains per ounce of white wax had been dissolved, but which had shortly afterwards crystallised out. Thirty grains of pure beeswax are not soluble in an ounce of benzol. Indeed, the wax is not entirely soluble in that menstruum, as a portion remains undissolved. Why we allude to this subject is that, for photographic purposes, white wax should be avoided, as it is so frequently adulterated with such things as paraffin, spermaceti, &c. The best yellow wax, particularly if it can be procured from a farm where bees are kept, can generally be relied upon for its purity. That is more than can be said for the more expensive white wax.

Poisoning by Cyanide of Potassium.—An inquest was held one day last week on the body of a young fellow, an amateur photographer, who died from taking cyanide of potassium. The remarkable feature about the case was that, as no one saw the poison taken, it must have been swallowed some considerable time before any ill effects were seen, and then death was almost immediate. This the medical evidence accounted for by the supposition that the cyanide had been swallowed in the lump, and that it might have taken ten minutes or more to dissolve. This is the first time we remember the cyanide being taken in the solid form; it has always been swallowed in the solution, then the effect has been almost instantaneous in all instances.

Developments of X-ray Work.—The close interest with which this subject is watched is seen in the number of references made in the science periodicals of the day. The photo-physiological aspect is perhaps less in evidence than the electrical, which still is unillumined by any definite discovery as to the nature of the rays. There seems to be a remarkable power in the Röntgen rays of leaving behind some evidence of their previous presence when the illumination of the Crookes' tube has been discontinued. Gas passed through a long tube after being subjected to the action of the rays, possesses a certain electric power for some time after the tube is extinguished, and it is thought, for example, that evidence of photographic action after the cessation of the glow has been brought about by some peculiar condition induced in the air through which the rays have passed.

Uranium Radiation.—We have on a previous occasion referred to the investigation of this subject by some members of the French Academy, and lately, M. Becquerel has presented to the Academy a further paper. He finds that the rays emitted by uranium and its salts have some properties in common with the X rays; but while no one has been able yet to prove definitely that Röntgen rays can be either reflected or refracted like light, the uranium radiations do suffer reflection. Even when the uranium or its salts (which have previously been placed in the radiating state) have been kept in total darkness for eight months, the radiation remains unchanged. Further, gas which has been exposed to this radiation, possesses the same curious electrical property referred to in the previous paragraph.

Research Photography.—The Royal College of Physicians of Edinburgh have spent ten thousand pounds in building and equipping a Research Laboratory, which was opened last month. One of the four objects kept in view in equipping the premises was "to provide a photographic department for micro-photography," and this has been done in a very complete manner. To the right of the entrance is a large, well-lighted apartment, which will be used as the general office of the laboratory, and for the examination of specimens. Opening off this apartment are two photographic rooms, the outer of which contains the micro-photographic apparatus, and an arc lamp in a lantern, while the inner is the dark room. The new laboratory, like the old, is freely open to those who desire to undertake original investigations in the medical sciences, on their giving evidence of being able to undertake such work with a prospect of success.

The late Eclipse Expedition.—At the meeting of the Royal Astronomical Society at Burlington House, on Friday last, Mr. A. A. Common in the chair, Professor Stone and Sir G. Baden-Powell gave an account of the expedition to Novaya Zembla in the latter's yacht *Otaria*. This expedition, it will be remembered, was more favoured by the weather than was the one to Vadsö, and for which more elaborate preparations were made, though it was not all that could be desired at the most critical time. Still, some very good photographs of the several phenomena were secured. These were, of course, projected on the screen in illustration of the remarks of the speakers, and excited great interest. Sir G. Baden-Powell, in his remarks, said that the sum—1200*l.*—granted for observing such an important event as a solar eclipse was strangely inadequate. So it would be if, for a larger amount, suitable climatic conditions could be ensured.

British Art at the Brussels Exhibition.—A meeting, presided over by the Lord Mayor, was held at the Mansion House on Wednesday last week, to consider the steps to be taken to raise the necessary funds for securing a proper representation of British art at the forthcoming International Exhibition at Brussels. From four to five thousand pounds were thought necessary. Sir E. J. Poynter, President of the Royal Academy, said he had written to the Councellor of the Exchequer asking the Government to contribute 1500*l.* The opinion was expressed that if the Government would contribute that sum no difficulty would be experienced in

aising the remainder. Since then Sir E. J. Poynter has been informed that the Chancellor of the Exchequer, Sir Michael Hicks-Beach, is able to comply with his suggestion, and the 1500*l.* will be granted. It is hoped now that British art will be able to hold its own in the Brussels show.

Leonardo da Vinci's Cartoon.—Five or six weeks back we mentioned that this famous work, in the Diploma Gallery at Burlington House, had been photographed by a foreign house. It is this reproduction that is now being issued to its members by the Burlington Fine Arts Club at a guinea and a half per copy. It may well be asked why so much of the most important work in art reproduction for this country is placed in the hands of Continental houses. It is often said the light is better on the Continent than here, but the light at Burlington House and the National Gallery is the same for a foreigner as for an Englishman; so it is at Buckingham Palace and Windsor Castle. It is said that the foreign houses work cheaper than English ones: that, as a rule, is not the case, as their prices are higher. In the case of the cartoon, the price charged for the photographing of it, we are told, was higher—very much higher—than that quoted on any English firm's price list, and so with the prints. In face of these facts, the most important reproduction work goes to foreigners. Why?

Artists and Railways.—Artists evidently don't like railways, or, at least, if they pass their way. When the new railway to Manchester was first projected, the artists in St. John's Wood were up in arms against it; but the railway is being made all the same. Now a new railway to Watford is mooted, and Professor Herkomer is protesting against its passing through Bushey, where he resides. To an interviewer, the other day, he modestly (so says the interviewer) said that his presence in Bushey means 10,000*l.* a year to the place. Moreover, that the railway would destroy the rural aspect of the place, and prevent young artists settling there. That may be so, but the railway, if decided upon, will come just the same; and, possibly, the inhabitants will find that it will prove more advantage, from a business point of view, than a colony of young artists. By the way, Watford and Bushey has become quite a colony of "process" workers and photo-engravers, and it is here that we believe Professor Herkomer works the process he exploited some time ago. Increased railway facilities would surely be a great advantage to them, as well as add to the prosperity of the neighbourhood. In this utilitarian age, art and artists do not weigh much against commercial progress.

Haze.—Since the exhibition of the deservedly medalled picture, *Misty Morning on the Wear*, the production of haze effects has been courted rather than shunned, as in former days; still, for the majority of photographic work (portrait or landscape) the advent of a misty state of the atmosphere is looked upon as a disaster. Hence a few notes on the conditions governing the probability of its occurrence will be useful. At a recent meeting of the Royal Meteorological Society, the Hon. F. A. Rollo Russell read a paper bearing on the subject, from which we may gather a few valuable hints. He points out that haze is most prevalent when the wind is from the north-east, and is probably due to excess of dust, brought about by conflicting currents. The causes of fog are, to a great extent, the same as the causes of haze, although here we have to take into account radiation under differing conditions of air and ground. With regard to the conditions of visibility of objects, they are most favourable with dryness of air near the ground level, uniformity of temperature and moisture, radiation below the mean, steady and homogeneous winds, through a great depth of the atmosphere, approximation of the temperature of sea and land, and a great number of dust particles less than the mean.

Avoidance of Vibration.—Some time ago we gave a description of an apparatus which might possibly be adapted for photo-micrography, devised by Professor W. H. Julius, with the object of suspending apparatus so as to ensure freedom from vibration. The form adopted has now been improved upon by him. It consists, as described in *Nature*, of three rods placed parallel to one another in triangular form, and coupled together at their extremities by two metal hoops. This framework is suspended by three metal wires, the latter extremities of which are fixed to it at three points near their middle parts, lying in a plane between two hoops referred to above; a third hoop is placed which can slide lengthways along the three rods. It is on this that the instrument to be free from vibration is placed. To bring the whole centre of gravity to a point in the plane of the three points of suspension, the framework is suspended horizontally temporarily by one of the wires; and the balance of the apparatus, with the instrument attached, is obtained by varying the position of the three weights placed near the end of the rods for that purpose. The adjustment of the special part of the instrument which must be freed from vibration is made by placing this as near as possible at the centre of gravity. To deaden any movements of the whole apparatus, three fan-shaped appendages are fixed to the hooks to which the wires are attached, and these are intended to be immersed in paraffin.

Chemists Fined.—Some amusing evidence was given at the Brentford Petty Sessions the other day, when two pharmaceutical chemists were each fined five pounds and costs under the Foods and Drugs Act, for selling "arsenical soap" that contained no arsenic. Part of the defence was that the soap did contain arsenic, and the maker of it said that two and a half grains were included in the composition of every three hundredweight of the soap. But this homœopathic proportion could not be detected by the county analyst. This witness added that there was no honey in honey soap, no elder in elder soap, no pears in Pears' soap, or cherries in cherry tooth paste, &c. But the Chairman of the Bench remarked that when the public is induced to pay sixpence for an article worth but a halfpenny believing it to contain arsenic, and that that is good for the complexion, they expect to get it. The magistrates decided that the soap was a drug, and that decision is to be appealed against. A few years ago, in the same district, several publicans were fined for selling sodawater that contained no soda, or not in the Pharmacopœia proportion, sodawater being ruled a "drug." However, magistrates in another suburban district decided that sodawater, as sold at public houses, was not a drug, and that people who drank it did not expect it to contain soda, and would not drink it if they did, and therefore they refused to convict. In the case of the "arsenical soap," it is pretty clear that it can be vended by oilmen and grocers so far as the Poisons Act is concerned.

BY THE WAY.

THE past month has not been particularly prolific in photographic matter, which is perhaps not to be wondered at, for the closing of the annual exhibition, or, perhaps I should say exhibitions, usually marks the commencement of the dead season for most things photographic, except those immediately connected with the lantern. Still there have been one or two topics stirring to keep up an indirect interest in camera work.

But, first of all, reverting to the closing of the exhibitions, the closing of the doors and the dispersion of the pictures does not appear to have blotted out all recollection of the rival shows, for we have been treated to a good deal of what looks remarkably like "washing dirty linen in public." It is an astonishing thing that, when in art matters a small clique detaches itself from its fellow and sets up a new "school," it should emphasise its superiority by so much patting of itself on the back and calling everybody else names. We have seen this sort of thing before in connexion with splits in and secessions from the various painters' societies, and now the supporters of the Salon appear to be desirous of establishing their artistic claims by following the lead of, shall I say, their betters?

It is too late in the day to reopen a discussion of "impressionism" (small "i," please) "naturalistic photography," or "fuzziness," whichever it may be termed, but it seems pretty evident by this time

that the chief exponents of the "new school" are not all Emersons, and that they know it. Indeed, even the best of them succeed principally by their selected exhibits. While it is quite possible that an out-of-focus photograph may be an artistic picture *in spite of* its technical defects, it does not by any means follow that a thoroughly bad one must rise to artistic heights *because of* those defects.

I have in my mind's eye, as I write, an instance of an individual, an amateur photographer, with no special leaning in any direction, who exhibited a picture and took a medal. It was not his first exhibit, but it was his first success; it was an outdoor figure study, the subject a very pretty girl naturally and gracefully posed—naturally, perhaps, because *self*-posed—and, while the figure itself was fairly or sufficiently sharp, the background, consisting of shapeless masses of foliage, was out of focus enough to hide its ugliness, and to be nothing more than "suggestive," whatever that may mean. Any how the *ensemble* was very pleasing and caught the Judges' eye. Unfortunately for the exhibitor, the impressionist critics praised it, and pointed out where its beauties and its virtues lay, with the result that he has persevered in perpetrating "fuzzytypes" for some three or four years now, without, however, so far, getting within touching distance of his second medal.

When we look at the vast number who have taken up the camera within the past few years, since it became possible to produce pictures without the trouble of learning the science of photography, we need not be surprised that a great many of them avowedly look with disdain upon what they are pleased to call the mechanical part of the work. But is there no "mechanical" part in painting or in any other form of art? Does the painter, who fails to master the elementary rules of perspective and drawing and the methods of laying his colours on canvas, get himself hung on the line by howling at technique? There was a time when the production of an artistic photograph, which was also technically excellent, was a far more difficult matter than at present, and when, indeed, any specially artistic quality was allowed to hide a multitude of sins of execution. Look at Rejlander's productions, and try and imagine what he would have done without present-day facilities! But now there is not the faintest excuse for "sloppy" work, and technical excellence, both in definition and gradation of tone, should be as important an item in the qualifications of a photograph as of a painting.

I am sorry to say it is not only the new men in photography who openly flout at the scientific side. Not long ago, so high an authority as Mr. H. P. Robinson was mildly sarcastic on the subject of formulæ. Now "H. P. R." has done marvellously good work in the old days, when I presume he had to study formulæ; at any rate, he did what was the fashion in those days, he went through the drudgery and mastered *photography* before he attempted art, and I do not recollect ever to have seen a production of his that was not at least as perfect in technique as in other qualities. The modern man attempts art, but gives up photography as too difficult a task. In times past even great painters were not above descending to such mechanical tasks as grinding their own colours and preparing their own canvases, and would do so again if such firms as Winsor & Newton, Rowney, and others, dropped out of existence; but, if our plate-makers shut up shop in a body, "impressionism" and half-modern photography would die with them. Focussing glasses and guides to development are quite as cheap as plates, and much more useful in turning out *pictures*.

There was a very suggestive leader a few weeks back on the *Future of Photography*, though I think the title should have been rather the "Future of Exhibitions," for fortunately the future of photography is not dependent on the question of focussing. What is photography? Surely picture-making, whether good or bad, does not constitute the beginning and end of it? My own impression is that the technical side is the real photography, while mere picture-making is but a side show. We should not be satisfied at an electric exhibition to find it confined to, say, telegraphy. At the same time a purely technical exhibition would appeal only to a comparatively small section of even photographers themselves, and to the general public not at all, and, I fear, a separate exhibition devoted only to the purely scientific and mechanical sides, even though modern printing processes were thrown in, would prove as serious a "frost" as the unfortunate show at the Imperial Institute last year. Then, again, to have a fairly representative show of modern technical processes and apparatus would require far more room than has hitherto been at the disposal of the parent society, and it is questionable whether the additional attraction would be great enough to repay the extra expense involved, so that, all things considered, the combined show would appear to be the preferable plan.

There is no reason why such a mixed exhibition, even on a small scale, should not be extremely interesting, but it would have to be on entirely different lines to former years. The apparatus department at Pall Mall has always been a farce and a disgrace. Any one can show anything, and the specimens of incomprehensible rubbish that sometimes find their way on to the table would be hard to beat at any other exhibition I ever saw. If only really novelties were admitted, and these subjected to a rigorous examination before acceptance, a good deal of useful matter might be got into the small space, and let the same system of weeding out be applied to the pictures. Then each exhibition might make a speciality of some particular branch or department of scientific photography, orthochromatics, colour photography, half-tone process, photogravure, &c., including processes, appliances, and materials, and, if necessary, demonstrations. These need not interfere with the general or "artistic" public, while they would prove sufficiently attractive to a large section of technical workers, who would not trouble to go to see the pictures alone, to say nothing of a perhaps not insignificant number of those whose interest in photography extends beyond the capture of medals.

One of the disputed questions of the day seems to be the safety or otherwise of acetylene. Either side can be taken according to the point of view of the observer. Thus let us take it that it is safe—"as safe as ordinary gas," as one writer says. So in the abstract it is, when all is right and you know perfectly well what you are doing. But it has to be borne in mind that acetylene gas is "made on the premises," while ordinary gas is manufactured by experts in properly constructed works, and "laid on" or supplied in a comparatively harmless form to the consumer. What would be the probable state of affairs if ordinary gas were made in the kitchen fireplace and carried about the house in a portable gasometer? Oxygen, again, is perfectly safe under proper conditions, yet how many fatal accidents have occurred in the manufacture and use of that gas.

As I say, acetylene may be perfectly safe and harmless under proper conditions, and when the generating apparatus is thoroughly understood and in perfect order. But no earthly power can guarantee that the apparatus will always keep in order, any more than that an oxygen retort or a gas cylinder will not sometimes explode with disastrous results. It is not the acetylene alone that is dangerous; it seems to me that the calcium carbide is most to be feared, and if any hitch occur in the working of the generator, and the gas goes on accumulating under constantly increasing pressure, what is one to do but wait the inevitable? It is all very well to say, as Mr. John Watson does, "Do not experiment yourselves, follow out the simple instructions given for your benefit." Simple instructions cannot prevent accidents, and the sequence of the same sentence seems to point very distinctly in the direction of danger, for it seems these "instructions" have been arrived at "the cost of the brave men who have risked and sacrificed their lives for the benefit of science." Doesn't it seem just possible that, if experienced men come to grief occasionally, outsiders may stand a chance of doing the same?

I was rather interested in an article on *Cycling and Photography*, but I cannot quite understand some of the conclusions of the writer. I fully agree with him that the "three-wheeler" is out-and-out the best machine, both for convenience, safety, and comfort, for the travelling photographer, but why he places the safety bicycle last I utterly fail to see. True, he says if any of the weight is hung on the machine, it will affect the steering; but why not carry it, except

the stand, on the back? He places the "ordinary" bicycle next to the tricycle; now, an old friend of mine over twenty years ago thought very little of mounting his 56-inch "spider" with his whole-plate "kit" on back, knapsack fashion, and stand strapped to the handle bar, and doing a day's spin out and home of sixty or seventy, and on one occasion eighty-four, miles. Now, if that were possible on a 56-inch wheel, how much easier it must be on a 28 or 30-inch "safety." I am acquainted with more than one cyclist-photographer who utilises the "safety" in this manner—camera and plates on back, and stand on handle or backbone, whichever may be most convenient; or, with a fourfold stand, it also can go on the back. But personally I am getting old enough to yearn for something safer even than the "safety," and so prefer the three-wheeler.

DOGBERRY.

PHOTOGRAPHERS' COPYRIGHTS.

THERE are two letters replying to my article on this topic. I will deal with the "Grateful Member" first. He says I have "unmercifully slated" the Photographers' Copyright Union, and suggests that I have "hurled cheap contumely" on them. Save us from our friends! I have simply given a brief abstract of the facts of my connexion with the Union touching a recent incident, as they declined to permit the correspondence itself to be published. "Grateful Member" clearly shows by these descriptive words how he thinks the facts tell against the Union, for I made no comments. He asks, further, whether I would have received these scores of fees, &c., had it not been for the Union. I did receive many of such fees and annuities before ever the Union took a case into court. The Secretary to the Union furnishes a still better reply. Writing of the Autotype Company, who received exemplary damages for a piracy in a few days after legal application to the pirate, without any assistance from the Union, he says the Autotype Company "carried their case through before the Union was thoroughly organized." In the recent case of a barefaced piracy of a very valuable copyright picture belonging to me, the Union obtained the ridiculous compensation of ten guineas and costs "after considerable difficulty."

I will now deal with the Secretary's communication. I accept his correction about the Whitlock case, which I only gave on hearsay, as I stated; the Union will no doubt be pleased to have the opportunity of preventing my informant having any excuse for repeating the tale. The "seventy-five per cent." I wrote was a clerical error for eighty, but in favour of the Union. Under the excuse of privacy, he declines to reply to various very pertinent queries I put. Readers will no doubt draw their own conclusione. It must be remembered that it was not I who suggested that the Union existed for the benefit of a London clique. The President mentioned the rumour. "Qui s'excuse s'accuse," the French say. Speaking for the Union, the Secretary quotes a letter written in 1894, giving prices to the *Christian Herald* for a *special set* of portraits (*that had already been published* elsewhere), inferentially suggesting that such terms must necessarily hold good for all future copyrights of *any* subject. This is a fair example of the way the provincial photographer's interests are looked after by the Union. I content myself again with drawing attention to their methods. Comment would be superfluous.

I now come to a very grave matter, in which the honour of the Union is compromised by their officials. The Secretary writes as follows:—

"Mr. Webster had, in his letter to the *Christian Herald*, dated November 10, 1894, given himself completely away by stating, 'I shall be pleased to permit the use of *any* of my copyright photographs for the following fees . . . . one guinea and two guineas.'"

This statement of the Secretary is inaccurate. I append an exact copy of a transcript, in his own handwriting, of my letter to the *Christian Herald* (omitting names), the letter *being a reply to one of theirs*:—

"*Studio*, 33, *Bridge-street-row*, *Chester*,
"*November* 10, 1894.

"The Manager of the *Christian Herald*.

"DEAR SIR,—In reply to your letter, I shall be pleased to permit the use of any of my copyright photographs for the following fees, viz.: —Cabinets: Lady ——, one guinea; H.S.H. Prince ——, one guinea; both together, one and a half guineas. Panels: Lady ——, two guineas; Prince ——, two guineas. For one issue of your periodical my name to appear under the picture as photographer and owner of the copyright.

"Yours faithfully,
"(Signed.) G. WATMOUGH WEBSTER.

"Per L. Cuzner, *Secretary*."

It will be observed that there is no italicising of the word "*any*," as Mr. Gower makes it; and further, that my letter quoted prices for five distinctly specified pictures, and not, as Mr. Gower puts it, for "*any*" pictures.

G. WATMOUGH WEBSTER, F.C.S., F.R.P.S.

THE PASSING OF THE PORTRAITIST.

IT seems probable that in the immediate future, the photographic world will be involved in a controversy similar in character to that which divides certain politicians—the members in one division being known to their opponents as "Little Englanders." The controversy is already in the air, recent events tending to precipitate it in a definite form. The issue, put plainly, resolves itself into two possible courses; on the one hand, shall photography be defined by this or that limited acceptance of the word? or shall it be broadly interpreted to include the whole body of persons in any way connected with photographic processes? In short, are photographers to adopt a policy of contraction or expansion?

This is not altogether a modern dispute, though it has recently entered upon a fresh phase through the introduction of new elements. In the past, the conflict was between science and art. To many photographers, science should only be introduced into photography to perfect and extend its methods the better to produce artistic work; to the men of science, art photography has been merely the appropriation to commercial ends of what should be rightly a branch of pure science. For many years the art photographer—who in practice means the portraitist—has held the field, being both in number and influence the predominant power. Thus the ethics and ideals of the portraitist have generally prevailed, these being modelled upon the customs and traditions of modern and bygone schools of art. The photographer was to be primarily an artist, producing works of art, having for his guides and masters men of the stamp of Rejlander, Adam Salomon, and H. P. Robinson; persons who did not work in this spirit, and with the same high ideals before them as these masters held in their day, had no claim to the name of photographer. The only photography was the pictorial photography.

But whilst the majority of photographers have been holding these opinions, and reducing them to practice according to individual ability, events have been rapidly progressing around them, they, meanwhile, remaining intellectually at a standstill. The portraitist, clinging to his artistic ideal, has been left stranded, and out of touch with the more recent advances of commercial photography. Ten years ago the artistic view of photography was the prevalent one, being applicable to the then existing body of photographers; since then an entirely new class of man has arisen, to whom the former ideals and artistic aspirations are unintelligible, because having no direct application to his work. This class the portraitist ignores, keeping strictly apart from its ways of business, and scarcely recognising its photographic character. The older societies and institutions take little notice of the dry-plate maker, the trade printer, the bromide enlarger, the lanternist, the view publisher, the provider of photographs for advertisements, Christmas cards, &c., the process operator, the process-block maker, the manufacturers of photographic materials, the more recent additions—the X-ray operator, the kinetographist, the three-colour process workers, and many others in minor branches of photographic work. The ideals of the portraitist cannot be applied to workers of this description, yet this class is rapidly growing, and perhaps even now equals in wealth, and will certainly soon outnumber, the artistic photographers. They will not be much longer pushed aside and ignored; but if the art ideals are to prevail, they must be classed as rude mechanics along with Abney, Bothamley, Pringle, and Co., as having no valid claim to the title of photographers. Should such an attitude of antagonism be persisted in, we shall have the spectacle of a comparatively small body of men taking up a position of lofty isolation, and alienating the more powerful and wealthier section of their own industry.

In place, therefore, of the old opposition between science and art, we have now this large and growing commercial class to consider. Meanwhile, the ascendency of the portraitist is also threatened by the increasing applications of photography to his old enemy science. Scientific men are using photography more than of old. It has almost displaced eye observations in astronomical observatories, hardly a science can be named to which it has not been applied, and it crops up in such unexpected places as the engineer's shop for gauging the dimensions of screw threads. The total commercial value of the scientific trade must now be considerable, large numbers of photographic workers gaining a livelihood in supplying the demand. Furthermore, it must be recognised that commercial and scientific photography will continue to advance by reason of new applications and discoveries, whereas portraiture has reached its maximum, and cannot now extend only in so far as wealth and population increase. With scientific and commercial photography, none can tell to what importance they may eventually reach, and it would be well not to undervalue their possibilities.

Besides these external causes which threaten the supremacy of portrait photography, there is an internal disruption, which seems destined to separate the portrait and landscape photographer, who, until recently, were regarded as one. Dr. Emerson showed what artistic work could be done in nature photography, pure and simple. His followers, upholding an even more transcendental view of nature photography, have created a

school of landscape photographers more ambitious, more cultured, though less confident of their powers, than the older workers. The portraitist called himself an artist, and claimed to be a photographer; the new man calls himself a photographer, and claims to be an artist. Not that he would identify himself with the scientific or commercial worker, but with the aim of lifting photography to art instead of bringing art down to photography. The outcome of the activities of this new school has been to limit the sphere of the portraitist, for it has raised in some degree the standard of quality of photographic views. A view must now have a pictorial beauty; more attention is required in its production, and considerable ability must be displayed if it is to be a marketable commodity

In every direction we see growth, it being evident that in the near future, portraiture will no longer be the leading interest in photography. In absolute amount of work required there will, of course, be no decline, the change being merely one of relative importance. It is hardly possible, at this late date, for portraiture to die out. In the future it will, therefore, be unreasonable to confine the meaning of photography to its artistic aspect, and to call its exponents representative. The only alternative is that the art photographer return to the older position, and designate himself an artist without the photographer. Some such distinctive title will have to be adopted by those who adhere to the strictly artistic side of photography, if they have any fear of lowering their art status by association with the commercial reproducers and scientific workers. They might also follow the custom of painters in using the descriptive names, "artist in oils," "artist in water colours," black-and-white "artists;" in agreement with such nomenclature we should have the terms "artist in platinum," "artist in carbon," &c. In the event of such departure, the name photographer would remain with the larger and more wealthy body about whose right to be called artists no quarrel would arise. Such a separation is, however, not desirable, the well-being of photography would be more certainly assured by a strong combination of all sections for educational and trade purposes.

The inclination to regard photography from a single point of view was evident at the last Pall Mall Exhibition, as this JOURNAL has already pointed out. An exhibition is in no way representative of an industry whilst it overlooks the more progressive sections; an exhibition being simply a means of marking progress. If the photographic profession is to prosper in the future, its commercial interests must be studied in the present, and likewise the interests of those workers who are extending its scope, and putting capital into the newer departments.

The policy of limitation has done some harm in the past, photographers having clung too long to the belief that artistic portraiture is the only legitimate and profitable application of photography. How far this opinion has stood in the way of the commercial prosperity of photographers as a body I shall not pause to inquire: one thing, however, is certain, the artistic ideal has not prevented the growth of a purely utilitarian photography. Had a more liberal view been taken of the profession in the past, we might now see the photographer engaging the process worker instead of the process worker engaging the photographic operator. Process work would then have been rightly regarded as a branch of photography, and not, as now, a branch of printing. The evolution of the process worker is not yet complete; with the cheapening of production there will be every inducement for him to supply ink portraits of large size to private individuals, and thus enter into direct competition with photographers. This would mean a loss not easily recovered.

From whatever side the question is looked at, it appears that the portraitist can no longer be regarded as the ruler of the photographic world; it only remains for him to decide whether he shall throw in his lot with the numerous other workers, or form a small clique having artistic aims and no pronounced commercial policy. To me it seems certain that in future photographic processes will come into use for the greater part of black-and-white illustration, and that three-colour photographic work will supplant much of the cheap colour work which is now done. Direct negatives will also be much in demand, this of necessity meaning the want of men who can produce artistic work with the camera. In such work the very best of artistic photographers will find employment, and so identify their interests with the most prosperous section of photography. Even now some of the leading portraitists are extending business in this direction, producing art studies and composition pictures fit for mechanical reproduction. By turning his attention to similar work, the portraitist might extend his business, and come within the scope of progressive photography. If this is not done, a class is sure to arise who will make a speciality of the work and render competition hopeless.

Those who reject these minor branches, and hope to depend solely on portraiture, will be compelled by circumstances to form themselves into a strong combination to prevent the overcrowding and severe competition which otherwise they must encounter.

JOHN A. RANDALL.

A DRUGGIST'S DILEMMA.

WHILE every one recognises that it is necessary for the safety of the public that there should be some restrictions on the sale of poisons, there are many who consider that the present state of the law of the subject is unsatisfactory. Under the present law, a class is given the monopoly of selling certain scheduled poisons, and even in their case there are formalities to be gone through, otherwise the sale becomes a punishable offence.

The Pharmaceutical Society is at present entrusted with the power of putting the law in motion against offenders, and it has been imputed to them that they have exercised their power, not with the common sense that should be exercised with regard to all laws, but sometimes rather as an instrument of persecution; not as a trust to secure the people against harm, but as the defence of a monopoly.

It has been contended that the Pharmaceutical Society is bound to prosecute in every case of infringement of the Poisons Act, and they cannot be charged with remissness when any unregistered seller is concerned, even though the poisonous material be in so small a quantity and in so diluted a state as to cease practically to be poisonous. *De minimis non curet lex* seems to be a maxim unknown to the Society, and if an unfortunate complexion specialist must be prosecuted for selling a lotion containing an almost inappreciable quantity of bichloride of mercury, what ought to be done to a registered chemist for a similar offence? What is sauce for the goose is sauce for the gander.

In connexion with the discussion of the administration of the Poisons Act which has recently taken place in THE BRITISH JOURNAL OF PHOTOGRAPHY, the following report, which is taken from the *Weekly Sun* of the 13th inst., will be interesting.

"ARSENICAL SOAP.

"A PECULIAR PROSECUTION AND AN INGENIOUS DEFENCE.

"At the Brentford Police Court yesterday, before Mr. G. G. Mackintosh (in the chair) and other magistrates, a remarkable charge under the Food and Drugs Act came on for hearing. The defendant, Mr. George Turner, a chemist, of High-road, Chiswick, was summoned for selling a quantity of 'Arsenical' soap, 'which was not of the nature and quality demanded.' Mr. Tyler, Inspector under the Act, for the Middlesex County Council, prosecuted, and Mr. Arthur Hutton, Barrister, represented the defendant. Mr. Tyler stated that a tablet of 'arsenical' soap was purchased at the defendant's shop, which, on being analysed was found to contain an insignificant amount of arsenic. It was estimated that a pound of the soap would only contain the one-hundredth part of a grain of arsenic. (Laughter.) This amount, the analyst considered, was of no practical value.

"Mr. Hutton raised a technical objection to the summons on the grounds that the wrapper which contained the soap stated that the amount of arsenic used was 'small and was perfectly harmless.' The definition of the word 'arsenical' in all the standard dictionaries meant the introduction of arsenic in any quantity into the composition of an article. (Laughter.)

"Mr. Tyler stated that an expert had given it as his opinion that to be of any service to the public, arsenic to the amount of one and a half grains to the pound should be introduced.

"The Chairman: But the British Pharmacopœia has not laid down a standard.

"Mr. Hutton contended that as arsenic had been introduced into the composition of the soap, in however small a quantity, the charge must fail.

"The Chairman expressed his concurrence with this contention, and the summons was dismissed."

Most chemists sell arsenical soap for the complexion, and even advertise it. It is to be obtained as easily as "old brown Windsor." It seems evident from the context that, in this case, the necessary ceremonies for the sale of a scheduled poison were not performed, and, if so, the Pharmaceutical Society is bound to exercise its powers. It is not likely to do so, of course, against a member of its own Trade Union, but if the defendant in the case had been a grocer he would have stood a good chance of being brought to book for his heinous crime.

Between inspectors under the Food and Drugs Act and the Pharmaceutical Society, sellers of arsenical soap ought to have a merry time of it.

J. W. SIMPSON.

THE DEMENY CHRONOPHOTOGRAPH FOR MOVING PROJECTIONS.

L. Gaumont & Co., 57, Rue Saint-Roch, Paris.

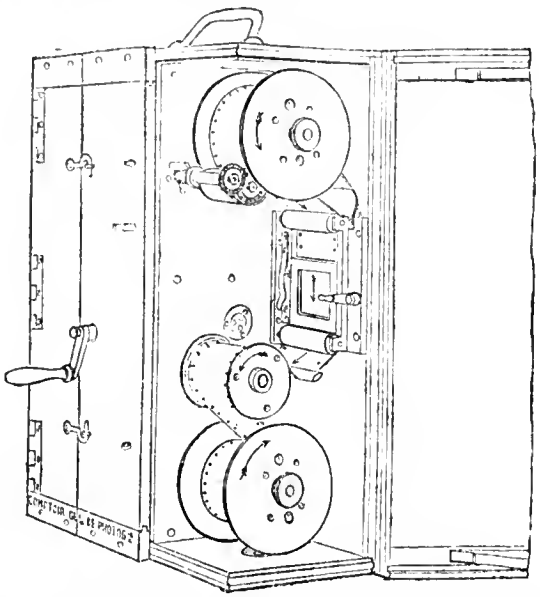
MONS. L. GAUMONT last week demonstrated the Demeny apparatus for taking and projecting "animated" photographs. We were enabled to examine some of the negatives, and prints and transparencies from them, that had been made in the camera. The pictures were beautifully defined, well exposed, and without flaws, and were the best we have hitherto seen—thus attesting both the good qualities of the Demeny camera and the film that was used in it.

The Demeny instrument takes and projects pictures, each of which gives an image having an area four times greater than animatographic pictures of the usual size. With regard to the appearance of the projected images on the screen, which were shown by means of the electric arc, they struck us as being the best, photographically and mechanically, that we have seen, making allowance for the fact that the demonstration took place in a comparatively small room. Shown on the stage of a theatre or in a large hall, we should imagine that there would be little or no perceptible movement.

It is a feature of the Demeny chronophotographic apparatus, that the camera is well adapted to form part of the projection system—the one instrument does for both purposes. The illustration shows the band of positives in process of being wound off, and the principle of the instrument will doubtless be grasped by means of the following brief descrip-

tion of the essential movements, understanding that the film works in the direction shown by the arrows:—

The bobbin upon which the pellicular band has been previously rolled by the aid of a winder is placed upon a fixed axis, and a friction-roller



drawer composed of a cylinder covered with an indiarubber casing and driven by a gearing placed in the interior of the apparatus, unrolls a given quantity of the pellicular band. This portion of the band engages itself between a guide and a friction roller along a passage, lined with velvet, in which is found a rubber frame placed opposite the window, and presenting an identical aperture to that forming the opening of this window.

This rubber frame, lined with velvet, is movable round a joint adapted to one of its sides, and when the film has passed, the frame is applied upon it, and it keeps it in gentle and continuous pressure by clasping in the spring wedge.

After having passed under the frame, the film engages itself *under* a friction roller, then also under a cam, then it is passed *upon* the dented cylinder, wherefrom it finally rolls itself upon the receptor bobbin previously placed upon the drawing axis.

It is claimed for the Demeny apparatus that it does not destroy or tear the films, and the examples shown bore out the claim. The mechanical movements appeared to us to be carefully devised and perfected, and, so far as we can judge, the Demeny apparatus is simple and certain in use, practicable, and effective. Certainly the results it has produced tell very largely in its favour.

THE BRISTOL EXHIBITION.

The International Photographic Exhibition, organized by the Bristol and West of England Photographic Association, was opened on Monday last at the galleries of the Fine Arts Academy, Clifton. It is to remain open until January 23. There are between eight hundred and nine hundred exhibits, many of them coming from abroad, so that the international character of the Exhibition is unquestioned. The energy of the Bristol Executive has been well responded to, and the result is that in the handsome galleries of the Fine Arts Academy a fine collection of works has been got together. It is not, however, representative of all phases of photographic art, inasmuch as the "Salon" element is conspicuous by its absence, although possibly this is no loss to the Bristol Exhibition.

The Awards.

Twenty-eight medals were placed at the disposal of the Judges—Messrs. Blanchard, Payne Jennings, B. Alfieri, R. Smith, and Hood Daniel—who in their report remarked: "The Judges consider that the exhibits, taken as a whole, fully sustain the artistic advance in photography, and in some cases they have felt compelled to award extra medals on account of the high standard of excellence of the work shown." As to the Champion Class, the Judges said: "In respect to this class the Judges feel that, notwithstanding the strong desire of the Association to award the medal, they could not select an exhibit that was, in their estimation, sufficiently in advance of its competitors to warrant them in making this high award."

Class I., Landscape or Seascape, half-plate or larger.—No. 14, silver medal, *An Old Hulk*, Charles Job; No. 51, silver, *The Crest of the Hill*, C. F. Tuston; No. 78, bronze, *Evening on Lago Maggiore*, M. T. Tylor; No. 22, bronze, *An Essex Homstead*, J. H. Gear.

Class II., Marine.—No. 475, silver medal, *The Harbour*, W. Norgrove; No. 476, silver, *Twixt Day and Night*, J. H. Gear; No. 460, bronze, *Twilight Grey*, W. C. Hemmons; No. 480, bronze, *Whitby*, J. Gunston; No. 469, extra bronze, *Seaside Snaps*, A. Lewis.

Class III., Landscape, 5 × 4 or under.—No. 233, silver medal, Series, C. F. Inston; Nos. 269 and 270, bronze, Thames Views, E. E. Barron.

Class IV., Architecture.—No. 302, silver medal, *Ann Hathaway's Cottage*, Harold Baker; No. 320, bronze, *A Bit of Old England*, Bulbeck & Co.

Class V., Portraits.—No. 494, silver medal, *Miss Lily Hanbury*, Harold Baker; No. 525, bronze, *Studies of Nan*, R. Ayton.

Class VI., Portraits.—No. 572, silver medal, *Study of a Head*, P. Lankester; No. 550, bronze, Portrait, O. W. Huntingdon.

Class VII., *Genre*.—No. 579, silver medal, *Chic*, B. Thornley; No. 596, bronze, *Lead Kindly Light*, R. Ayton; No. 602, bronze, *A Studio Corner*, F. P. Moffat.

Class VIII., Pictures by Artificial Light.—No. 648, silver medal, *The Miser*, H. E. Brightman; No. 658, bronze extra, *Study of Costume*, Harold Baker.

Class IX., Enlargements.—No. 369, silver medal, *Miss Lily Hanbury*, Harold Baker; No. 374, bronze, *Early Morning, Interlaken*, Rev. E. Rainbow.

Class X., Transparencies.—No. 774A, silver medal, set of eight, E. Brightman; Nos. 763 to 774, bronze extra, series, J. Phillip; Nos. 758 to 762, bronze extra, series, C. A. Brightman.

Class XI., Lantern Slides.—No. 780, silver medal, set of twelve, J. H. Gear; No. 779, bronze, set of twelve, F. Howard.

Class XII., Scientific.—Nos. 699, 700, and 707, silver medals, *Animals at the Zoo* (three sets), H. Sandland.

Class XIII., Process.—No. 719, silver medal, Three-colour Work, The Heliochrome Company; Nos. 723 and 735, silver, Collotype Reproductions, The Autotype Company.

Class XIV., Apparatus.—Silver medal, Gwyer's Improved Limelight Jet.

With a great deal of the work at Bristol we were already familiar, by reason of having seen it at various exhibitions during the past three years. The Judges appear to us to have acquitted themselves of their task with great success, for in this large display of singularly good and qualitatively even work, they must have felt no small difficulty in coming to their decisions. The award list shows that they have in many instances confirmed verdicts that have already been passed.

We think, as we thought three years ago, that the Bristol Committee adopts an unnecessarily minute classification, and that fewer classes are desirable. We have always been at a loss to understand why direct photographs should be judged according to area, *plus* quality, instead of by quality alone. We also desire to enter a friendly protest against the action of the Committee in hanging one of the exhibits. This is No. 197 in the Champion Class, *A Study*. It is a beautifully executed photograph on surface paper of a well-favoured young woman quite *in puris naturalibus*, with the exception of a piece of fabric which she holds to shield a small part of her person. We are quite sure that Mr. G. Lafayette is thoroughly sincere in regarding this exhibit as a work of art, and that the Bristol Committee are of the same opinion, but to us it appealed simply as the mere picture of a naked woman, having no other quality than that of being a good photographic record of a physical fact. Hence, we cannot think its inclusion in the Exhibition dictated by prudence or wisdom; and we repeat the hope we have often uttered in these pages, that Exhibition Executives will take the greatest care in dealing with photographs of this class. This photograph hangs in the Champion Class, in which the Judges withheld the gold medal. The class is only moderately good. We think that Champion Classes at photographic exhibitions are going out of favour, for some of the best work of the year is not now submitted to competition, so that the award, when made, by no means implies the value that once attached to it.

The Exhibits.

One result of what we may term the monotony of excellence which characterises this Exhibition, is to render the task of particularising the pictures at any length both difficult and undesirable, inasmuch as it would be hard to avoid platitudinous repetition. Let us, therefore, confine ourselves to the expansion of a few notes that we made during our survey. One is, that, since the last Exhibition here, the practice of "close-up" framing has come in for more general adoption, the result being that it is now possible to divest a wall of the spottiness and inharmony which once was a feature of most exhibitions. Again, we thought that white skies had long been relegated to neglect, but, in Class I., Mr. F. Spalding, with two views, *Waiting the Fox* and *Where Shadows Hide*, reminds us that progression in this important detail has not been so general as we imagined. He is one of several sinners in this respect We note in the class some capital Italian outdoor scenes by M. Victor Selb—a well-known Continental worker—and admirable examples by Gear, Gunston, Lintott, and many other habitual exhibitors.

The Champion Class contains such works as Alfred Werner's *Jadis*, a Reynolds-like portrait effect shown in the 1895 Salon; Bulbeck's *Ely Cathedral, Organ Staircase; The Master Hand*, by F. Moffat; a very good Portrait Head by R. S. Webster; Mr. R. J. Fry's last year's Pall Mall exhibit, *Parting Day;* Mr. Gear's *Silvery Morn;* Mr. Stieglitz's *Scurrying Home;* and many other well-known works. Lafayette, Harold Baker,

and Lankester also show fine examples of their skill in portraiture. But we thoroughly endorse the action of the Judges in withholding the gold medal, for there is nothing pre-eminently good in the class—nothing, that is to say, that has not, as the phrase runs, been done before, or can escape inclusion in the now classical Robinsonian description of "the usual thing."

Perhaps one of the strongest classes of the Exhibition is III., apparently devoted chiefly to hand-camera pictures. The forty odd exhibits are capital specimens of this class of work. Mr. Bulbeck's Thames Embankment views, printed in platinum, are little pictorial gems. These, with his other exhibits, place him quite at the head of the class. Mr. Inston and Mr. E. Evelyn Barron are also here prominent.

Architecture monopolises Class IV., among the ninety odd entries being contributions of great excellence from E. R. Bull, E. R. Ashton, Bulbeck & Co., J. T. Hopwood, Harold Baker, H. W. Bennett, Ernest Marriage, E. Brightman, and other masters of this branch of work. The class is, perhaps, one of the best collections of architectural photographs that we have seen for a long time.

In the Enlargement Class one has an opportunity of comparing the original with the enlarged picture. Mr. Harold Baker, a victorious pluralist here, and a worker of many-sided ability, shows a superb red carbon of *Miss Lily Hanbury*. The enlarged Swiss views of the Rev. E. Rainbow are exceptionally good in technique, and popular attention is sure to be arrested by the Autotype Company's well-executed enlargement from Mr. Watmough Webster's negative of Mr. Gladstone and Li Hung Chang. Mr. Harrison's seashore piece, depicting a dismantled craft *After the Storm*, also demands a word of praise. Messrs. West, F. Howard, Sandland, and T. H. Morton are also represented in the class, which is full of good examples of enlarging work.

We must own that the classes devoted to portraiture afforded us the most pleasure. To the Bristol Exhibition Committee we feel no inconsiderable gratitude for their encouragement of professional portraiture—portraiture not merely produced to gratify the whims of an individual exhibitor, out of whose hands it seldom goes, but to appeal to the public. We clearly recollect the portrait section of the 1893 Exhibition at Bristol—the "commercial" work suffered from an excess of retouching On the whole, the commercial portraiture of this Exhibition is an improvement on that of its predecessor, in that the art of the retoucher is less in evidence.

Mr. Yeo excels with several portraits of children, and of older subjects. His work manifests great improvement on past efforts. Mr. Harold Baker's contributions are marked by wonderful command over posing and lighting, and an unequalled power of infusing character into his sitters' faces. He is at home either in photographing a beautiful woman or a man with a rugged face. Mr. Lafayette has some highly finished specimens, and we welcome Mr. Byrne, who sends some charming studies of children. Three large portraits, by Mr. O. W. Huntingdon, are conspicuously good, but the exhibitor has a tendency to make the lights of his prints too hard, thus jeopardising the harmony of his effects. Lankester and Ernst Lambert also figure prominently in these classes.

The class for *genre* is well supported, and contains some undeniably clever things and some that just miss their mark. For example, Mr. R. Pratchett's boy who is unwillingly doing his *Home Lessons*, is taking the matter in a spirit of philosophy quite foreign to youths who are compelled to do as he is doing. We welcome the work of Mrs. Walter Gardiner, who shows two studies of an old rustic over his Bible on *Sunday Evening* and also over his pipe in *Quiet Enjoyment*. Such work, however, presents very little difficulty, although it is so good as to encourage us to hope that Mrs. Gardiner is capable of striking out into more original lines. Mr. C. M. Wane aims high in *Memories*. A girl has entered her father's study and is playing him a violin solo. The music evidently touches the widower's heart, for he looks sad and reflective. It is a cleverly executed bit of work, although we doubt the probability of a business man, seated at his study table and engaged with his papers, being consoled by the presence of a musical daughter. Orchardson once handled a similar theme—*Her Mother's Voice*—and the young lady, if we are not mistaken, was singing to her father in the drawing-room after dinner—a much more sensible plan than invading the poor man's study when he was writing cheques. *Lead Kindly Light*, a devotional subject, by Mr. R. Ayton, is clever of its kind. There are many other really able things in the class, particularly those by B. Thornley, Victor Selb, T. Lee Syms, F. P. Moffat, Miss Muriel Bell, and Dr. J. Griffiths, to which we wish we had space to refer in detail.

Subjects taken by artificial light occupy Class VIII. About thirty are shown, and the portraits by Mr. Baker and Mr. Lafayette betray all the softness of lighting of good daylight work. Mr. Fred Marsh has several examples of great technical excellence, depicting paper mills, gas works, &c., and a humorous study of a couple apprehending the presence of *Burglars* in the house.

The Photo-mechanical Class (XIII.) is notable for its interesting entries. Three-colour work is shown by Raithby, Lawrence, & Co. and the Heliochromo Company; half-tone by both firms; collotype by S. B. Bolas & Co. and the Autotype Company. The latter firm's collotypic reproductions on satin are of exquisitely beautiful quality. Flowers, animal studies, and the now inevitable skiographs appear in Class XII. (scientific).

With mention of the fact that the Lantern-slide Class is well supported in quality, we pass to the Transparency Class—always a strong one at Bristol. Mr. H. N. King has a series of stereoscopic transparencies, and single views from his well-known architectural subjects—quite in Mr. King's old and familiar delicate style. Mr. E. Brightman has some beautiful local views on glass, and it must be a source of satisfaction to this well-known old-time worker to find, side by side with his own pictures, two series from his sons—Mr. H. E. Brightman and Mr. C. A. Brightman, chiefly of West Country ecclesiastical architectural subjects, and quite irreproachable in execution.

Among the other contributors to the Exhibition are Messrs. W. C. Hemmons, J. Kidson Taylor, H. O. Isaac, F. H. Worsely Bennison (he shows some of his favourite sea pieces), H. Smith (some charming East Anglian landscapes), S. G. Payne, T. M Brownrigg, Charles Job, J. H. Coath, W. Norrie, Captain H. Owen, John Warrack, &c.

The Apparatus Section.

Mr. Harold E. Brightman has a large collection of Ross, Zeiss, and Goerz lenses, Beck's Frena cameras, and Optimus apparatus, with examples of work done therewith. Mr. Henry Park's cameras, &c., are also shown by Mr. Brightman. Mr. M. W. Dunscombe has a case of lenses and cameras, and Watson's and Marion's apparatus, &c. The display of Messrs. Husbands comprises cameras of various kinds—hand and stand, lenses, shutters, enlarging cameras by Hume, projection lanterns, &c. A pretty and attractive exhibit is that of Messrs. Ferris, who have a case of specimens of chemicals used in photography tastefully displayed in an elegant show-case. Messrs. Willway show the Gwyer jet and saturator, the former of which obtained an award.

We conclude by congratulating the Bristol Executive on having got together a splendid Exhibition, and we remind them that in the year 1899 the opportunity will be theirs of closing one century and opening another with an Exhibition of photographs which, if it is as worthy of photography as is that just opened, will reflect nothing but credit upon all concerned. The Exhibition Committee consists of Messrs. H. W. Atchley, F. Bligh Bond, Edward Brightman, T. Butler, H. A. Hood Daniel, Thomas Davey, T. Taylor Genge, T. G. R. Harding, W. C. Hemmons, Sydney J. Hill, Thomas Letchford, W. Norgrove, Colonel Playfair, Geo. H. Perrin, John Phillips. Hon. Treasurer: Wm. Mohne. Hon. Secretary: Martyn Lavington.

The Inquirer.

*** In this column we from time to time print questions that may be addressed to individual contributors to our pages, or such as are sent to us with the view of eliciting information from a variety of sources. We invite the co-operation of our readers in rendering this feature of the* JOURNAL *useful and instructive.*

QUICKLIME.—(To J. Hastings.)—"Let this correspondent raise the 'perished' lime to red heat in a crucible or other suitable vessel, and after cooling he will find it all right."—J. BEAVIS.

ACTION OF SALT.—(To Cum Grano.)—T. R. writes: "Your friend probably has an active imagination, or, if he finds salt removes stain from negatives, it is not 'good old pyro' stain, while its hardening action is *nil*. Probably he has found a 'mare's nest,' and persists in sticking to it."

SULPHITE OF SODA.—COLLODIO-BROMIDE writes in reply to J. B.: "Sulphite of soda, and more especially the bisulphite, and I dare say metabisulphite of potash, have undoubtedly a decided effect upon the colour of the developed image in collodion emulsion; the larger the quantity used apparently the redder the image. But in using the two last, great inconvenience arises from the uncertain quantity of ammonia required to neutralise the free acid they contain before the development can proceed. In fact, it is extremely difficult to know what is the real developing strength of the solution, and whether an image that is backward in coming up is suffering from under-exposure or over weak developer."

TONING WITH MERCURY.—F. V. says: "I notice, in last week's JOURNAL, reference is made to a method of toning gelatino-chloride and collodio-chloride prints by means of a solution of mercuric chloride and salt. But I gather from the paragraph that this treatment is to be preceded by toning with gold, so that there appears to be little advantage in the use of mercury. Is it not possible to utilise a very weak solution of mercuric chloride in place of gold, and in the same manner? When 'purple' tones are not desired, I think such toning is feasible, and as to permanence, I see no reason why it should not be sufficiently stable for much of the work now turned out."

SYNTAX also writes: "In reply to Cum Grano, although salt probably possesses no hardening action upon gelatine, it may possibly act as a preventive of frilling, and was, in fact, recommended for that purpose some years back. Its action in that direction depends upon the rapidity and ease with which it diffuses itself when in solution, a property that enables it to penetrate quickly into and out of the gelatine film. Frilling has been set down by some writers to the action of the strong hypo solution in forcing its way out of the softened gelatine film, and the action of the salt by aiding its easy diffusion, as well as by supplying a solution of higher specific gravity *outside* the film, was supposed to relieve the over-pressure from within. In a similar manner it has been used for the prevention of blisters in albumen paper. The power of salt in removing pyro stain—or, indeed, any kind of stain—is not very apparent."

"PITS" IN GELATINE FILMS.—J. H. P. writes: "A week or two back Mr. A. L. Henderson spoke of 'pits' in gelatine negative films. I should like to know if he refers to a defect that I have recently met with in using a well-known brand of plates, though I have never experienced it with any other. I was under the impression it was purely a hot-weather trouble, but it has reappeared within the last few days, when, although the weather has not been severe, it can scarcely be called warm. The defect takes the form of small hollows or depressions in the film, which only make their appearance after the film has been developed some time. They vary in size, are cup shaped, and, in the large ones, the centre is transparent, and, of course, they show to the greatest advantage (?) in the sky of a landscape, or in a portrait negative. I should be glad if Mr. Henderson, or any other reader of these lines, could suggest a remedy, as I do not wish to relinquish that brand of plates."

Our Editorial Table.

THE "AMBER" CAMERA.

The Thornton-Pickard Manufacturing Company, Altrincham, near Manchester.

IT is somewhat difficult nowadays to introduce a camera which may be allowed to possess any points of novelty, but in this task Messrs. Thornton Pickard have, we think, succeeded. The Amber camera, which we have subjected to thorough examination and trial, is their latest introduction, and it not only embodies some useful and fresh features, but it has the further advantages of being practical and effective and extremely cheap.

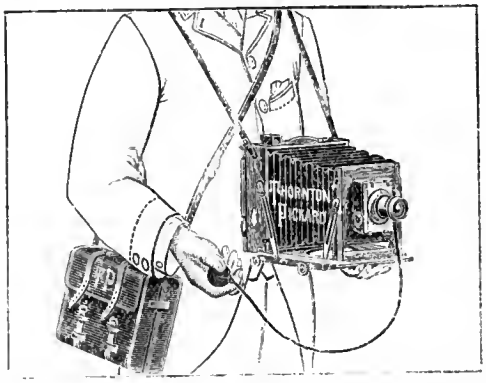
The Amber is of the now familiar conical-bellows form, and is extremely light and portable. It is fitted with a turntable, and, by the simple pressure of two springs on the camera front, and the elevation of the stretchers, the front folds down into the open base-

board without detaching. The front has an independent rising movement, and can be inclined to give the necessary swing that may be required. The shutter—one of the firm's well-known blind instruments—is fitted behind the lens.

By means of screw adjustments, an extension of some seventeen inches is obtainable, while, on the other hand, the instrument, when racked in, is so compact as to allow of the use of extremely short-focus lenses. The back, of course, has a swing movement, and also reverses; while other special features of the camera may be briefly indicated as self-locking stretchers, a spring-hinged detachable focussing screen, a plumb indicator, and a focussing scale for hand-camera work, thus constituting the Amber really a photographic luxury.

Perhaps the most novel feature of the camera lies in the way in which the dark slide is manipulated. The slides are of "solid" form, the plates being inserted from the front and firmly held by spring catches. The slide, as shown in the illustration, slips in from the top between the screen and the camera. No side-push is necessary, and the slide is removed by merely lifting the spring bar

at the top which holds it in position. We can testify to the fact that the movement is a very simple and effective one, working well



in practice, and when the camera is slung round the neck by means of a strap for hand-camera work is a great convenience.

There is one characteristic of Messrs. Thornton-Pickard's productions which always goes a long way towards making them popular. We allude to their "sweetness" of movement. The camera before us, in spite of its cheapness, is beautifully made and finished, and folds and unfolds, racks in and out, and generally comports itself with all the precision of the most delicately constructed scientific instrument.

The Amber camera is easy and pleasant to use. It does almost everything that a camera can do, and we have no doubt that in the coming season it will be popular among our amateur friends, for whose requirements it is well adapted.

News and Notes

THE Scottish Acetylene Gas Company, of Glasgow, have now two studios in Glasgow working acetylene with their generator.

ALPINE CLUB.—The Club is holding an Exhibition of Alpine Photographs and Old Prints at the Club-rooms, 23, Savile-row, W. The Exhibition remains open till December 31, from nine a.m. to six p.m.

THE AUSTIN-EDWARDS MONTHLY FILM NEGATIVE COMPETITION.—The Prize Camera for current month has been awarded to Mr. J. A. Wilson, Knowehead, Ballymena, Co. Antrim, for his negative, *Shoeing the Old Horse.*

MR. ESMÉ COLLINGS, of 175, New Bond-street, writes:—"In your notice of Mr. Friese-Greene's lecture, you state that the 'Lord Mayor' film was taken by Mr. Wrench. This is an error, as it was taken by Esmé Collings, of London and Brighton."

PHOTOGRAPHIC CLUB.—The next weekly meeting of the Club will be held in the Club room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock on Wednesday evening, December 23. Mr. John McIntosh will read a paper entitled *Intensification and Reduction*, which he will illustrate with lantern slides. Visitors are welcome.

TERRIBLE ACETYLENE EXPLOSION IN BERLIN.—The Berlin Correspondent of the *Daily Chronicle* telegraphs:—"On Saturday afternoon, in the Moabit quarter of Berlin, a fearful explosion of acetylene gas occurred in the laboratory of Herr Georg Isaac, manufacturing chemist, which resulted in the death of Isaac and three of his assistants. The bodies were found horribly mutilated and burnt. The laboratory and its contents were wholly destroyed by the terrific force of the explosion."

THE FACTORY ACTS: A PHOTOGRAPHER PROSECUTED.—More than usual interest was taken in a case which came before the magistrates sitting at the Oldham Police Court recently, inasmuch as a lady factory and workshops inspector appeared to prosecute Joseph F. Beaumont, photographer, No. 6,

Park-road, for having committed a breach of the Factory and Workshops Act. Adelaide M. Anderson, factory inspector, stated that on Sunday, the 18th ult., about eleven o'clock in the forenoon, she called at this photographic establishment, which was a workshop within the meaning of the Act, and found a young person employed. An abstract of the Act had previously been forwarded to the firm. This Sunday work seemed to be a systematic arrangement, for they had two young persons who worked alternate Sundays. The points were not, she understood, disputed. This case had been taken more as a warning to others than anything else. Mrs. Beaumont, who appeared on behalf of her husband (the defendant), pleaded ignorance of the law. She did the business, and did not notice particularly the abstract when it was sent to her. It was entirely an error. A fine of 2*s.* 6*d.* and costs was imposed.

A WARNING.—Messrs. Major & Darker, of Falmouth, write:—"We think if you insert the following particulars, you may save a brother photographer being victimised by a swindler, who is evidently going from one situation to another, leaving suddenly with all he can lay his hands on. In our case we engaged him as operator and retoucher a month ago, and on December 5 he suddenly disappeared, taking with him a complete half-plate outfit, and also a 5×4 Perken & Rayment R.R. lens, which he had been sent to do an outdoor job with. From information received, he evidently left Plymouth on the fifth, and the police cannot find out his whereabouts. While he was with us, he mentioned that he had some cameras and lenses in pawn if we wanted to buy any, which, without a doubt, he obtained in the same way. The man is about 5 ft. 9 in., of a military appearance, rather fair, with long moustache only; when he was focussing or retouching, he wore eyeglasses, as he was rather short-sighted. If any of your readers have engaged a man of his appearance between the fifth and now, this will put them on their guard and perhaps save them being victimised. We may say we have a photograph of the man, which we would be willing to send to any one in doubt."

THE ACETYLENE EXPLOSION AT OLNEY: INQUEST.—An inquest was held at the Bull Hotel, on Friday, December 11, by Mr. J. Worley, to inquire into the circumstances attending the death of Ernest Munro Field, who was found dead in the cellar of his father's house. Mr. A. Field, father of the deceased, said his son was eighteen years old on Sunday, December 6. He last saw him alive on Wednesday evening, December 2, about 7.20, when he (deceased) was going to a drawing class. Witness did not reach home until eleven o'clock on Wednesday night. He noticed that his son's boots were not in the room, and sat up till 11.30, when he went to bed. As he did not hear his son arrive he arose about twelve, and on going into the cellar found deceased lying there dead. He called his wife, and then fetched the doctor. The deceased was very fond of engineering, and had been making acetylene gas in a generator of his own manufacture for two or three months. The generator was formerly in a shed in the yard, but had recently been taken into the cellar. Mrs. Freeman, who lives next door, said on the evening in question she heard a report as of a large gun, about 8.30. The report seemed to come from deceased's home, but as they could see nothing to cause alarm either at the back or the front of the house, no notice was taken of the matter. Dr. Grindon said he was summoned by the father of the deceased a little after twelve on the night in question. He accompanied him home, and found deceased lying on his back in the cellar quite dead. There was a severe wound on the face, the nose being cut clean through. The wound had bled profusely. There was a quantity of lime on deceased's hair and on his cap, which was on the generator. In his opinion death was caused by concussion, the effect of the blow on deceased's face. Mr. G. C. Rabin, one of the jurymen, said in his opinion deceased had gone down the cellar to recharge the generator, and on removing the lid the gas remaining in the generator exploded through coming into contact with the candle deceased was supposed to be carrying. The explosion forced the generator (an oil drum) sharply upward, striking deceased on the face, and inflicting the wound on deceased's face. A verdict of "Death by misadventure" was returned.

"IS A PORTRAIT A GOOD TRADE MARK?—This point," says *Invention*, "was settled in the Court of Appeal on December 2. In the case of Rowland *versus* Michell, an appeal against a decision of Mr. Justice Romer, the plaintiff was Mr. James Rowland, of Lant-street and Little Suffolk-street, Southwark, who is a manufacturer and wholesale dealer in confectionery, including certain cough-drops known as the 'Army and Navy Paregoric Tablets.' These are done up and sold in twopenny tins and penny packets. The labels on the tins and packets bear amongst certain other words those of 'Rowland's Army and Navy Paregoric Tablets,' and a mark or device of an oval ring enclosing a portrait of the plaintiff. This portrait is the substantial part of the plaintiff's trade mark, No. 155,638 (Class 42, Confectionery), which was registered in 1891. The defendant was John Michell, of Parkhouse-street, Camberwell, against whom the plaintiff commenced this action in October, 1895, to obtain an injunction to prevent infringement of the plaintiff's trade mark and imitation of his goods. The defendant, on the other hand, moved to expunge the registration of the plaintiff's trade mark. The defendant alleged that the portrait of an individual was not the proper subject of a trade mark, that it was not a 'distinctive device' within the meaning of Section 10 of the Trade Marks Act of 1888. He also alleged acquiescence on the part of the plaintiff, and that the plaintiff had in practice misrepresented the nature of his trade mark. The learned Judge held that the portrait formed a good trade mark, and overruled the other defences. He refused the motion to expunge, and granted an injunction restraining the defendant from selling his goods under three labels particularly complained of, or in any wrapper or in any manner calculated to pass his goods off, or enable other people to pass them off, as the goods of the plaintiff. The defendant appealed. The Court dismissed the appeal. The Lord Chief Justice thought that the portrait was a 'distinctive device' within the Act. The mark ought to be something capable of distinguishing the particular goods with which it was used from other goods of the same kind, and there could not well be anything more distinctive than the portrait of the manufacturer. His Lordship also held that there was no foundation for the other defences. Lord Justice Lindley and Lord Justice A. L. Smith concurred."

Patent News.

THE following applications for Patents were made between December 2 and 9, 1896:—

CAMERAS.—No. 27,363. "Improvements in or connected with Photographic Cameras." W. E. ASQUITH.

CAMERAS.—No. 27,433. "Improvements in Photographic Cameras." B. F. S. BADEN-POWELL.

SCREEN KINETOSCOPY.—No. 27,585. "Improvements in Apparatus for Taking and Exhibiting Photographs in Series." Complete specification. E. WERNER and M. WERNER.

PRINTING FRAMES.—No. 27,619. "Improvements in Photographic Printing Frames." H. J. SPRATT, A. S. SPRATT, and G. A. SPRATT.

OBJECTIVES.—No. 27,635. "Improvements in Photographic Objectives." P. RUDOLPH.

KODAK FILM CABINET.—No. 27,647. "A New or Improved Kodak Film Cabinet for Preserving Kodak Negatives and the like." M. L. SANDERS.

FRAMES.—No. 27,723. "Improvements in Frames for Photographs, &c." D. A. P. ANDERSON.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

December.	Name of Society.	Subject.
21	Bradford	Members' Lantern-slide Competition.
21	Ealing	Discussion: *Backed Plates versus Films or Sandell Plates.*
21	North Middlesex	*General Survey of Year's Work.* H. Smith.
21	Richmond	*Finishing the Negative.* The President.
21	Southland	Instantaneous Effects.
21	Stafford Y.M.C.A.	*Intensification and Reduction of Negatives.* Mr. Cooper.
22	Birmingham Photo. Society	Members' Lantern Evening.
22	Hackney	*The Manufacture of Wall Paper.* Jno. Gardner.
22	Newcastle-on-Tyne	*Pictorial Photography.* A. H. Hinton.
22	Rotherham	Prize Slides, 1896.
23	Borough Polytechnic	Members' Open Night.

23	Photographic Club	*Intensification and Reduction.* John McIntosh.

ROYAL PHOTOGRAPHIC SOCIETY.

DECEMBER 15,—Photo-mechanical Meeting,—Mr. Leslie E. Clift in the chair

PHOTO-ENGRAVING TROUBLES.

Mr. ANDREW WYBRANDT PENROSE read a paper on

SOME PROBABLE CAUSES OF TROUBLE IN PHOTO-ENGRAVING,

dealing in a simple manner with the purity or otherwise of some of the chemicals employed in process work, and demonstrating methods for the detection of impurities. Ammonium bichromate nearly always contains free chromic acid, which he had no hesitation in saying was the cause of bichromate poisoning, and the only remedy was the use of the recrystallised variety. Ammonium sulphydrate, or "stinko," was often watered down, when it merely blackened the outer surface of the silver salt in the negative, producing bad stains, and operators should only ask for and accept that of the strength known as "fort." Glacial acetic acid should have a specific gravity of 1·058, and should solidify at 50° Fahr.; if, on the addition of a few drops of a solution of $AgNO_3$, the acid remained clear, sulphates and chlorides were not present. The presence of sulphuric acid in nitric acid might be detected by the addition of a few drops of a solution of barium chloride, when a white precipitate would be formed if sulphuric acid were present. The so-called explosions of nitric acid were probably not explosions at all, but breakages of carboys, arising from accidents, or were due to NO_2 not finding room for expansion. Dragon's blood had found little favour in England, although much used in America, and this was probably due to the fact that the sources of supply were different. The American variety was drawn from a tree growing in the West Indies, and called *Pterocarpus draco*, while that met with in England came from the East Indies, and was obtained from a palm-tree called *Calamus draco*, and from other plants in Guiana and South Africa, and was always more or less adulterated. A rough test for dragon's blood consisted in igniting a small heap upon a good burning paper; it should burn readily and steadily, leaving but little ash, and giving off an agreeable odour, not unlike gum benzoin. The most suitable strength of cyanide was about thirty-five per cent., which would do its work in less time, with less staining, and would last longer than the lower grades. The specific gravity of ether should not exceed ·725; it should have no acrid smell, should be washed and redistilled at least once, and if one drop of tincture of iodine were added to one ounce of ether, the colour should not be discharged after standing for three or four hours. The use of a hydrometer or specific gravity bottle was strongly recommended. Filter-papers frequently contained impurities, the Swedish variety being the best and the Dutch the worst. Silver nitrate solution should never be filtered through paper, but should be allowed to subside and then decanted. In boiling down silver baths, the cracking of the "crock" might be obviated by covering the top of the tripod with fine copper gauze, or by placing the basin in a sand bath. The paper concluded with the expression of the opinion that the severe competition in the photo-engraving business had compelled principals to buy rather from considerations.

of cheapness than quality, and that depreciation in quality must inevitably follow when the market value of an article was reduced to the lowest point.

Mr. W. E. Debenham understood Mr. Penrose to say that bichromate poisoning was caused by free chromic acid in ammonium bichromate, but he was under the impression that cases had occurred where bichromate of potash was used. He had never traced any injurious effect to filter papers, and pointed out that it was not easy to discontinue their use, because, although sediment might be got rid of by means of decanting, anything which rose to the top of a solution could not be so treated. He did not think the quality of chemicals had deteriorated with the reduction in price which had taken place in recent years.

Mr. H. Chapman Jones said his experience was that the standard of purity in chemicals was well maintained.

Mr. T. Bolas also said that when chemicals were obtained from reputable firms, they could be depended upon to be as represented.

Mr. Carl Hentschel wished something had been said upon the subject of fish glue, which he thought was liable to be affected by atmospheric influences. He had noticed, also, that bichromate of potash, when mixed with other chemicals, was considerably affected by a thunderstorm. He asked whether there was any objection to filtering silver baths through the finest and purest cotton wool.

The Chairman complained of the great variation in different samples of fish glue which were supposed to be identical.

Mr. W. Gamble agreed that fish glue was subject to atmospheric influence, a good many difficulties arising during cold weather. Greasy spots sometimes appear, due, he thought, to the partial solidifying of the essential oil used in the preparation of the glue. He had got over this trouble by shaking up a little ether with the glue, and afterwards filtering. Temperature was at the bottom of a good many faults for which chemicals were blamed.

The Chairman's experience was that ordinary fish glue gave better results than the clarified variety.

After further remarks by Messrs. Vincent, Gamble, Herbst, Hentschel, and the Chairman.

Mr. Penrose replied to some of the points which had been raised. He thought the Swedish filter papers could be relied upon, but absorbent cotton wool was a very good filter, and acted rapidly. It was possible that nitric acid might explode spontaneously under some extraordinary conditions, probably due to the liberation of nitric peroxide within a confined space, and without a ready outlet, but the so-called explosions were generally caused by the fracture of a carboy. Fish glue was a subject calculated to send the student to an early grave, and any one who discovered practical methods of remedying the evils arising from its use would render a valuable service to photo-engravers.

The Chairman, in moving a vote of thanks to Mr. Penrose, invited all who were interested in process-work to attend the monthly photo-mechanical meeting of the Society, and to take part in the discussions.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

December 10,—Mr. T. E. H. Bullen in the chair.

The Chairman referred to a new form of permit for the reproduction of copyright pictures as suggested by Mr. Gambier Bolton in the Almanac, with the stipulation that after its use for the purpose agreed, the block shall be destroyed by the printer. Speaking from his own experience with engravings, the Chairman said it was hardly safe to depend on the good faith of the printer to do this. The plates, or reproductions of them, generally found their way into the market after ten years or so, and, in his opinion, the only safe course was to have the block returned after use. The form given in the trade, and used by Cassell, Routledge, and others, was in terms which gave the right of reproduction, for a certain sum, in the publications of the party, and those only, the block to be returned and not otherwise parted with or sold. A short discussion ensued.

Mr. Paul Martin asked for information as to the best way of coating plates with gelatine. His idea was of making lantern slides by the carbon process, but he had been much troubled to avoid bubbles, which appeared in very minute form.

Mr. A. Haddon said the gelatine should be filtered, and recommended the use of a teapot for pouring the same. He proceeded to sketch a contrivance consisting of a tube, one end of which was covered with a muslin strain, passing through a bung fixed in the teapot, through which the surplus of gelatine from the plate is filtered before mixing with the bulk itself.

The Chairman added that a slight addition of alcohol to the gelatine enabled the latter to flow with more ease.

Pyro-metol Developer.

The Chairman said he had recently been experimenting with various developers, and had found very extraordinary results from the use of pyrogallic acid and metol in combination. The mixture possessed all the energetic qualities of the metol, and at the same time the density giving power of the pyro. The tests were made with a Warnerke sensitometer, to which two plates were exposed in the ordinary way. These were developed for ten minutes with a pyro-soda developer, and, at the expiration of this time, washed. He then tried to see whether they would go any further, and to one plate put a fresh pyro-soda developer, while the other was placed in a pyro-metol developer. The former seemed to have attained its utmost, however, and the second treatment had apparently no influence whatever. The second plate, however—that in the pyro-metol solution—developed up four or five more numbers on the scale: and, while the highest tint with the pyro-soda was about twenty, that of the pyro metol reached twenty-four or twenty-five. Further experiments were made with two plates which were exposed in the same way, and developed, one with pyro-soda and the other with pyro-metol, from the commencement. This latter showed ten numbers and considerable density in the lower numbers before any image was shown by the pyro-soda, but the ultimate result was not so great, the pyro and metol having an advantage of three or four gradations. In reply to a question, he said he judged by the negatives.

PHOTOGRAPHIC CLUB.

December 2,—Mr. Stretton in the chair.

Messrs. George Hana, Thomas Fall, and George J. Wright were elected members of the Club.

Mr. James Sinclair gave a practical demonstration of the process of

Carbon Printing without Transfer,

commonly known as the Artigue process. Touching lightly upon the history of the process, Mr. Sinclair said that it was the oldest of any carbon printing method. The Artigue tissue was probably coated with a gelatine substratum, upon which was spread some vehicle, perhaps albumen, containing the pigment. Only one colour, black, was available at present. The tissue is fairly translucent, and this is a factor essential to success. The demonstrator recommended the immersion of the tissue in a two per cent. bichromate bath, which might advantageously contain a small percentage of alcohol. By this addition certain troubles which might arise during the drying of the tissue if the temperature of the drying-room exceeded 65°, or during its sensitising should the temperature of the solution exceed 60° Fahr., are avoided. Five per cent. of alcohol is a suitable amount. The tissue can be sensitised by brushing a five per cent. solution of bichromate of potassium over the back, but the immersion method was preferable. The tissue should be used soon after being sensitised. The continuing action of light is slight, but success is assured by using freshly sensitised tissue and developing the pictures without unnecessary delay. The time of printing required must be first ascertained by a trial print. A sensitometer is necessary, and he preferred a strip of paper sensitised in the same bichromate bath as the tissue. This paper turns brown upon exposure to light. After exposure, the image is slightly visible by transmitted light—if very strong, over-exposure may be anticipated. Development is effected by soaking the exposed paper, first in cold water, and then in warm water—temperature 82°. This must be ascertained accurately with the aid of a thermometer. The image appears in relief in this second bath, and must subsequently be "developed" by pouring upon the tissue (which must be properly supported for the purpose) the special "sawdust soup" at a temperature of 65° to 70°. In effect, the real development depends upon the erosive action of the moist sawdust. For over-exposure a thicker "soup" is required, in order to remove, by increased friction, more of the pigment. For under-exposure the printed tissue may be placed direct into the warm-water bath—temperature 82°—without previous immersion in cold water, and this variation should be followed by the use of a thinner "soup." The image must be developed until it appears rather lighter than it is ultimately desired to be, as the print darkens in drying. When sufficiently developed, wash the print in cold clean water, and place in an alum bath. As an alternative the print may be dried before the aluming, and the development may be afterwards carried farther if desirable. It was added that a brush might be used as a substitute for, or as an assistance to, the "sawdust soup" in the development if it were desired to give a quasi-artistic appearance to the prints. Mr. Sinclair gave a successful demonstration of the process. He also showed some examples of work by it which were excellent in every way.

December 9,—Mr. George W. Tottem in the chair.

Major Thomas was elected a member of the Club.

Mr. Hedley M. Smith described the

Chronophotographer,

a new cinematographe apparatus made by Mr. Gaumont, Paris, said Mr. Smith, was the home of the cinematographe. There were good machines and bad ones there as elsewhere. For the best machines the very highest prices were willingly paid, whilst the inferior articles could be bought as low as seventy-five francs each. Mr. Gaumont's apparatus moves the film without relying upon the dragging action of a toothed wheel, and in this differs from most other machines. The positive image upon the film occupies four times the usual area, and the instrument therefore gives a more luminous projection. Films of any length can be used in the instrument, and the electric light is to be preferred on account of its greater power.

Mr. Gaumont demonstrated the use of his machine, and showed a succession of pictures comprising the following subjects:—Oxen ploughing, Japanese ballet, Soudanese bathers, departure of the motor cars for Marseilles, Loie Fuller in the Serpentine dance, dragoons at exercise. The instrument worked in a smooth and comparatively noiseless manner, and the steadiness of the image was noticeable. After the demonstration Mr. Gaumont showed the working parts of the instrument, and through Mr. Hedley Smith answered several questions.

Mr. Drage said he was sure that everybody was pleased with what had been shown, and especially pleased to see Mr. Hedley Smith. The meeting was indebted to him and to Mr. Gaumont for a very enjoyable exhibition.

Mr. Smith returned thanks for an attentive hearing on behalf of himself and Mr. Gaumont. He was very glad to meet with his old friends again.

Mr. Charles Wallis gave a short lantern lecture entitled,

My Holiday Trip with the Camera.

Mr. Wallis accompanied the exhibition of his slides with a running fire of characteristic humour and wit.

Hackney Photographic Society.—December 8, Mr. R. Beckett presiding.—Mr. J. H. Gear gave a lecture on

Combination Printing,

and showed a number of fine prints and slides to illustrate his remarks. On the question of getting clouds on the same plate as the landscape, he said that in most cases such was not desirable, because, if the clouds were secured, in all likelihood, they would not agree with the composition of the subject. No landscape or seascape should have a perfectly white sky, neither should the latter be represented of one uniform tint. It might be argued that, occasionally, this was a perfectly natural condition—that, when the view was taken, there were no clouds. To this he would reply by asking, Why should nature be portrayed in her inartistic moods, rather than be represented in a way that would appeal to the cultivated taste? The lecturer then dealt thoroughly

with the various methods of combination printing, such as the introduction of figures into landscapes, printing in skies under different conditions of subject, &c. After showing the need for, and application of, combination printing, Mr. Gear warned those who contemplated taking up the subject of the necessity of being careful in every detail, or their sins would find them out.

North Middlesex Photographic Society.—December 14, Mr. A. J. Golding in the chair.—The following gentlemen were nominated for membership:—Messrs. R. J. Wilson, J. Durston, C. S. Ball, J. Angus, Ernest Clarke, C. H. Wilkins, and Albert Lord Tyler. The CHAIRMAN read a telegram from Mr. Horsley Hinton, regretting he was unable to read his paper on

PICTORIAL PHOTOGRAPHY.

In his absence, the paper was read in a very able manner by Mr. MARCHANT. The paper provoked a great deal of discussion, in which Messrs. Child Bayley, Cox, Bennett, Golding, Goodwin, Marchant, Mattocks, and Mummery took part. A vote of thanks was passed to Mr. Horsley Hinton for his paper, and to Mr. Marchant for reading it.

Polytechnic Photographic Society.—December 9.—The HON. SECRETARY gave a demonstration with the oxy-hydrogen lantern, explaining the various parts of a lantern, jets, limes, &c., and passed some slides through illustrative of the many tones, shapes, and processes used in lantern-slide making. Special tones for special subjects called forth many opinions. The meeting closed with the addition of two new members. At the New Year there will be an exhibition of members' work.

Putney Photographic Society.—December 7, Dr. W. J. Sheppard in the chair.—Mr. JOHN A. HODGES (Vice-President) gave

HOLIDAY RAMBLES WITH A CAMERA.

A most excellent set of slides, including scenery of Devonshire, Wales, the Lake District, &c., was shown. One or two had white margins, which formed quite a pleasing variation to the usual close-masked slide. The hall (specially hired for the occasion) was well filled with an appreciative audience of members and friends.

Richmond Camera Club.—December 7, Mr. Purcell presided.—Mr. EF DOCKREE, of the Brixton and Clapham Camera Club, gave an exhibition o, lantern slides. Mr. Dockree's work is well known in the photographic world and the slides he showed were as varied in subject as they were excellent in quality, and were described in a lucid and humorous manner. The evening was voted by common consent one of the pleasantest in the annals of the Club.

South London Photographic Society.—Mr. H. E. Farmer in the chair.—The PRESIDENT (Mr. F. W. Edwards, F.R.P.S.) gave an address on

ISOCHROMATIC PHOTOGRAPHY.

He first gave an outline of the subject, afterwards dealing with the advances made during the last two or three years. He afterwards, by means of a lantern, projected images of various coloured objects under notice on the screen, and, by means of a second lantern, photographs of the articles taken with ordinary and the different isochromatic plates on the market, with and without colour filter, were thrown on the screen and explained. The PRESIDENT promised to give a lecture on the making of colour filters at a later date.

Woolwich Photographic Society.—December 10, Mr. H. H. Barker in the chair.—A popular lecture was delivered to about 100 members and friends by Mr. F. O. BYNOE, of Messrs. R. & J. Beck, entitled,

INSTANTANEOUS PHOTOGRAPHY,

illustrated by lantern slides taken with the celebrated Frena cameras. Mr. Bynoe gave some very practical hints as to holding a hand camera for exposure, also the use of the swing back, showing pictures taken with and without the swing back. The slides shown were of excellent quality, and quite bore out the lecturer's statement that a swing back was an absolute necessity for certain kinds of work. Mr. Bynoe also explained the use of the Frena magnifier by means of a mechanical slide, which showed clearly the means of bringing close objects in sharp focus with a fixed-focus camera. A very hearty vote of thanks was accorded Mr. Bynoe for his very interesting lecture.

Birmingham Photographic Society.—December 8, Mr. G. F. Lyndon, J.P., in the chair.—About thirty members present. Mr. P. T. Deakin Hon. Assistant Librarian) gave a One-Man Exhibition and a short account of his methods of working. The Exhibition consisted of 150 half-plate pictures printed in bromide, platinotype, and carbon, the subjects being very varied, comprising landscape, architecture (interior and exterior), cloud, flower and figure studies, and portraiture. In his remarks upon his method of working, Mr. Deakin explained his very systematic way of keeping a record of all negatives and prints. The developer used was pyro-soda, and during the last twelve months or so he had taken to printing in carbon, as, in his opinion, it was by far the best process for rendering all the delicacy of the negative. He worked entirely with home-made apparatus. A collection of views of Cannock Chase showed that Mr. Deakin knew how to make a picture from very simple surroundings. The CHAIRMAN, in proposing a vote of thanks, congratulated Mr. Deakin upon the excellence of his exhibits and the care with which they had been printed and titled. Mr. ROBINSON, in seconding the proposition, also congratulated Mr. Deakin upon the excellence of his work and the variety of the subjects selected. Messrs. UNDERWOOD and FOWLER supported the proposition.

Cardiff Photographic Society.—December 11.—Mr. HARRIS made some interesting remarks on

BROMIDE PRINTING,

handling his subject in a very scientific manner. There was a good deal of discussion upon the points raised, but Mr. Harris laid stress on there being, as a rule, too little importance attached to varying the distance from the source of light in making contact prints. Several examples were shown of prints produced under the conditions recommended. The relative speeds of the various commercial papers was mentioned in connexion with remarks upon the scale of gradation obtainable from slow and rapid kinds. Mr. Harris succeeded in showing that, in a great measure, success in bromide printing depended upon the selection of a suitable distance from the source of light as much as anything else, and that this distance depended upon the character of the negative and the result required. The acetylene light was shown by Mr. Jesse Williams, and much admired. In the club lantern it gave a well-illuminated six or seven feet disc at about twenty feet from the screen. The light was very steady and appeared likely, with ordinary care, to give no trouble.

Liverpool Amateur Photographic Association.—December 10, the Annual Meeting was held in the Artists' Club, the retiring President (Mr. J. Sirett Brown) in the chair.—Sixteen new members were balloted for and elected. Dr. J. W. Ellis, F.E.S., was elected President for the ensuing year, the Vice-Presidents being Messrs. W. Prior Christian and E. Rimbault Dibdin. The Hon. Treasurer (Mr. P. H. Phillips) and the Hon. Secretary (Mr. Fred A. Schierwater) were re-elected. The customary votes of thanks to the officers and Judges for their services, and to the Artists' Club for the use of their room in which to hold the meeting, were passed unanimously. The Judges' awards in the annual competition were then announced as follows:—Champion Class.—Challenge cup and gold medal: Dr. J. W. Ellis. Half-plate and under: silver medal, Rev. William Smith; bronze medal, Mr. J. D. Paterson. Over half-plate: silver medal, Dr. Llewellyn Morgan; bronze medal, Mr. E. R. Dibdin. Lantern Slides.—Silver medal, Dr. J. W. Ellis; bronze medal, Dr. Llewellyn Morgan. Enlargements.—Silver medal, Mr. Joseph Appleby; bronze medal, Mr. Edwin Simnett. Stereoscopic Slides.—Silver medal, Mr. J. T. Norman-Thomas. Hand-camera Work.—Silver medal, Dr. J. W. Ellis. Portrait.—Bronze medal, Dr. Llewellyn Morgan. Ladies' Competition.—Silver medal, Mrs. Bell. Members and their friends are invited to view the pictures, which are now hung in the Society's rooms, Eberle-street, until the end of the month. The Judges were Messrs. J. Lederer, G. Watmough Webster, J. W. Wade, G. E. Thompson, and W. I. Chadwick.

Wakefield Photographic Society.—December 11.—The meeting was devoted to an exhibition of lantern slides made by members, and slides by J. Briggs, H. M. Briggs, Robson, Holmes, Wilcock, and Hon. Secretary were shown. After the exhibition, Mrs. Aspinall Addison presented to Dr. Clarke a silver medal, and to W. Holmes a bronze medal, being the first and second prizes for prints in the recent competition; also a silver medal to R. Robson, and a bronze medal to J. Briggs, jun., being first and second prizes for lantern slides.

Dundee and East of Scotland Photographic Association.—December 5.—A successful *conversazione* was held in University College, Dundee. The Council of the Association received the guests in the Botanical Class-room, after which an adjournment was made to the Mechanical Laboratory, the interior of which was converted into a tea-room for the occasion. The company then assembled in the Mathematical Lecture-room, where Professor Steggall, President of the Association, delivered an address on the progress of photography. The President was accompanied, amongst others, by Messrs. D. Ireland, Thomas Berry, V. C. Baird, W. F. Hill, G. G. Maclaren, W. H. Tittensor, and Andrew Stewart. The PRESIDENT, at the outset, in name of the Council of the Dundee and East of Scotland Photographic Association, extended a hearty welcome to the assembled guests. He then proceeded to sketch the earliest beginnings of photographic art, and passed on to deal with some of the considerations that seemed to him essential in deciding for a society like theirs not only its *locus standi*, but its actual value as an educational and refining influence in their midst. He glanced back to the earliest observations made on the effects of light in the nature of bodies. They now knew that this was the chemical action of light, and they recognised that light was inseparable from heat, even although heat might exist without light being created, as far as their only test, their sense of sight, detected. It was not easier to suppose an earlier effect of light than the growth of trees, or an earlier observation than that of the colouration of the human skin by light—what was commonly called sunburn. It was truly an astonishing fact that their vast deposits of energy in the form of coal were simply products of the tireless action of sunlight. Millions of pounds of oxygen were daily consumed by everything that breathed, by every fire that burned, by every metal that rusted, and millions of pounds of carbonic acid were thus produced. They did not always remember, however, how the atmosphere, that great storehouse of oxygen, was from day to day replenished. In the presence of light, but not otherwise, all growing vegetable matter had the power of assimilating the carbon in which its structure mainly consisted from this carbonic acid, and of delivering the oxygen pure and restorative to the exhausted air. By that action were formed the prehistoric forests that in the convulsions of the geologic infancy of their planet were crushed together to form the coal measures of later days. That great fact was never chronicled through contemporary observation, and doubtless the first recognition of the photographic action of sunlight was really afforded by its effect on the complexion. It was only in the latter part of the eighteenth century that the celebrated Priestley called attention to the wonderful powers by which Nature through light renewed the air they breathed, but from that time onwards vigorous efforts were put forth to determine accurately the nature of the chemical action that underlay the visible influence of light on certain substances, and these efforts resulted, in the years 1826 to 1829, in the practical applications of this action to the production of photographic pictures. The progress had been vast, but even after fifty or sixty years of research and knowledge as to the real action of light on the silver salts usually employed in photography, it was in such a state that they were forced still to regard these actions as in the highest degree complex and baffling. Photographers, however, could claim some credit for the progress attained during the past year or two—progress that, inspired by the claims of this art alone, had been of immense value in all the range of optical and many other sciences. The demand for transparent films had been accompanied by a vast improvement in the manufacture of celluloid, and that material had again been applied to many other practical purposes. The demand for lighter lenses had helped to teach the working of aluminium. The exigencies of the focus had stimulated the glassmaker, until glass could be produced to satisfy the most extreme requirements of the photographer, astronomer, and microscopist. The speed of plates had been gradually improved without that loss of fine texture which

used to attend rapidity. In 1844 a writer said that in good sunshine an edifice could be copied in a minute; nowadays, one hundred well-exposed views of the same subject could be taken consecutively within a second. The mechanical processes of printing were being daily improved. Advances had been made in colour printing sufficient to occasion several pretty quarrels, enshrined within the pages of the photog aphic press, and some of the results were fairly satisfactory. The real problem of colour printing had not progressed far, and the medium required for a simple process had yet to be found. Proceeding, he alluded to the two recent inventions of the cinematograph, and a discovery that consisted in the revelation by the camera of rays of light that did not affect the sense of sight. Alluding to the Rontgen rays, the remarked that many of the most interesting specimens of the action of these rays yet produced had been made in the laboratories of University College. Continuing, he said that a society like theirs must depend on other considerations than those of research and invention for its permanence and its success. The human interest, in which were included the love of Nature, appealed more strongly to them than any other. Appreciation of Nature was, he thought, the greatest gift to man, and the development of that appreciation was an educational power of the greatest value, and he claimed for the photographic art that its reproduction of the features of the places they had seen tended to cultivate an artistic appreciation of Nature. Before closing, Professor Steggall alluded to the aids afforded to amateur photographers through the Association, remarking that it was a historic fact that their club-rooms, with their dark room, enlargement and other apparatus, helped to draw the members together.

Capetown Photographic Club.—November 14.—The Annual Meeting of the Capetown Photographic Club was presided over by the Vice-President (Professor W. S. Logeman), and there was a large attendance of members. A number of new members were admitted, and the following report was read:—In submitting the sixth annual report, the Council have to state that, although a number of members have removed from Capetown during the year, and the roll has been cleared of several more who have not paid their subscriptions, yet there is a small increase in numbers, the roll now standing at ninety members and eight honorary members. The balance-sheet shows a balance due to the Treasurer of 3*l.* 19*s.* 6*d.*; assets, 10*l.* 18*s.* 9*d.*; liabilities, 3*l.* The attendance at monthly meetings has been good. A very successful *conversazione* was held in November, when the prints sent in for the 1895 competitions were on view, and also a number of other contributions from members. The competition slides, with a number of others, were exhibited during the evening, and light refreshments were provided, under the superintendence of a committee of ladies. The photographs were on exhibition to the public on the following day, but only some twenty-five persons visited. In consequence of the alteration in the rules, the number of prints sent in to the monthly entries have been exceedingly few, and, in fact, for the last few months none have been received. The Council much regret this, and would urge the members to remedy this matter during the forthcoming year. The value of these monthly entries, especially to the younger members, is great, and, in addition, the valuable collection of photographs is lost to the Club album. In connexion with the annual competitions, the Council have to acknowledge the kindness of Mr. E. R. Morris in having prepared and presented to the Club a number of certificates of high artistic merit for use at the annual competitions. Also to the following members for placing silver medals at their disposal for the purposes of this year's competition:—Messrs. D. C. Andrew, J. R. Wignall, Colonel Homan-ffolliott, and Professor W. S. Logeman. The 1896 competitions were arranged with a larger number of classes than the previous year, but the number of members entering for the various classes was only twenty, one more than last year. Very few entries were made in the junior classes; in fact, in four classes there were none, in two classes there were only two, and in one class only one entry; it would therefore seem advisable to discontinue the junior classes. In the classes open to members of any photographic society of South Africa, Class XX., for general work, the competition was not so keen, eight entries only having been received against a much larger number last year. The other societies represented were the Kimberley Camera Club and the Port Elizabeth Society. It was thought advisable that all the classes "open to members of any photographic society" should be sent to England for judging, so the Council wrote to the Secretary of the Royal Society of Great Britain requesting that, if possible, he would arrange for their Judges to adjudicate on them. Mr. Charles Mills (who was just visiting England at the time) very kindly took the prints (eight sets of six) and eight sets of lantern slides with him, and delivered them to the Royal Society with our request; but, after some little delay, they were returned to him, with a letter intimating that the Judges had so much work to do in connexion with their own Exhibition that they did not feel justified in asking them to devote any more time to such matters. The Council regret that they are not yet in possession of the awards for Class XXI., stereoscopic slides, which, although sent to Mr. Chadwick, of Manchester, a week previous to the other English parcel, have not yet been reported upon by him. The most cordial relationship continues to exist between ourselves and other kindred societies in South Africa, the only club not in frequent communication being that of Natal. Some good field days have taken place, notably to Groot Constantia, to Oude Kraal, to Lourensford, the residence of Sir James Sivewright; and also in connexion with the Mountain Club, on October 5, to Tulbagh. The report having been unanimously adopted, the following gentlemen were elected as officers for the ensuing year:—*President:* Dr. David Gill, Astronomer Royal at the Cape.—*Vice-President:* Mr. A. J. Fuller.—*Council:* Messrs. T. W. Cairncross, H. E. Cope, J. P. Edwards, A. McLeod, J. Powell, E. J. Steer, J. R. Wignall, and Dr. D. J. Wood.—*Secretary and Treasurer:* Mr. E. E. Harrhy, G.P.O., Wale-street.

1896. FORTHCOMING EXHIBITIONS.

December 29–Jan. 2. Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.

Dec. 1896–Jan. 1897 Bristol International. Hon. Secretary, 20, Berkeley-square, Clifton, Bristol.

1897.

January 14, 15 ..... Weymouth and District Camera Club. E. C. Bennett, 10, Newberry-terrace, Weymouth.

February 1–27 ..... Glasgow *Evening Times* Camera Club. The Secretaries, *Evening Times* Camera Club, 46, Gordon-street, Glasgow.

March 6–13 ..... South London Photographic Society. Charles H. Oakden, 30, Heaslowe-road, East Dulwich, S.E.

Correspondence.

☛ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

THE ROYAL PHOTOGRAPHIC SOCIETY.

To the EDITORS.

GENTLEMEN,—It was announced at the last meeting of the Royal Photographic Society that I had resigned the Presidency. I think it due to the fellows and members of the Society that I should state the reasons which led me to take this step, so that no misconception may arise. My resignation was announced from the chair, but I am uncertain whether a correct explanation of its cause was given by the chairman.

I will now give my own statement, which is based on facts which all members of the Society must know. The Council appointed a Committee (all the Council were appointed on it) to consider the expediency of altering the Articles of Association. (This I announced from the chair in October last.) This Committee reported to the Council at its November meeting, and one of their recommendations was that the articles should be so altered as to exclude the five senior members of Council from re-election. The Council, after considering the report, adopted this recommendation, together with others to which I need not allude. On certainly two if not on three occasions within a few years, a somewhat similar proposal has been brought forward, and as lately as when the Articles of Association were drawn up, was rejected, and the present freedom of election maintained. This freedom of election, entailing as it does the eligibility of any member of the Society for a seat on the Council, I have strongly advocated ever since the "house-list" system was abolished; for it appears to me to be contrary to reason to disqualify a member for the sole cause of having faithfully served the Society for a certain number of years. The rule, if made, would place such a disqualified member in the same position as a felon or bankrupt in a parliamentary election—a position which is scarcely desirable.

When a Council has, by the rules of a Society, to submit a "house-list," there is much to be said in favour of insisting that a certain amount of fresh blood should be included in it; but where the whole Council has to be annually nominated and elected by the members at large, any disqualification to some seems to me thoroughly wrong in principle. For a member to have won the confidence of the electors for several years in succession, will be pretty much akin to the shearing of Samson's locks. He will become sport for the Philistines.

The resolution having been adopted by the Council, it must of necessity come before a special meeting of the Society for approval; and, if I were President, it would be my duty to take the chair on that occasion. In the capacity of Chairman, I should have to sit passive (which might be taken that I was acquiescent), except when necessary to act as a moderator in the discussion, and to count the votes, which could not include my own, I believe. Holding the views on this question that I do, I felt that my only course, with due regard to self-respect and to the majority of the Council, was to resign, and thus make way for some one who was more sympathetic with them. It is true I was elected by the Society and not by the Council, and it may be thought that the resolution adopted by the latter was not sufficient reason for my resignation of the important office I held. Had the Articles of Association expressly allowed voting by voting papers on changes of constitution, as it does for the election of officers and Council, I should probably have remained, for I have but little doubt that I am in harmony with the majority of the Society. As, however, any change that may be made will be made according to the views of the majority in a meeting of seventy or eighty members, who happen from circumstances of residence to be able to attend, and which is a small proportion of the Society, I felt that any obligation to remain was cancelled.

The Articles of Association may not be faultless in more directions than in that I have just indicated, but it is better to leave them as they are than to be perpetually revising them. Perpetual tinkering at rules is subversive of the proper work of any Society. Personally, I have no spare time to devote to such a waste of energy. An hour's discussion of rules means an hour withdrawn from scientific work. If there were a real necessity for the change of rule, I would say nothing as to this waste of time; but as statistics show that the infusion of new blood into the Council, which some clamour for, is automatically taking place (being very little short, I believe, of the average of five a year), I protest against it being forced on busy members of the Society. If the change be made,

the infusion will be made at the expense of probably the most efficient and experienced members, instead of through natural causes.

Perhaps some way of testing the real feeling of the whole Society on this subject might be found at the approaching annual election of officers and Council, when every member can exercise his vote regardless of distance from London. If this can be done, I shall be glad; for what is wanted is not only an expression of opinion by the London members, but also by the country members of the Royal Photographic Society.—I am, yours, &c., W. DE W. ABNEY,

Late President of the Royal Photographic Society.

December 12, 1896.

P.S.—I find that Mr. Chapman Jones, the Hon. Secretary, has also resigned his office. I should like to state emphatically that he has acted quite independently of myself, and no doubt will give his own reasons for having done so.

To the EDITORS.

GENTLEMEN,—Although I was appointed the Hon. Secretary of the Royal Photographic Society by the Council of the Society, and technically, therefore, am responsible to them, I feel that I owe a duty to the members that can only be discharged by stating publicly why I have resigned that office.

I am not opposed to having a regular number of new members of Council at each annual election, indeed, I suggested that the number now adopted by the Council should be increased; but I regret that what I consider to be a harmful method of effecting the change has been carried by a majority of the Council, and that it has become my duty to make the most emphatic protest I can against the proposed method by placing my resignation in the hands of the Council. I have been told that this is a trivial matter, and not worthy of so emphatic a protest. A small hole in the embankment of a great reservoir is a very little thing, but if the directors by a majority determined to have a little hole, if only as an experiment, what would be the duty of the engineer? I cannot consent to take part in the carrying out of a resolution that is not unlikely to prove disastrous to the Society. This is the main and decisive reason of my resignation.

But I have also expressed to the Council my feeling that it is a great pity that the time and energy of the Society and its officers should be spent in such frequent and generally unnecessary alterations of the Society's rules, instead of devoting them to the work that the Society exists to do.

I wish to thank the members for the cordial assistance and sympathy that they have extended to me during my years of office. On resigning the Secretaryship I ceased to be a member of Council. The Council, however, elected me to a vacancy that existed, so that I shall continue to do the utmost that my position will allow to help forward the best interests of the Society.—I am, yours, &c., CHAPMAN JONES.

December 11, 1896.

P.S.—I have heard a rumour to the effect that I resigned at Captain Abney's desire or suggestion. Nothing could be further from the truth than this.

A PHENOMENON IN PRINTING.

To the EDITORS.

GENTLEMEN,—Some time ago I asked you to explain the reason of a white halo around dark outlines, but I have not received any satisfactory answer as yet. Here is another experience I have had lately, which I am unable to answer for. I have some 10 × 12 inch negatives of buildings which fill the plate more or less on account of height or width of buildings, allowing on the plates next-door houses of no account. These houses I want to eliminate while printing the negatives on ferro-prussiate paper, 14 × 17 inches in size. To obtain this and a white band all around the principal subject, I acted as follows:—

I pasted all around the 10 × 12 negative double thickness of a non-actinic yellow paper, leaving only in the centre the principal building. Now I take a printing frame 14 × 17 in which I put a glass. In the centre of this I lay my negative, and on top of this I put a black paper, 14 × 17, in the centre of which I have cut out a square piece of 9 × 11 inches more or less according to the reduction of the negative to be printed from. Over this I put my 14 × 17 piece of ferro-prussiate paper, some padding, and close it all up and expose to light. When finished and washed, I expect a picture in the centre, and a clear, white band all around. Not so, however, in practice. I obtain regularly a fine picture in the centre, but (and here is the trouble) a tinted rim, exactly the reproduction of the 10 × 12 negative, and all the remainder of the paper perfectly white. Why? If the paper is left between black paper and padding, why is it not left the same when between negative, yellow, and one black paper? Does strong pressure allow light to pass more than when lying loose, or does pressure alone make a print in this case, and through three sheets of non-actinic paper?

I would add, that the print from the negative itself shows clear whites in the high lights, and good deep blue in the shadows.—I am, yours, &c.,

A LEVY.

SCIENTIFIC INSTRUCTION AND THE PHOTOGRAPHIC PROFESSION.

To the EDITORS.

GENTLEMEN,—The long letter in your issue of the 11th inst. is altogether beside the mark of what I advocated, viz., practical application of the old adage, "*Knowledge is power;*" whether it be for an artist or a mechanic, a jeweller or a brass-worker, a cloth-weaver or a photographer. Knowledge of the nature and uses of the materials he employs in his craft, must enable the man to be a more skilled worker in his daily vocation.

If I were to desire a son of mine to take a high position as a photographer, I would place him with the photographer who turned out the best work in the town; who was not wise in his own conceit, and thought there was nothing to be learnt in the profession except what he already knew; one who aimed at excellence in results, and always demanded best pay for best work.

I would cause my son to give some time to the study of chemistry, and some to the study of "Art," pure and simple.

Fortunately, we have now in Birmingham ready means at very moderate cost, for the youth of the city to acquire knowledge in each of these departments, and in almost every other relating to "arts and crafts" practised in the city.

It is useless to say the photographer requires no knowledge of chemistry, "because he can buy his chemistry, ready made, in the market." It is this ignorance of the nature and application of the "materials" of his trade, which has been a cause of injury and loss to the workers in many of the trades in our country, and, *per contra*, the study and possession of this knowledge has given foreigners an advantage over ourselves.

The absurd *dilettanti* nonsense, stated in the letter, as my views, are not my ideas or wishes, nor have I advocated in any way the manufacture of exhausted book-worms, so I need not waste your space by explaining statements which I never made.

I do not advocate "theory," but "practice." I do not want "class" to displace the studio and the workshop. I have not stated that "polytechnic teaching has proved so exceedingly beneficial," but I have lamented the absence of something higher than "rule of thumb" in the arts and crafts of this country, a state of ignorance which we have only recently set ourselves to remove.

As to "profits," I have it on the highest possible authority from professional photographers of high standing, that they have always got best prices for best work, and it is in the power of the juniors and assistants to do the same.

I do not want to make invidious selections, but Messrs. Van der Weyde, Fall, Elliott, Byrne, Whitlock, Freke, Mendelssohn, and a host of others (whose names I trust I may be pardoned for not naming), will all support the views I have expressed in my previous letter and in this one.—I am, yours, &c., D. J. O'NEILL,

Secretary of the National Association of Professional Photographers.

47, *Charlotte-road, Birmingham, December* 14, 1896.

THE OWNERSHIP OF MEDALS.

To the EDITORS.

GENTLEMEN,—In the correspondence column of your last issue, there is a reply bearing on the ownership of medals. It appears to me a subject of vital interest to the profession.

Is it a fact that artists of the brush transmit to canvas their own ideas and are the authors of their work? If that is so, what is the position of a much be-medalled photographer whose talented assistant produces work which he, personally, is wholly incapable of producing beyond, perhaps, developing the plate?

As things are, the employer is considered a hero with honours, whilst the author of the work must not, on any consideration, be mentioned, and may not breathe the truth to any one without libelling the dignified holder of the medal.

We have Linked Rings and a Convention. Would it not be well for this subject to be taken up during the winter months by some of the societies, and a committee formed from them to prepare general rules, &c., which could be adopted and made to govern the present unhealthy and loose system?

Many will agree that honour should be given where it is due. We may some day have a Royal Academy of Photography, but not until these matters are properly adjusted.

Hoping my letter may not be out of sympathy, and thanking you in anticipation for bringing it before the profession,—I am, yours, &c.,

56, *St. Mary-street, Weymouth, December* 14, 1896. H. G. STEPHENS.

THE LATE R. KENNETT.

To the EDITORS.

GENTLEMEN,—I was very sorry to see recorded in THE BRITISH JOURNAL OF PHOTOGRAPHY of last Friday, the death of my old friend Mr. R. Kennett. Not only was he an enthusiastic worker, but he also invented several useful pieces of apparatus—his tripod legs are very simple and rigid, carrying great weights. I used some of his dry plates about thirty years ago with good results.

It may interest some of the younger practitioners to read that the very first plates made by Mr. Kennett were of great rapidity; he was under the impression that they could not be as sensitive as wet collodion, although his younger son, a good photographer, was always telling him they were too rapid, and he showed me that he could print on them with four thicknesses of red fabric over the negative. At last he came to the conclusion that his son was right. At one time, he was much worried how to get rid of the unnecessary salts in the emulsion, and he told me that he thought out the method in his sleep, showing how his mind was full of the subject. He was first-rate in his own business, and a very skilful worker at the lathe; a genial, well-informed man with whom it was both pleasant and profitable to spend a couple of hours, and one to be remembered by photographers.—I am, yours, &c., FRANK HAES.

December 13, 1896.

THE REAL TRUTH.

To the EDITORS.

GENTLEMEN,—In an editorial article last week, p. 786, at the head of the second column, you speak of the "real truth." I am so bothered. My old friend, "Junius Junior," used to teach me through your pages, and now that he is dead I have to turn to you.

The "real truth." Then, is there truth which is not real! Some leading men of thought suggest that somewhere there may exist a fourth dimension. Two and two may not always make four. So many difficulties would vanish if this could only be proved. It may be that it will be found in photography. Do you think so? I do. I meet with so many difficulties which nobody can explain. "Junius Junior" tried and died—two years ago.

Does "real truth" refer to the three known dimensions, and when the adjective is omitted does it refer to the fourth, or what? I get my English from the JOURNAL.—I am, yours, &c., RICHARD.

[Possibly "Junius Junior" may at some future date resume his contributions to our pages and answer our correspondent's question. Contrary to what "Richard" supposes, "Junius Junior" is not dead.—EDS.]

THE PHOTOGRAPHIC SALON.

To the EDITORS.

GENTLEMEN,—You draw me, of course. Because I take it that an opinion expressed by "Cosmos" is equivalent to the opinion of the Editor of THE BRITISH JOURNAL OF PHOTOGRAPHY, and that you, Sir, therefore consider that the letters lately published in your columns demand replies from those who are attacked.

But am I to understand that whenever letters reflecting on others, written by no matter whom, whether from persons of importance or not, are published in the newspapers, silence on the part of those against whom the attacks are directed implies, as "Cosmos" says, that their "critics have left them, metaphorically speaking, without a leg to stand on?"

I beg to say that it is in no way because the letters are unanswerable that I have not, as you seem to expect I should have done, replied to them. There are occasions when one may safely leave such things to the unprejudiced judgment of the public, and this is one of them—if, indeed, which I doubt very much, the public cares to trouble itself about such trivial word-splitting.

With all deference to yourself, Sir, and "Cosmos," I am happy to believe that the opinion of the photographic world concerning the Salon is by no means one of "extensive disfavour," as asserted in "Jottings." I know that there are those who would shrink from no device to have us believe that this is the case; but the Salon can well afford to smile at such efforts, and, as a rule, refuse to notice them. I, myself, only do so now on account of what appears to me to be a call from yourself. About the merits of the correspondence I say nothing.

May I ask those who agree with the writer of the *Indian Photographic Society's Journal*, if they can state any instance to justify the use of such a phrase as you quote, viz., "If the Linked Ring will only give up its rather undignified appeals for flattery and commendation," &c.? Does this mean anything or nothing? By whom has it been done, and when?—I am, yours, &c., ALFRED MASKELL.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2, *York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

Edmund Eccles, Bury, Lancashire.—*Photograph of Rev. John Mather, Bury.*

Gilbert Wilson, West House, Grange-over-Sands.—*Photograph of Yewbarrow Crags from the shore, Grange-over-Sands.*

Thomas Burns, 5, West Maitland-street, Edinburgh.—*Three photographs of the Rev. Thomas Harvey, and one photograph of Mrs. Harvey.*

Wilkinson & Co., 29, Rampant Horse-street, Norwich.—*Photograph of T.R.H. Prince and Princess Charles of Denmark in "Victoria."*

H. BARTHOLOMEW.—Thanks very much for the cutting, which will suffice.

FLASH.—We believe that Perken, Son, & Rayment, Hatton-garden, supply the form of lamp mentioned.

O. C. VANSTON.—Communicate with the superintendent of police of the locality where the man resides.

MERCURY-BLEACHED NEGATIVES. TYRO asks: "Will negatives bleached with mercury fade if I do not at once blacken them?"—In reply: No; the bleached image will not fade.

GILDING.—M. DE S. & Co. We believe the advertising tablets are gilded with gold leaf, applied at the back. We are not aware of any process for depositing the gold, as silver may be deposited.

A. SQUIBBS.—1. Probably what you take to be halation in the case of the wide-angle lens may be flare. We cannot otherwise account for the phenomenon. 2. We presume it is one of the Euryscope form working at *f*-5·6 (approximate).

STEREOSCOPY.—BEGINNER sends us some examples of his work in this branch of photography, and says that, when he looks at them in the stereoscope, he gets no effect. He asks the reason.—In reply: The prints have not been transposed in mounting.

COPYRIGHT DECISION.—G. & J. HALL ask: "Can you oblige by telling us copy of JOURNAL in which appears the copyright case, Nottage *versus* Jackson?"—The reports of this case, and the appeal, will be found on pp. 380, 392, 436, 453 of the volume for 1883.

EMULSION.—PERPLEXED. The reason why the proportion of silver bromide is greater in the one formula than the other is that their authors have different ideas on the subject. The chloride is to modify the colour of the slides; the quantity is that given in the formula. Other formulæ for bromide emulsion will be found on p. 976 of the ALMANAC.

THE FACTORY ACT.—MESSRS. WELLS & Co., write: "In your answers to correspondence of December 11, we notice you tell F. E. G. he can employ young persons from 9 to 6, or 8.30 to 7, every day of the week. We think this must be a mistake, as our abstract states young persons can only be employed on Saturdays from 6 to 2, or 7 to 3, or 8 to 4."

OLD CELLOIDINE PAPER.—M. PELLECHET (Paris) says: "I have some celloidine paper yellowed by age; could I not modify the toning bath (acetate of soda and gold, with some sulphocyanide) in order to lessen the yellow tint? I am sure I have read somewhere something about it, but cannot remember."—We know of no method by which the paper can be used so as to yield prints with pure whites.

LANTERN SLIDES.—G. E. B. says: "Can you inform me where I can procure lantern slides, or, if not these, prints of photographs taken from a balloon, of 'composite' photographs, of photographs illustrating combination printing, and of the well-known photograph of some object (such as a portrait of the Queen) taken through a fly's eye?"—Probably Mr. W. I. Chadwick, of 2, St. Mary's-street, Manchester, can give our correspondent the information required.

AN INDEX QUESTION.—CYMRO LLOYD says: "1. Will you please inform me on what dates have Mr. H. P. Robinson's works appeared on the subject, *Digressions*, &c., in your paper? I should like to have his work from beginning to end. 2. Also Mr. T. N. Armstrong on his subject, *Outdoor Studio Work*."—In reply: Mr. Robinson's articles appear in the JOURNAL published on the first Friday in each month. The Index to the volume will be published on January 1, 1897; this will give you all the information you require.

COMPARATIVE EXPOSURES.—H. FURNISS. It is impossible to give any reliable information on the relative exposures required on the data given, "A fine day in June" and "A thick and hazy day in December or January." Yours and your friend's argument can only be decided by experiment. Select a day that fulfils both your ideas as to "dull and hazy," and then expose a few plates, giving different times to each—giving, say, for the first ten times that you know was required on the fine June day, and longer for the others. Then compare the results.

STAINED PRINTS.—PERPLEXED PRINTER writes: "I enclose some prints showing stains, with which I have several times been troubled during the past two months. I always work in the same way, using the same dishes, &c., which are kept exclusively for toning and fixing. Monday, Tuesday, and to-day I have used the same toning bath. Monday and to-day my prints were all right, yesterday forty, out of a batch of nearly 200, were stained like the enclosed. Can you help me to account for it?"—The stains are caused by imperfect fixation. Either the fixing bath was too weak or the time allowed too short. When the hyposulphite solution is cold, a longer time must be allowed for its action. Probably this has not been the case during the time the trouble has been met with.

PRINTING NEGATIVES IN A GROUP.—S. JAMES says: "Could you inform me the best method for printing the following? I have thirty cabinet negatives to print from, which have to be arranged into a group, of course to be copied into a 12×10 negative (they are all full-length figures)."—There are many ways of doing this. Sometimes the prints are simply cut oval and mounted on an ornamental design, at others they are combined by arranging the full-length figures, after they have been cut round their outlines, as a group, and mounting them and then introducing a suitable background in water colour. This column is too limited to give practical details of the methods. Many articles on the subject will be found in back volumes. One on p. 82 of the volume for last year, for example.

CHRISTMAS HOLIDAYS.—*Will our correspondents note that, in consequence of Christmas Day falling on Friday of next week, we shall publish a day earlier than usual!*

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1912. Vol. XLIII.—DECEMBER 25, 1896.

Contents.

EX CATHEDRÂ.

The Photographers' Benevolent Association ceased to exist some time ago, although it has a considerable sum of money standing to its credit, upon which, however, a draw cannot be made without the sanction of the Registrar of Friendly Societies. The Benevolent died through the neglect of those for whom it was instituted. A well-known gentleman in the photographic world is, nevertheless, sanguine of being able to resuscitate the Association and probably will shortly make the effort to do so. We wish him success in his enterprise. There is, unfortunately, room for the Association, and, well supported by photographers and their assistants, it might be made an excellent agency for the relief of distress, and other desirable objects.

* * *

A further stage in the history of Mr. J. W. Bennetto's alleged "discovery" of photography in natural colours has been reached. The following announcement appears in our Newquay contemporary of December 18.

* * *

"Colour Photography.—On Tuesday last, December 15, at the Atlantic Hotel, a financial transaction in this matter was concluded, the details of which we are not permitted to divulge, except to say that, in our opinion, never before in Newquay has such an important (both historically and financially) business been conducted. It is, of course, public property, that a saloon carriage brought from London a party of well-known and distinguished persons from America and London to Newquay, to see Mr. Bennetto's work, and the result is that Mr John Wallace Bennetto, the once derided of that photographic luminary, The British Journal of Photography, will shortly be receiving the hearty congratulations of his fellow-townsmen, and we trust that there will be no hanging back even on the part of those who, having not seen, have not believed. We are glad to authoritatively state that Mr. Bennetto will not be leaving Newquay. Many months ago, amid the sneers of our contemporaries, we congratulated Mr. Bennetto on his work, and now we are glad to congratulate him on having reached such a successful issue of his labours."

* * *

It would appear from the foregoing that Mr. Bennetto has profited financially by his "colour photography" work, and we congratulate him upon his good fortune as sincerely as does the amusing little publication which so valiantly shields Mr. Bennetto from our "derision." The process having become the object of a financial transaction, we may assume that in due course some examples will be submitted to public, if not to expert, scrutiny. If the result of that scrutiny is to confirm Mr. Bennetto in his claim made on November 6 in our columns, that in his process he possesses "a jewel," we, as we have all along endeavoured to make plain, shall not withhold recognition of his achievements.

* * *

Writing on the subject of acetylene burners, a correspondent gives the following hint: "Two or three weeks ago I noticed a correspondent inquiring if the light from acetylene would not be better for projecting purposes were the burners arranged with the flames at right angles to the condenser, as in an oil lantern. No one seems to have replied to him. I therefore write to inform him that burners so arranged are unsatisfactory. I have found the most satisfactory arrangement for lantern projection is to place three burners in an equilateral triangle with burners three quarters of an inch apart, the flames of the burners forming a triangle." We may remark that we ourselves have found the placing

of the burners at right angles to each other a perfectly satisfactory arrangement.

* * *

The sympathy of our readers will, we are sure, be extended to our friend Mr. G. Watmough Webster in the death of his wife, which took place suddenly, on the 14th instant, at Brook-lane Lodge, Chester. The deceased lady was a frequent attendant at the Convention, the Photographic Society *Soirées*, and similar gatherings. Her kind and amiable disposition had won for her wide esteem in the photographic world, wherein her death will be very much regretted.

* * *

In connexion with Cruft's Dog Show, at the Agricultural Hall, Islington, N., which is to be held in February, 1897, there will be an Exhibition of Canine Photography. A similar Exhibition held in the early part of this year was very successful.

THE CROSS-LINE SCREEN FOR ORDINARY COPYING.

All who have had much to do in the way of copying photographs, a branch of business that is by no means uncommon in the majority of studios, will be aware how difficult it is in most cases to secure a perfect, or even sometimes a moderately passable, result, owing partly to the irregularities in the surface of the original, and too frequently to its deficiency in detail either in the high lights or the shadows, which combine to rob the copy of its proper gradation.

On the other hand, those who are engaged in process work, or, for that matter, all who are in the habit of examining half-tone reproductions from photographs—and who at the present day is not?—must have noticed how, in the hands of a skilled operator, the reproduction is not only quite equal both in delicacy and in vigour to the original, but not unfrequently far superior, by reason of the power the screen gives of modifying or altogether altering the gradations of the subject to be copied; besides which, the grain or dot of the screen entirely hides or suppresses any texture or surface inequalities unless these be very pronounced indeed.

Bearing these facts in mind, it occurred to us some time ago that the cross-lined screen might prove useful to the ordinary photographer whose business does not include the production of process blocks or negatives, but who may possibly have frequent occasion to execute copies of old photographs of deceased relatives; and, upon putting the matter to the test with a variety of different styles of originals, we found that in every case, so far as delicacy, vigour, and gradation are concerned, it is possible to secure reproductions at least equal to the photograph copied, and, in the case of inferior or defective ones, actually far better. So far as the presence of the mechanical grain in the reproduction is concerned, if this be objectionable, which it need not be, it can be minimised by the employment of a sufficiently fine ruling, or practically can be done away with in the manner we shall indicate.

It may be urged at the outset that the ordinary photographer is not usually the possessor of a diamond-ruled screen, and that such are costly luxuries to be kept for occasional use for chance cases of copying, to which we reply that a half or even a whole-plate, diamond-ruled screen of the very best quality is not such a very expensive article, while for the purpose in question a cheaper collodion copy will answer just as well, provided it is fairly uniform in its grain; in fact, we have obtained very satisfactory results with collodion screens, which for actual process work would be perfectly useless, owing to the insufficient opacity of the lines.

The production of a perfect process negative, *i.e.*, one that possesses the requisite qualities for the formation of a printed image that will resist the etching acid, is a very different matter from the simple process of breaking up an ordinary half-tone image into dots to form a negative of sufficient density to print upon the usual modern printing papers. In the first case, the gradation of the picture depends upon a combination of circumstances, of which absolute opacity of the deposit and as nearly perfect clearness of the intervening spaces form only two, and these not the most important; but even these two may be comparatively ignored when the object is only to print a half-tone "dot" negative on ordinary paper. The function of the screen in the two instances is entirely different, and for the purpose we have in view it is simply to mask any inequalities of surface and to enable imperfect gradations in the original to be modified. In what way it performs these offices we shall endeavour to show.

First as regards the screen, we think that no coarser ruling than 133 or 140 lines to the inch will give really satisfactory results, especially for small work. With 120 lines to the inch, unless the quality of the negative is nearly as perfect as would be required for half-tone etching, the screen effect will be too pronounced in a cabinet-sized picture, though it may pass muster for whole-plate or larger sizes; but, with the rulings we have named, very good results can be obtained, even for *carte-de-visite* size. Although, as we have already hinted, the same skill in manipulation is not necessary as for process negatives, still a certain amount of care must be given to the adjustment of the screen distance and the size of stop, so far, at least, as to avoid a harsh and "screeny" effect. Thus the employment of a small stop with the screen in contact with the sensitive plate would result in a too perfect reproduction of the lines of the screen; whereas, by setting the screen farther away, and using a larger stop, the dot formation would be secured, and, if not in a sufficiently satisfactory manner to fulfil the requirements of the etchers, the needs of mere copying will be met.

But, if the screen grain be an objection, it may be almost entirely got rid of in the high lights, at least where it is the most likely to prove undesirable, by setting the screen at a sufficient distance, or by using a sufficiently large stop to entirely close up the dots in the high lights, and then to give a supplementary exposure with a smaller stop in order to get detail in the heavy shadows in the manner well known to process workers.

Ordinary gelatine plates may be employed; indeed, for the purpose, they are preferable to any other, since wet plates would entail more or less elaborate arrangements for separating the plate and screen, and, as regards special process plates, while their particular qualities are not of importance, they would entail a greatly increased exposure without any corresponding benefit. With the usual studio plate, the screen may usually be placed in contact with it in the ordinary dark slide, either single or double, the thickness of the cover glass being sufficient separation if a moderately small stop be used. If, however, this gives a too "screeny" effect, a mask or strip of cardboard or thin millboard may be used to secure greater separation, and the proper distance can be judged by inserting a sheet of ground glass in place of the sensitive plate, and examining the effect produced at different distances and with different stops. The same arrangement answers also for

focussing, for it must be borne in mind that there will be the thickness of screen *plus* the screen distance to allow for, if the ordinary focussing glass be used.

The exposure will be four or five times longer than would be required under similar conditions without the screen, and the development will be precisely the same as for an ordinary plate. In fact, in the dark room, it will be quite impossible, with the best eyesight, to detect any signs of the screens having been used. The image is watched and judged, for density and gradation, in exactly the same manner as if the screen had not been used, and, if any difference at all is made, it will be to carry density a little farther than under every-day circumstances, since the image, being more or less broken up into dots, and not homogeneous, allows proportionately more light to pass.

A few words may be said on the treatment of different kinds of subjects. If the original is perfect in gradation, no special departure from ordinary rules will be requisite. It will be desirable to bear in mind, however, that grey tones, whether platino or bromide, have a tendency to copy proportionately flatter than black or albumen purple, and that albumen shadows generally copy rather heavier than they appear, and bromides the reverse.

In the case of a harsh under-exposed print, in order to improve the result as far as possible, give what appears to be a sufficient exposure with a moderate-sized stop, say *f*-11 or *f*-16—that is to say, give four or five times the exposure that would be judged necessary to secure the best result possible without the screen. This will render the gradations of the general image, leaving the shadows still heavy. To overcome this defect, insert a smaller stop, say *f*-32 or *f*-40, and give a further exposure, judged according to the depth or heaviness of the shadows to be lightened. The second exposure will have little or no effect on the previous one, as it only superposes smaller dots on those already formed, while it allows any dark details in the shadows to creep up. If, however, the shadows are altogether devoid of detail, although it is impossible to supply this deficiency, the heavy mass may be lightened generally, and the *ensemble* of the picture improved. The best way of effecting this will be to give a short exposure with a small stop to a surface of white paper, by which means the shadows will be filled up with a shading of minute dots, while the gradations already formed will be practically unaffected, since, as in the previous case, the dots are superposed on others larger. But this auxiliary exposure must not be carried too far, or the shadows will appear flat; what is required is simply a shading of *very faint* dots which would be entirely useless to the etcher. It is here chiefly where the difference of the screen is found in making negatives for the two purposes.

In the case of an over-exposed or flat original, or one in which the high lights are wanting in detail, as short an exposure, with a moderately large stop, should be given as will just suffice for the lighter gradations of the picture, followed by a fuller auxiliary exposure with a small stop. In fact, *under-expose* with the large stop, and make up the deficiency with the small one, thus getting all the contrast possible, for the shadows, however flat, will necessarily suffer most in the primary exposure.

We have said sufficient to indicate the manner in which the lined screen can be utilised for modifying the gradations of the original image. This power is, of course, perfectly well known to the process worker, who makes constant use of it in his daily work; but it is of even greater utility where real half-tone printing is concerned, because the faintest indications of dots, that would be entirely eaten away in etching, are faithfully reproduced on the photographic paper.

In conclusion, it may be added that prints from such negatives in platinotype or on "platino-matt" bromide paper, make most charming imitations of half-tone etchings, though with this difference, that the delicacy and gradation are far superior for the reason already mentioned, that the half-tone paper renders the faintest detail produced in the camera, which is what the etcher cannot do. Some years ago it was proposed to make photographs in this manner in imitation of photo etchings, and we cannot do better than conclude by offering this suggestion for a new style of picture.

Objectionable Photographs.—On Saturday last a bookseller was committed for trial from the Marlborough-street Police Court for selling indecent photographs. A couple of detectives first purchased some of the photographs, and afterwards a number of others and some books were seized by the police. At one time a considerable trade was done in this class of work, but now, thanks to the vigilance of the police, or a decline in prurient taste, we are pleased to learn that the traffic in obscene photographs is almost stopped—we hope for the latter rather than the former reason.

Photography in the Argentine.—At the meeting of the Photographic Club, last week, several albums of photographs produced in the Argentine by Mr. A. S. Witcomb, of Buenos Ayres, were shown, and they were very fine. They were collotypes, which process, we believe, Mr. Witcomb works largely. We have since had an opportunity of examining these pictures, also some examples of portraiture, printed in collodio-chloride, shown at the Club a few weeks before, and we have no hesitation in saying that photography in the Argentine, as exemplified by Mr. Witcomb, has nothing to learn from the best photography here; even some of our highest-class workers might take a lesson. As to the collotypes, they are equal to the very best produced here, and far above the majority of the work issued commercially. Mr. Witcomb is an Englishman, but has long been located in Buenos Ayres.

Students' Work at the National Gallery.—The students at the National Gallery have just gained an important concession. Some time ago they petitioned the Committee for a means of exposing the copies they made from the old masters for sale in the building. The Committee, after duly considering the subject, have now decided to grant them the use of a room where their works can be exhibited for the purpose of sale. This will, no doubt, prove a great boon to many needy art students, who will probably realise a much better price for their productions if sold in the building than they could possibly expect from the picture dealers. This concession is no more than might be expected, seeing that the authorities have for years past permitted the sale of photographic copies of the pictures in the building, as well as giving facilities for their production.

Poisoned by Bichromate of Potash.—A woman died recently at Crewe from poisoning by bichromate of potash. It appears that she was given a recipe for a cough mixture which contained, amongst other things, bicarbonate of potash. The husband sent to a chemist's for it—its name being written on paper—but was supplied by an assistant with bichromate of potash instead; and this he used, thinking he had the right thing. The result was that the woman died. The parcel was not labelled "poison," and at the inquest the vendor said that bichromate of potash was not a scheduled poison; but the coroner remarked that the Act said that all poisons should be labelled, and intimated that the matter should be brought before the Pharmaceutical Society. It will be interesting to see what, if any, action it may take. We doubt if any photographic dealer would

supply two-pennyworth of bichromate of potash without labelling the packet "poison."

Another Projected Balloon Expedition to the North Pole.—When M. Andrée first announced his intended expedition to reach the Pole by means of a balloon, its success was looked upon with scepticism by scientists here. After all preparations were made, however, adverse conditions prevented a start being made till next year. Now, however, another expedition of a similar character is being projected in Paris. MM. Louis Godard and Edouard Turcouf announce that they intend to explore the Polar region in a monster balloon. Both gentlemen are said to be experienced aeronauts. The balloon is to hold between ten and eleven thousand cubic metres of pure hydrogen, and will have an ascending power of twelve thousand kilogrammes. The aeronauts calculate that with this balloon they will be able to remain in the air for forty days. However, they also intend to take with them a dozen vessels of compressed hydrogen, each containing two hundred and fifty cubic metres, suspended round the car, to fill up the balloon as required. These vessels are to be of equal weight to the ascensional force of the gas they contain. It is calculated, with this supplementary supply of gas, they will be able to remain above for sixty days. After this gas has been used, it is proposed to use the metal vessels as ballast. By the way, if any of this "ballast" happens to land on polar bears, it will not certainly prove good for the animals. The project is only in embryo as yet. Its estimated cost is 225,000 francs, and the money is not yet subscribed.

Acetylene Explosions.—As we briefly announced last week, there has been another fatal accident from acetylene: this time in Berlin, where four lives were lost. The details of the catastrophe to hand are very meagre. It seems that the use of acetylene is forbidden in Germany on account of its alleged dangerous character. It appears, however, that a chemist, Herr Isaac, had for some time past been experimenting with the material to deprive it of its dangerous nature. This he thought he had succeeded in doing, and had even demonstrated its "safety" before some high officials. On the day of the accident he was preparing to give a demonstration on a larger scale than hitherto before the head of the Imperial railways when the explosion occurred, blowing him and his three assistants to pieces.

A LATER telegram says that the Emperor has directed the Home Minister to investigate the matter and report to him. Herr Isaac, it is said, was shortly to have described his method of using acetylene to the Emperor himself. As all in the place at the time were killed outright, it is a little doubtful if much really reliable information will be forthcoming as to the immediate cause of the explosion. One thing, however, seems certain, namely, that the gas was compressed in a cylinder, as was that which exploded in Paris a few weeks back when two or more were killed and others injured. It seems pretty evident that, with our present knowledge of its properties, acetylene is very erratic in its behaviour, for, when a chemist has, as he thought, rendered it perfectly harmless, it scatters death all round. During the last few months acetylene has perhaps claimed more victims than has compressed oxygen since the time it was first introduced.

RESIDUES AND THEIR COLLECTION.

IT is not too much to say that, whilst during the summer the photographer is busy making negatives and printing, the winter too often is a time of enforced inaction, and it is then that there is time to look over one's negatives, to classify them, and generally clear up after the rush of work. Whilst the summer is the time of heavy work, it is the time of heavy residues, but there is no leisure to attend to them, and the only thing that can be done is to take care that they are collected as carefully as possible. In the old days of wet collodion and albumenised paper sensitised at home, the residues were valuable, but, when dry plates came in, and albumenised paper was bought ready prepared, the value of residues dropped. At the present time, when collodion and gelatino-chloride papers are more general, the residues should be valuable.

At least sixty per cent. of the silver used in the paper can be collected in the shape of residues if care is taken. The most of the silver is in the fixing bath, but the first washing water contains a good deal. If, as is sometimes the case, the first washing is performed either in a solution of carbonate of soda or salt, the soluble salts of silver are converted into insoluble carbonate or chloride, and then the whole of the residues may be in the fixing bath; in this case it is not worth while saving the first washing water. If, on the other hand, plain water can be used, it should certainly be collected, and, in order to precipitate the silver, it should be well acidulated with nitric acid, and then some hydrochloric acid added. Acid is preferable to salt unless care is taken not to add too much, for, if this is done, some, though a small quantity, of silver chloride will be dissolved. The washing waters will be, of course, rather plentiful, and very fair-size tubs must be used in order to collect them. In order to test whether the whole of the silver is precipitated, it is advisable to test a small quantity with a little pure hydrochloric acid, and, if no precipitate is formed, the whole of the silver is down. The chloride should then be collected and well washed till quite free from hydrochloric acid. If this is then dried, it should be kept separate and not mixed with the other residues, for it is fairly easy to reduce to the metallic state.

The reduction may be effected by means of zinc or magnesium, and either by the acid or alkaline method. For the latter, the chloride of silver may be merely made strongly alkaline with strong ammonia and water, and then fine granulated or filings of zinc added, when the silver will be precipitated. Almost a better method is to dissolve the silver chloride in ammonia; but this is costly, as regards ammonia, for it requires nearly seventy parts of ammonia to dissolve one part of chloride. Preferable to zinc is the use of powdered magnesium, which is considerably purer than zinc, and therefore the reduced silver does not afterwards require so much purification. If, in a fairly large vessel, sheets or bars of zinc are placed, in the proportion of about twenty-three parts of zinc to every hundred of silver chloride, and this then covered with a mixture of one part of ammonia to two parts water, and the silver chloride be suspended in a muslin bag, so as just to touch the liquid, the chloride of silver will gradually dissolve, and, in consequence of its greater specific gravity, will fall to the bottom, and there coming into contact with the zinc or magnesium, which may be used instead, will be reduced to the metallic state, and thus be obtained with the absolute certainty of not being at least mixed with unreduced silver chloride.

Instead of using ammonia the chloride of silver may be acidified with hydrochloric acid, and the silver will be reduced with zinc, and any zinc which is not decomposed may be dissolved out with dilute sulphuric acid.

If one has a silver dish, which, I must confess, is hardly a utensil that will be found in a photographic laboratory, and if an induction coil, or one or two Leclanché, Daniell, Grove, or Bunsen cells are handy, the chloride of silver may be placed in the dish, and covered with a saturated solution of sal ammoniac; the positive pole being placed in the solution, and the negative being attached to the dish itself, the chloride will be decomposed into metallic silver.

Müller suggested some years ago placing the silver chloride in a porcelain dish, covering it with dilute sulphuric acid and placing the negative pole of a Bunsen or Grove battery in the chloride of silver, whilst the positive is merely allowed to touch the liquid, when the silver will be deposited.

Old fixing baths should, of course, be collected whether of paper or plates, and the addition of hydroxylamine hydrochloride, and caustic soda solution, which can be obtained in an impure state commercially, will soon reduce the silver. The use of liver of sulphur, as the sulphydrate of potassium is known, is to be deprecated, unless it can be done out of doors. Far preferable to this is the use of zinc or magnesium powder, as no fumes are given off, and a tub under the developing sink will be out of the way and handy when the fixing bath gets dirty.

Paper clippings should be burnt, and the best method of doing this is to place the paper in a tin baking dish and burn from the top; if burnt, as usually recommended, in a flue, the draught is so great as to carry off some of the ashes. After burning, the ashes should be heated in a porcelain dish with about ten per cent. of sulphuric acid for about half an hour. This dissolves out all the carbonates of potash, &c., and then the residue should be washed and then treated with nitric acid, strong, with a moderate amount of heat, and the solution allowed to cool, filtered, and the silver precipitated in a pure state, and again dissolved in nitric acid or gold.

When we come to the combined toning and fixing baths, we have

solutions of silver with gold, and the process is more complicated. The best method of treating these and sulphocyanide baths is certainly to evaporate to a fairly small bulk, and to add about four times the bulk of concentrated solution of sulphate of iron—boil, collect the precipitate, wash and boil with nitric acid, which will dissolve any iron and silver and leave the gold behind. The silver may be precipitated as already described, and the gold well washed and redissolved in aqua regia to form chloride of gold.

The increased use of platinotype paper and the chloro-platinite of potassium as a toning agent should induce photographers to collect the residues. The developing solution contains all the chloro-platinite that is not reduced to metal to form the image, and it is only necessary to add sufficient ferrous sulphate solution to form ferrous oxalate to precipitate the whole of the platinum. Paper clippings should be merely reduced to ashes, and then treated with sulphuric acid to dissolve out the alkaline salts: then the residue redissolved in aqua regia to form platinic chloride, which can, of course, be converted into chloro-platinite.

It may he considered that the collection of residues is a troublesome process, and one not worth the game, too, in respect of cost, but during the winter months there is considerable time to spare, and the necessary outlay is small. A. D. Pretzl.

UNTIL NEXT SUMMER.

Falling leaves with chilly nights and mornings are unfailing reminders of fast-approaching winter, and of the prevalence of choking fogs, slush, discomfort, and bad light. *The* so-called season for photography has passed; cameras, lenses, and the odds and ends of the amateur's stock in trade are usually laid by until the ensuing summer, that, with its leafy glades and sparkling streams, will lure the photographer into a dalliance with art.

I am about to advocate a discontinuance of this shelving of apparatus during the winter, and so missing some of the most glorious chances that Nature affords us for picture-making. It goes without saying that during the winter there are many days in which it would be useless to try to photograph with any probability of success; but now and then, much more frequently than might be expected, breaks in the weather occur, giving us wonderful displays of light and shade that would be vainly looked for in the more genial summer time. The sun keeps low in the heavens, in this country at any rate, consequently the shadows are longer, and, owing to haze, which is seldom altogether absent, more picturesque effects are seen than in the warmer months of the year.

With respect to haze, a very little of it goes a long way. The light in the winter weather has less actinic power; a winter haze has therefore a more obstructive effect to sunshine than a summer one, a fact that has to be considered in photographing. I believe it was Artemus Ward who said, "You should never prophesy unless you know," but one might, I think, venture to hazard an opinion that, owing to the wet autumn, we shall have more than the average amount of fog and mist during the cold months, and we may also get some unusual picturesque effects, if we keep a look out, for dense mists in frosty weather mean hoar frost, affording us, perhaps, the most charming of all winter photographs. However, under any circumstances, the best plan is to be prepared in case of unusual or exceptional effects occurring.

We may divide the winter into three photographic sections, each supplying pictures that require special treatment. When we reluctantly leave our beds in response to the awakening rap and announcement of hot water, when getting up reminds us of getting into a cold bath, when the windows are crystallised all over with fancy foliage sparkling in the morning light, when the whole landscape is covered with a snowy mantle of the pureat white, when voices and sounds seem isolated and float about without seeming connexion with solid bodies, when a good breakfast haa been disposed of, we are then in a condition to appreciate the beauty provided for us on a perfect winter day, and should by rights be prepared to take advantage of it. If we, according to custom, have stored our traps for the winter, the trouble of getting them together, and filling the slides, &c., if we are lucky enough to have a stock of plates, will, in all probability, occupy just the best time of the day for work, and fill us with vain regrets that we were not prepared for the emergency, as quite perfect days for photography in winter are not very plentiful. The moral is, *Always* be prepared, for there is no telling what a day may bring forth, or how long suitable conditions may last when they do happen.

The most perfect snow scenes are those taken when the snow has recently fallen and appears feathery and light, with the sun shining from the side. The direction of the strongest light is very important. The kind of treatment for a snow scene is identical with the reproduction of shallow carvings on white marble, that is, we want the greatest possible contrasts, so that every inequality may be properly rendered without sacrificing the texture; this does not mean a hard, dense negative, printing black and white, but one possessing good contrasts, combined with good gradations. Many snow scenes are represented as if the snow consisted of solid chalk instead of the feathery masses of crystals lightly laid together that form its substance; in a short time it partially melts, losing its transparency and much of its beauty, so the proper time to secure our photographs is as soon as possible after it has fallen.

There are many things to contend with in making good snow negatives. As I have already said, the direction of the light is very important, every little shadow has to be made the most of, so that we can get the idea of depth and lightness, instead of solidity and weight. An under-exposed snow scene always fails in this respect, the gradation of tint in the lights being represented by solid opacity, and in the print by white paper. Over-exposure, on the other hand, means a weak, flat negative, that gives a dirty-looking print at best, entirely destroying the sparkle and pure effect of clean snow. Correct exposure is absolutely necessary, and this, owing to the limited experience most of us have in this particular direction, is the chief difficulty. Actinometers do not seem to be of much service in the work; it is true they give the value of the light, but there is something more wanted than a mere knowledge of the power of the light to succeed with snow. A sheet of white is very misleading, and, after being accustomed to the varied colours of autumn scenery, it is hard to think the exposure is so little different to it. Under-exposure, besides destroying modelling in the lights, renders the dark portions devoid of detail, which, in contrast with the snow, gives a *silhouette* appearance to those objects possessed of soundness and solidity. The piling on of density in trying to get out detail of course exaggerates this effect. Snow negatives should be *rather* thinner than other landscape work in order to reduce this extreme contrast.

There are other conditions adverse to success in this department. Not the least is the bad light and fogs that frequently prevail in snowy weather, especially in the neighbourhood of large towns. The finest work is undoubtedly produced when the sun shines clearly on the snow. The beautiful shadows produced are well worth the most careful attention. Nothing conduces so much to make snow look like snow in the picture than well-rendered cast shadows upon it. The shaded side of an inequality in the snow is quite of a different character to a cast shadow from some opaque object. It is as well to thoroughly realise this difference by careful *study* of the snow itself before proceeding to develop.

The protection of the lens by a surrounding hood from *all* light other than that forming the image is a *very* important precaution. The neglect of this tends perhaps as much as anything to make snow pictures flat, on account of the immense amount of light reflected from all points, often more from the ground than the sky. We all know what improvement is effected in ordinary photographs by the judicious use of a sky-shade. With snow we require the sky shade *all round* the lens. A contrivance like a black funnel projecting from the front of the camera is about the best form. If a pneumatic shutter is used, working in or behind the lens, the hood may be fixed to the lens itself, and will not require to project more than five or six inches in front; but, if a cap is used, the contrivance should be larger, so that the hand can be easily inserted without touching it; under all circumstances it must be sufficiently large to avoid cutting off any of the image. This must be carefully remembered when wide-angle lenses are used alternately with lenses of narrow angle. The use of an expanding hood, constructed of wire and black silk or other material, is a great advantage at all times in outdoor work, although especially so in snow scenes.

The *highest* lights on snow should be sufficiently dense to print without a tint; a difficulty sometimes experienced is in getting the snow to print lighter than the sky, and many discussions have been held on this point, the contention being that the sky, being the source of illumination, ought to be the lightest portion of the picture. The portion of sky *that appears in a picture* is frequently far less brightly illuminated than the snow, and is practically not the source of light so far as the picture is concerned; it is, on the contrary, very much lower in tone than the light reflected from the snow, that absorbs but little when the sun is at the side or behind the camera.

A well-lighted snow scene always has a sky darker than the snow, but, if it is falling snow, the particles, being more or less opaque, look darker than the sky, which acts as a background, the surface reflecting

the light being much less noticeable in the detached flakes as they slowly fall to the earth than as they lie massed upon it.

In prosecuting all winter photography, waterproof boots and leggings, with warm stockings, are advisable. A tramp for a few miles, ankle deep in snow, is, without adequate protection, a toil of a pleasure, for there is as much standing about, selecting the views, &c., as in summer, and health demands that one should keep dry and warm about the feet under these conditions.

Hoar frost is another winter subject more fleeting than snow, and rarely lasts long; in fact, so evanescent is it that in a few minutes its beauty may be gone. A slight breeze of warmer air causes it to vanish like magic. At other times it may last a day or two; but it rarely retains its best form more than a few hours. Lucky is the photographer who happens to be on the spot at the height of its beauty if he is prepared to secure it. Owing to its reflecting less light than snow, it is more easy to photograph. A mist is always required to produce it; it is as the mist clears off that it is seen in perfection, just as crystals look best after drawing off the mother liquor from which they have been deposited. The hoar frost has been crystallised out of the mist, adhering to anything offering a support, especially to the bare, rough branches of trees and other vegetation, an unattractive clump of sedge and dead stalks becomes, under the magic touch of hoar frost, a veritable fairy garden. No particular precautions are required in photographing it other than apply to snow; but, as it reflects rather less light, it requires *rather* longer exposure. In this, as with snow, the negatives must be somewhat thin than otherwise, and the most effective pictures are undoubtedly obtained when the sun shines from the side, although without sunshine very good results are also obtainable. Hoar-frost pictures will be always popular if good, as they make excellent enlargements, and look well on the lantern screen.

Ice forms the other division into which we have arbitrarily divided winter work. Ice itself, unless in large masses, such as were seen on the Thames a few years ago during the great frost, does not offer many attractions, except as a setting for skating scenes, &c.; very pretty and attractive pictures may be made, providing the light is clear and the sun shines. Some time since, I had in my possession a *wet-collodion* negative taken with an instantaneous exposure of a skating scene in the North of England, in which all the figures, some fifty or so, were sharp and full of detail; so now, with our more rapid plates and improved appliances, there should be no difficulty in securing good results.

The crystallised ice on window panes will make attractive pictures; providing dark screens are so placed that the pattern is thrown up into the strongest relief; a rather short exposure is generally best.

EDWARD DUNMORE.

THE PYRO-METOL DEVELOPER.

[Wilson's Photographic Magazine.]

SOME weeks ago I had a call to do a little street photography. The day was very far from being suitable for snap-shot work, but it had to be done then or not at all. It had been raining, so that the atmosphere was clear, but there was very little light. The lens I used will work at *f*-4, but, in order to get better distance, I used the stop *f*-8. It was with some fear that I entered my dark room to develop the plates, but I had the satisfaction of having them turn out all right. I attribute my success to a modified pyro or pyro-metol developer, which I have employed for some time past with general satisfaction. Those who have a little time to spare, and who are fond of trying a new thing once in a while, will possibly find these few notes of interest. In the following formula No. 1 is for use when it is desired to produce a strong negative; No. 2 is a milder form of the same; No. 3 is the usual alkali solution.

No. 1.

Water	8 ounces.
Metol	18 grains.
Sulphite of sodium (crystallised)	360 ,,
Pyro	22 ,,
Bromide of potassium	4 ,,
Citric acid	24 ,,

No. 2.

Water	8 ounces.
Metol	18 grains.
Sulphite of sodium (crystallised)	360 ,,
Pyro	22 ,,

No. 3.

Water	8 ounces.
Carbonate of potassium	1 ounce.

For use, take one part of No. 1 (or No. 2, according to the kind of negative desired) to one part of No. 3, and add one part of water.

I find that the above quantity of sulphite gives a slight tint, which produces an excellent printing negative, but, if you desire a grey negative, you can get it by increasing the quantity of sulphite. I think those who try it will like it. I have had better results with this formula, both under skylight and landscape, than with any developer I have ever used. You can modify the printing qualities of your negative to almost any extent by increasing or decreasing the quantity of sulphite.

JEX BARDWELL.

X-RAY EXPERIENCES.

To the amateur who would essay a venture into the worlds of mystery and science surrounding the theory and practice of Radiography, the advice of *Punch* would, as a rule, be most appropriate.

That this new art-science has come to stop, and that it will unquestionably become of the highest value, may be taken for granted. There is, again, no doubt whatever that a field, small, certainly, but fresh, is provided for those few men who may have made themselves competent for such work. In every hospital or infirmary of any size or importance there may be, in course of time, work in plenty for those able to perform special duties in connexion with X-ray investigations.

Already much that was written in connexion with this subject early in the year reads strangely. We had, it will be remembered, promises of "special editions" as any new fact came to light. Did any one radiograph a coin through his trousers pocket, or reveal the bones of his matutinal "kipper," the fact was recorded in a "special;" and some enthusiasts went so far as to say "they never had any failures," and, what is worse almost, put their names to it in full! Coils were at a premium, or, to be exact, were not to be had fast enough. "Now," as one maker remarked to me, "you can't give them away;" which is, no doubt, true in more ways than one.

We are not quite so cock-sure nowadays, and take our successes with due modesty and an air of mild surprise, as who should say, "Look at that, now; I wonder how *that* came about!" whilst our wives look on rather pityingly, and tell the children, "He (meaning the husband) is all right now, he has got something to play with."

Seriously, we may be thankful that, for the main part, the best work has been done by men who have been actuated by no private greed, but have freely published, discussed, and exhibited their results with the ready willingness of the real amateur. It might easily have been so different!

But I must get on with what I was about to say. It cannot be too often remarked that primary batteries are a great source of trouble, are most unreliable, and most expensive. Let no one of your readers imagine he will economise by investing in primaries. He will quickly find, in his determination to get results (unless, of course, staggered by the worry and outlay), he is spending as much as would provide him with a good accumulator.

Accumulators, let it be understood, are not quite the simple, innocent things some people imagine. It is not all plain sailing with them, and it will not always follow that "all you need do is use it for so many hours, then send it away to be recharged," which sounds very simple. My advice is, Don't have an accumulator unless you can yourself see to its "charging;" test the voltage and current, &c., and see that everything is in proper working order. The man who can use the main current is, of course, in luck's way, and, his mind relieved of one care, can devote his attention, all of which will be wanted, to other matters.

Tubes are still to be improved. I am not so sure about the size, but I think they would be better if made longer, the terminals somewhat further drawn out and more completely insulated. To prevent "sparking over" the tube, I have found the following simple plan to answer: cut two short lengths of quarter-inch glass tubing, and attach these with shellac or cement to each end of the tube over and around the terminals; the wires from the "secondary" pass, therefore, down an inch or so of tube before coming to the terminal.

Occasionally one finds, particularly with primary batteries, the fluorescence uneven and "flickering." This need not imply that X rays are not being formed; but I, for one, judge the working capacity of my tubes largely by the amount and evenness of the fluorescence. I find it an advantage sometimes to attach a *short* spiral of wire to the "anode" terminal of tube. This usually *steadies* the current and evens the fluorescence.

One focus tube I had, after giving some very sharp images, failed entirely in this respect, and gave shadowgraphs greatly varying. Sometimes there would be two or three shadows outlined as if the tube had been shifted. I found on examination the square platinum plate inside tube had become loose, it quite "shook" in its socket. This caused an oscillation during a tiny radius for the whole time of the exposure, and led, no doubt, to the want of sharpness complained of. I can account for it in no other way.

A tube suddenly becomes practically useless; the sparks play about outside perhaps, but fail to go through the tube. It is unsafe to overstrain your coil, and your three-inch tube appears to have become a six-inch! Increased vacuum, no doubt. Not only that, but I have noticed what I suspect to be a deposit of platinum on the inner surface of glass, just as, after long use, incandescent lamps get smoked with carbon. A

tube in this depraved condition can be remedied by heat. This fact does not appear to be so well known as it might be. Make the tube as hot as possible over a spirit flame—until, in fact, it is too hot to hold—then pack away in a box of cotton-wool to cool. It will be found all right at next time of using, and I think, after several heatings, I notice a diminishing of the inner coating. This latter is, of course, mainly conjecture. I haven't broken a tube in order to make a minute examination.

Temperature is of particular importance. The work-room should be *dry* and fairly warm. I suppose there are no two opinions about this in the interests of *success*, to say nothing of personal comfort.

As to plates, is there any advantage in the use of *isochromatic* plates? I used them at starting, but gave them up for the most rapid plates to be had. One brand of colour-corrected plates I have certainly found better and more sensitive to X rays than any other. I have not found them so troublesome or difficult of development as might be supposed. Amidol and sulphite of soda, the usual solution, with a trace of bromide, is used. Use the smallest amount of red light, and canary screened. Place the plate in a dish of normal developer, cover it, and leave it. I have had one in this way for over an hour, and been gratified with quite fair and passable results, developed practically in darkness.

The use of a fluorescent screen makes all the difference sometimes between a rather thin negative and one of good and easy printing density. Dissolve the contents of a tube of potassium platino-cyanide (equal to thirty grains) in a drachm or less of water, and saturate therewith a piece of blotting-paper, $6\frac{1}{2} \times 4\frac{3}{4}$. Attach this, when dry, to a piece of cardboard of the same size. This makes a very fair screen for "backing up a plate," but I do not use a screen invariably.

We have had from time to time startling announcements relative to the effects on the skin and tissues of X rays. We don't hear enough of these cases. It is not too much to ask that they be investigated and reported upon, for, if while investigating the troubles of others we lay ourselves open to attack from an insidious enemy, the game will scarcely be worth the candle; but, in the mean time, I confess to a good deal of scepticism, merely advising all operators to keep their fingers out of the developing solutions.

J. P. Nott.

SIMPSON'S PRINT-WASHING APPARATUS FOR PHOTOGRAPHIC PRINTS.

Mr. W. M. Simpson's invention consists of a tank in which trays are arranged horizontally, one above another, with a suitable space between each. The trays consist of a rectangular frame, across which tape is interlaced, so as to form a suitable lattice-work on which the prints to be washed are supported. One side of the frame is made of tube, preferably brass, of suitable substance. The other sides are made of stout wire, suitably bent, and attached to the tube at a short distance from each end thereof. Such attachment may conveniently be done by forming eyes at the ends of the wire, through which the ends of the tube pass, the eyes being soldered to the tube in such a manner as to leave about half an inch of tube projecting beyond the eye at each end.

Mr. Simpson says: "In one corner of the tank I place an upright supply pipe, having a row of holes along one side of it at a suitable distance apart, and in an adjacent corner of the tank I place an upright bearing piece, pierced with holes corresponding oppositely with those in the supply pipe. This bearing piece and also the supply pipe are suitably attached to the tank. The holes form bearings into which the short ends of the tubes are inserted. The ends of the tubes bearing in the supply pipe are left open, and the opposite ends are closed. Small jet holes are bored at intervals in the tubes in the direction of the plane of the frames. I provide suitable step pieces, or feet, to support the sides of the frame opposite to the tubes, so that the trays may be parallel to each other. These feet may conveniently be made as shown in fig. 3, where B is a blank of sheet metal, of which the wings, D, D, are to be bent as shown at the dotted lines. The slot, S, may conveniently be used for attaching the ends of the tape at the corners of the frame, and the flat part behind the slot forms a support for the foot of the next frame above.

"The frames are made each one a little larger than the one immediately below it, and the tank is preferably made wider in one direction at the top than at the bottom. The trays can be turned from a horizontal to a vertical position, turning in the bearings before mentioned. The action is as follows:—The prints to be washed are placed on the trays, beginning with the lowest tray. The other trays are in the vertical position while this is being done, and are turned down successively as required. Water is then turned on to the supply pipe, and thence, traversing the jet tubes, issues from the small jet holes and gradually fills the tank. When the tank is filled, there will be a constant circulation of water between each tray of prints. I provide a suitable overflow, which is preferably of syphon form, so as to draw off the water from the bottom of the tank, and, in the case of large tanks, I place an air tap or valve at the top of bend of syphon, so that, when the tap is closed, the syphon will act so as to empty the tank, but, when the tap is left open, the water will not sink below the level of the bend. In smaller tanks it is only necessary to pierce a small hole in the top of the bend. I sometimes modify the arrangement of jets and jet tubes by placing one or more jet tubes behind the series of trays in a vertical position, the jet holes being in such pipe or pipes so as to send a stream of water between each tray of prints. In this case the frames may be made of wire only, the ends being secured as by soldering into a short sleeve of metal, the bearings on which the frames turn being then placed within the frames.

"In the accompanying drawing fig. 1 shows the tank, of which two

FIG 1

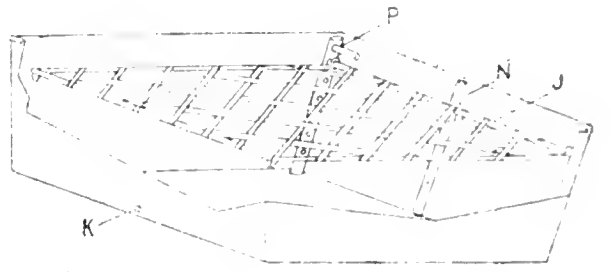

FIG 2

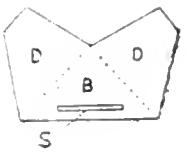
FIG 3



sides are partially cut away, with top tray in position. P is the supply pipe, J the jet tube, and N shows position of jet tube when placed behind trays, K the outlet for insertion of syphon.

"Fig. 2 shows foot attached to corner of frame, A; also attachment of frame to jet tube, J. H shows one of the jet holes.

"The claims are:—

"1. In an apparatus used for washing photographic prints, the arrangement of trays so mounted that they may be turned from a horizontal to a vertical position and *vice versâ*.

"2. The combination of jet tubes to form part of such trays.

"3. The combination of jet tubes with such trays so arranged when the jet tubes are placed behind the trays."

ELECTRIC LIGHT IN THE DARK ROOM.

It might, at first sight, seem to an outsider somewhat paradoxical that there should be any light at all in a dark room, but the intelligent amateur will immediately recognise that what is meant is the subdued red light required in the photographer's developing room, dark as regards actinic light, to enable him to see what he is about. This light, insignificant as it is, is a not by any means unimportant factor in the operator's comfort, if not in the success of his various operations, for it must be of the required quality and intensity, or it will spoil his materials, and it should be under his control, so that he may increase or diminish its brilliancy at will. It is, as regards this last qualification, that the majority of our dark-room lamps fall so far short of the ideal, for most of them will burn just as they like, high or low, or go out altogether, according as they are influenced by that mysterious something, not yet recognised by physicists, which influences the behaviour of inanimate objects. Gas is perhaps the best illuminant we possess, in this respect, but it has great disadvantages, arising chiefly from the heat it gives off, and products of combustion.

The incandescent electric lamp offers by far the most satisfactory means of supplying our developing tables with the necessary red light, in all respects but one, and that is the great difficulty there is in providing the electric power to light up the lamp, except, of course, in those cases where a beneficent vestry has provided the current, at so much per unit. But these cases are few and far between, so it falls to the lot of him who would revel in the delights of electric light in his dark room to find a means of producing his own electricity. Now, I have tried, I think, all the practicable ways of making the "subtle fluid" at home, and I have come to the conclusion that the best way of all is to buy it ready-made.

Secondary batteries, or accumulators, as they are often called, are devices which convert electrical energy into chemical action in such a manner that it is ready at a moment's notice to be converted back again into electricity. This is rather a crude explanation certainly, which probably would not bear strict examination by an electrician, but it is all right in spirit, and will serve our purpose. A secondary battery com-

posed of six cells will be the best for the purpose of the photographer, and such a battery, divided into two parts, so as to be more convenient for carrying about, can be easily procured, although, it must be confessed, at a cost considerably in excess of that usually paid for a dark-room lamp. Indeed, the expense of running an electric lamp in your red lantern being so very much in advance of the cost of paraffin or gas would be a very serious bar to its employment for the purpose, but that so very little is consumed that the extra expense which it involves cannot be weighed against its undoubted convenience and superiority.

This six-cell battery will have an electro-motive force of about twelve volts, that is to say, it will supply power enough, with a little to spare, to run a ten-volt lamp at high efficiency. A ten-volt "high efficiency battery lamp," as it is called, can be procured at about eighteen pence, and it will be as well to get two of them, so as not to be left, when the first one gives out, in the unenviable predicament in which, according to popular report, the patriarch Moses once found himself.

But it is not only as an illuminant for the red lamp that this electric light on a small scale is useful to the photographer. As a light for bromide printing, or lantern-slide making by contact, it is quite unequalled, for the ease with which it can be turned on or off at a moment's notice, coupled with the fact that, when the light is not burning, there is absolutely no glow whatever, as there is with gas that is turned low, make it invaluable for this class of work. Besides, from the moment when the newly charged battery is brought into requisition, to the time when it is so nearly exhausted that it is no longer advisable to use it further until it has been recharged, the quality of the light emitted by the lamp is practically constant, and this, it will readily be seen, is a most important factor.

One of the most attractive features of the light from the photographer's point of view is its ready amenability to any particular uses that his experience or ingenuity may suggest. Let me give an instance which will serve to suggest several similar cases in which the light will adapt itself to particular uses. I had a number of lantern slides to make by contact from various portions of rather large negatives, and I thought it would be a great convenience if I could illuminate the printing frame from below as it lay face downwards upon the table, so that I could see comfortably to place the sensitive plate in the right position upon the negative previous to exposure. I found a box that was about seven or eight inches deep, and of such a size that the printing frame, when placed upon it, fitted over it like a lid. In one side of this box a small hole was cut, in order that the battery wires could be conveniently passed through, and to these a small incandescent electric lamp was attached and wrapped up in orange-coloured paper. The printing frame rested on the top of the box, with the negative in position, and just before putting the sensitive plate in the place it was to occupy during exposure, the light was switched on for a few seconds, so that this operation could be accomplished in comfort and with accuracy.

Then, for developing, the light can be suspended from the ceiling so as to hang about a foot above the dish, and surrounded by a metal reflector that will concentrate the illumination upon the work in hand, and at the same time effectually prevent any of it reaching the eyes of the operator. Those who have been used to a red lamp placed in such a position that most of its rays stream right into their eyes can have little idea of the comfort which such an arrangement as that just described brings into the oftentimes tedious operation of developing. Not only can the process be better watched and controlled when all the light is shining upon the plate and none of it going to confuse and dazzle your eyes with its red glare, but a far greater amount of light can be used with impunity, for it need only be switched on for a second or two at first when the plate is in full possession of its sensitiveness, and can be turned out immediately that you have satisfied yourself that the developing solution is flowing evenly. Then, when the operation is reaching the critical stage, when it is of advantage to watch it carefully, and the plate is no longer so very sensitive, the light can be turned on in all its intensity until development is complete.

If it be preferred to use a weaker light during the earlier part of the development than that which is known to be harmless in the later stages, an artificial resistance can be included in the electrical circuit, which will have the effect of reducing the intensity of the light to, say, one-half, and this can be gradually shunted out as development proceeds, and the plate therefore grows less sensitive. Such a resistance is very easy to make. If the electric current that supplies the lamp be made to pass through a length of thin, tinned iron wire, such as the florists use for binding flowers into wreaths and bunches, it will be found to reduce the intensity of the light in proportion to the length of wire through which the current has to pass. The wire should be coiled up into a spiral, and that bent round into the form of a ring, so that a contact piece working from a central stud may be brought to touch it at any point, and you have a means of regulating the quantity of light to the greatest nicety. The energy which is thus prevented from transforming itself into light in the lamp will reappear as heat in this wire, but there will not be sufficient heat generated to do any damage or cause inconvenience.

The printing lamp may either be a suspended one, like that described for developing, in which case the printing frame would be laid on its back upon the table beneath it, or, if the box which I have described for lantern-slide work be adopted, a white lamp may be laid therein alongside the red one, so that it is merely necessary to switch the current from one to the other after the lantern plate or bromide paper has been placed in position—a plan which has its obvious advantages, among which may be mentioned the fact that the printing frame may be made a fixture. Both these plans, however, have the disadvantage that the exposure must be made at one fixed distance from the source of light, and it is well known that it is decidedly desirable to be able to alter this printing distance according to the character and density of the negative to be printed. Hence it will perhaps be better to so arrange matters that the frame may be supported vertically at a variable distance from the lamp, and this may be well accomplished by standing the frame upon its side (to which end it might be fitted with a kind of baseboard), and fixing the lamp upright in a stand that can be placed in any required position.

It is better to have a separate switch for each lamp, and these should be placed far enough apart to obviate all risk of accidentally turning on the wrong light. A multiple switch with several contact points is not so good, because there is always the liability of placing the contact piece upon the wrong button, with the probable result of lighting up a white lamp instead of a red one, and thereby spoiling a plate. The best position for the switches and the resistance, if one be used, is just on the under side of the developing table, where they are quite out of the way, while, at the same time, they are within easy reach of the operator's hand.

With regard to the battery cells, no very special precautions are necessary, and, unless they are grossly ill-used, they will require no attention whatever until their charge of electricity is exhausted. Care must, of course, be taken that they are properly connected up in the first place, that is to say, the positive terminal of one cell must be attached to the negative terminal of the next, and so on, and they should stand upon insulating trays, so that there shall be no fear of leakage. It must be remembered that there is a supply of electricity in the battery waiting to get across from one terminal to the other, and only too glad of any opportunity to do so quickly with as little delay as possible. Consequently, great care must be observed that this opportunity is not provided, except through the legitimate channel of the lamp, for, if by accident a path through which the current can flow quickly be provided, it will immediately take full advantage of it, and, there being nothing to say it nay, as it were, it will rush across and exhaust itself in a very few minutes, doing the battery considerable, and often irreparable, damage at the same time. This is called "short-circuiting" the cells, and is usually brought about by allowing the wires from the terminals to come into contact with one another.

It is a good plan to take a hint from the electricians, who have to deal with heavier currents, and include in the circuit what they call a "fuse." This is simply a short piece of tin wire placed between one terminal of the battery and its wire connextion, and through which the current has to pass before it can by any means reach the other terminal. The tin wire is very thin, so that it will only just carry the amount of current that is wanted for the work in hand without getting hot, and, when this quantity of electricity is accidentally exceeded, the wire immediately becomes heated, melts, and drops out of its connexion, and so cuts the circuit effectually.

Secondary batteries or accumulators should never be used to complete exhaustion, as such a practice is exceedingly harmful to them, and shortens their life to a considerable extent. They should be recharged directly they show signs of weakness, that is to say, as soon as the lamps begin to yield a less brilliant light, they should be used no longer, and the battery taken to be charged before it is attempted to work from it again. The recharging only takes a few hours, and is not costly if you go to a fairly honest place, and, if care be used and the batteries taken to be charged as soon as they have arrived at that stage when it is no longer advisable to draw further current from them, they will keep for years, and work as well as when they were new. The length of time which they will run at a stretch depends entirely upon their size, and, if you say when purchasing what lamp or lamps you purpose running from them, you can buy a battery that will last for any given time before it will require recharging.

CECIL M. HEPWORTH.

IMPROVEMENTS IN PHOTOGRAPHIC DEVELOPERS.

MESSRS. LEMBACH & SCHLEICHER'S invention consists in the employment of hydrated oxy-quinolines and oxy-tolu-quinolines, and of their substitution products for developing photographic impressions in halogen silver containing media.

Heretofore, only those bodies have been known as organic developers from the aromatic series which contain in their essential structure at least two hydroxyl groups or at least two amido groups, or it may be hydroxyl and amido groups together. The substitutes are in this connexion either in the ortho or in the para position, whilst the meta-substitution products are wholly inoperative.

Of the quinoline series there have been heretofore proposed for use as photographic developers di-oxy-quinolines, di-amido-quinolines, and amido-oxy-quinolines which have, however, not till now come into general use in photographic work, because their complicated and tedious pro-

duction have rendered them too expensive, whilst their developing power is considerably less than that of the developers already in general use such as rodinal, eikonogen, methol, hydroquinone, pyrogallol, &c.

The fact, however, that hydrated oxy-quinolines have also the power of developing a photographic picture is entirely novel. It has been discovered that especially the tetra-hydro-compounds of the oxy-quinolines and oxy-tolu-quinolines, and also their "substitution" products (such, for example, as tetra-hydro-ana-bromine-o-oxy-quinoline) (O. Fischer and Renouf, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvii. p. 760); tetra-hydro-di-oxy-quinoline (Bayer and Homolke, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvi. p. 2217); tetra-hydro-ana-amido-o-oxy-quinoline; tetra-hydro-o-oxy-quinoline-ana-sulpho-acid; and tetra-hydro-o-oxy-quinoline carbo-acid (Schmidt and Engelmann, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xx. p. 1219, and Heyden, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xx. p. 443); are capable, by reason of their powerfully reducing properties, of furnishing photographic developers of high excellence which, even when diluted to the utmost conceivable extent, develop the latent photographic picture in a perfectly clear and extremely rapid manner and with sharpness of all details. Fogginess, such as is usually produced by over-developing, has not been observed with their use.

As compared with the substitution products of oxy-quinoline proposed by Auguste and Louis Lumière (*Jahrbuch für Photographie und Reproductions-technik*, 1892, p. 93) as photographic developers, these improved addition-products of oxy-quinoline or of oxy-tolu-quinoline have the great advantage that they possess a considerably greater developing power than the former, and that the developing solutions prepared from them are extremely durable and can be prepared in a very concentrated condition.

In addition to the aforesaid hydrated oxy-quinolines and oxy-tolu-quinolines, photographic developers of high excellence and great power are also constituted by the hydrides of the oxy-quinolines and oxy-tolu-quinolines in substitution in quinoline-nitrogen, and also by the substances produced by the action of monochlor-acetic-acid upon the hydrated oxy-quinolines and oxy-tolu-quinolines.

Of the substances coming in question in this connexion, the following may be mentioned:—

O-oxyhyro-methyl quinoline (O. Fischer, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvi. p. 714).

O-oxyhydro-ethylquinoline (O. Fischer, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvi. p. 717);

(Fischer and Renouf, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvii. p. 756.)

O-oxy-hydropropylquinoline (O. Fischer, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvi. p. 717).

O-oxy-hydro-butyl-quinoline (O. Fischer, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvi. p. 717).

O-oxyhydro-amyl-quinoline (O. Fischer, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvi. p. 717).

O-oxy-hydro-benzyl-quinoline (O. Fischer, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvi. p. 717).

O-oxy-hydro-phenyl-quinoline.

O-oxy-hydro-acetyl-quinoline.

O-oxy-hydro-benzoyl-quinoline.

O-oxy-hydro-methyl-quinoline-carbo-acid.

(Schmidt and Engelmann, *Berichte der Deutschen Chemischen Gesellschaft*, vol xx. p. 1219.)

Furthermore, the corresponding compounds of p-oxy-quinoline hydride and of the oxy-tolu-quinoline hydrides; and also the products of reaction of mono-chlor-acetic acid upon o-oxy-quinoline hydride (Kairocoll O. Fischer, *Berichte der Deutschen Chemischen Gesellschaft*, vol. xvi. p. 719); p-oxy-quinoline hydride and oxy-tolu-quinoline hydrides.

In order to prepare the developing solution from the aforesaid compounds, proceed as follows:—

Twenty-five grammes of neutral sodium sulphite and four grammes of caustic potash are dissolved with the aid of heat in 100 grammes of water, and to this are added ten grammes of tetra-hydro-o-oxy-quinoline or a corresponding amount of another of the aforesaid substances.

The claims are: 1. The use of hydrated oxy-quinolines and oxy-tolu-quinolines and also of their substitution products, in particular of the hydrides thereof in substitution in quinoline nitrogen, and also of the substances produced by the action of mono-chlor-acetic-acid upon the hydrated oxy-quinolines and oxy-tolu-quinolines for developing photographic pictures in halogen silver containing media.

2. A developer for photographic pictures which is prepared with the use of the substances mentioned in Claim 1, consisting of a solution of tetra-hydro-o-oxy-quinoline or of another of the before-mentioned substances, in an aqueous solution of neutral sodium sulphite and caustic potash, the concentrated durable solution thus produced being diluted with water before use.

STEREOSCOPIC PHOTOGRAPHS WITH TWO CAMERAS HAVING LENSES OF DIFFERENT TYPE AND FOCAL LENGTH.

[The Shashin Sowa.]

PERHAPS your readers have not all even heard of the very remarkable ice caves at Shoji, Yamanashi-ken, that is to say at the foot of Fuji-san on the side diametrically opposite Hakone. These caves, one of enormous size, are floored with ice, summer and winter, of such a depth that it has never yet been fathomed. During winter, water, dropping from the roof, produces wonderful and beautiful stalactitic and stalagmitic ice formations, which glisten and sparkle in the presence of any artificial light, no ray of daylight ever penetrating more than a little beyond the mouth of the great cave.

Photographs of the lower end of the cave, showing these strange ice shapes, have been made, using magnesium ribbon light, by myself and by several others, but single photographs, for some reason, fail utterly to give any impression of the remarkable effect produced on the eye.

I have frequently visited the ice caves, and have several times photographed the interior of the great cave, with varying success, but I soon recognised that any photograph, to give an idea of the place, must be stereoscopic. Last year Mr. Sydney Keith, an ardent amateur photographer, made stereoscopic exposures, but with what result I do not know, as he took his plates undeveloped back to England. I made an attempt myself with an inferior make of stereoscopic camera, but will not trouble your readers with a description of the reasons why the results were failures.

Early this year I was at Shoji with a friend, each of us having a hand camera. The cameras differed in type, and had lenses differing both in type and in focal length. One lens was an anastigmatic of five-and-a-half-inches focus, the other a rectilinear of four-and-three-quarters-inches focus. The former with a maximum aperture of *f*-6·3, the latter *f*-8. The only thing in common, so far as the two cameras were concerned, was that they were both for quarter-plates.

This gear—different cameras, different lenses of different focal lengths, each for a plate larger than stereoscopic size—could not be called very hopeful for stereoscopic work, and it was, indeed, only after some hesitation that we decided to attempt, with this very unpromising machinery, a stereoscopic effect. The supplement to coming number will, however, show that we met with a fair amount of success. The following is an exact description of the method used. The cameras were placed side by side, as nearly level as circumstances would permit, and, the lenses being stopped down to the same aperture (*f*-11), a large quantity of magnesium ribbon was burned at points behind, and at one side of, the cameras; ribbon to the length of about thirty yards, platted into torches, was burned for each exposure, of which three altogether were made. Development showed that one-third the quantity of ribbon would have been sufficient; but such moderate over-exposure could, of course, be easily rectified in development.

After the plates were developed, fixed, &c., the best one from each camera was selected, that from the camera with the longest focus lens was taken, certain fairly prominent points near each of the four edges were selected, and, lines being drawn through these, the limit of the picture was determined. The lines were drawn (actually scratched with a needle point) parallel to the edges, because it was known that the camera had not been canted sideways to any appreciable extent. The next thing was to draw a *corresponding* base line on the negatives taken with the shorter focus lens, which was, of course, on a smaller scale. This was a little difficult, as the camera with the shorter focus lens had been canted a little. It was necessary to select *two* points on the base line of the first negative, to find corresponding points on the second, and to draw a line through them. It was then easy to draw the top line, it being, of course, parallel with the bottom line, and through a corresponding point.

The side lines present a complication. In a pair of prints mounted for the stereoscope, that to be seen by the *right eye* should show a little more subject at the *left* side than at the right, and *vice versâ* as regards the *right side*, and as regards the print to be seen by the *left eye*. The object is to give the impression of an opening in the mount *through* which the object is seen. The amount of difference might be calculated mathematically were all factors, such as distances of objects, focal length of lenses (both of the camera and of the stereoscopic), &c., known, but it is usually determined empirically. About one-eighth of an inch will be found to give a good effect. In the case in question, allowance was made on the negatives, *right side* being substituted for the *left side* given above, and *vice versâ*, and the allowances were made proportionate to the sizes of the images.

Transparencies were now made in the camera from each of the two negatives, the size being reduced to stereoscopic size, and the greatest care being taken, using a pair of hair dividers, to observe that the transparencies, from negatives of different scales were reduced to precisely the same scale, and that the transparencies were of the same density (though the negatives were not). The transparencies were then mounted on a sheet of patent plate, taking care that that representing the right-hand image was to the right, that representing the left-hand image to the left. From this double transparency there was then made, by contact, a double negative, from which prints could be made direct. The half-tones have suffered somewhat from the repeated operation of negative to positive, positive to negative, and once more negative to positive, but it will be seen that the stereoscopic effect is perfectly retained. Indeed, it is somewhat exaggerated, because the axes of the cameras could not be got nearer to each other than four and a half inches, whereas, for true stereoscopic effect, they should not be more than about two and three-quarters of an inch apart.

It might be supposed that reducing the size of the negatives as described would counteract this exaggeration, but this is not the case. The distance apart of the cameras, when the negatives are first taken, absolutely fixes the amount of "stereoscoposity" (if the word will pass), no after alteration in size having any power to alter it.

W. K. Burton.

[With such a slight difference in the foci of the lenses of the two cameras employed, we should expect passably good results to be obtained; but the use of *one* camera moved laterally the requisite distance would have given perfect results.—Ed.]

PHOTOGRAPHY IN RELATION TO ART.

[Dulwich Photographic Society.]

The subject about which I venture to address you to-night is one of unquestionable interest. It should be of interest, in the first place, to all who follow the cult of the camera, but especially to those who have acquired, by study and practice, a knowledge of its manipulation. More particularly is this so as respects those who have acquired a competent acquaintance with those theoretic and scientific developments which have done so much to place photography in the advanced position to which it has now admittedly attained. It has been urged by some that photography is rather mechanical than artistic; that the potentialities of light—not always that evolved by the direct action of the sun—have been simply utilised by mechanical contrivances, supplemented by chemical accessories, and that the picture produced upon the plate is the result of mere skill, such as may be and is habitually employed in connexion with many industrial avocations. Indeed, it has been said that it requires as much aptitude or skill to make a good glass-blower as to make a good photographer. No doubt, there is a substratum of truth in this contention.

No one, I take it, will dispute as to the fact that all that is necessary to obtain a picture by means of the photographic camera is the possession by the operator of a mastery of certain practical details, and of facility in their use. Given this, he is able to effect a more or less truthful reproduction of such object or objects as he may desire to make the subject of his portraiture. But, granting this, if the operator has no higher qualifications, he is nothing more than a neophyte, he is nothing more than a waiter at the gates opening to a nobler and more august interior, in which the brighter trophies of photography are enshrined. It is when photography is associated with art that a spirit of life and divinity is, so to speak, infused, which enhances its beauty, and invests it with a power to seize upon the richest faculties of our nature. If you will allow me, I would compare photography to a marble statue—lovely in its immobility, but it breathes not, it moves not, it is without a soul, and its stillness is almost oppressive. Now comes Art, with its glorious baptism. Behold, it breathes, it moves, it is no longer without a soul.

For a marvellous change has taken place, and so evident is this that no one can fail to observe it. Let the work of an operator, who has no knowledge or care for the artistic, be compared—even where the same subject is in question—with that of a photographer who has, as it were, combined the illumination of art with the light of day, and the merest tyro cannot fail to discern, though he may not be in terms able to explain, the subtle difference that recommends the contribution of the atter to his preference. The reason for this is not far to seek. It is because the first appeals only to the eye, whereas the second appeals to the heart as well as to the eye.

I will go so far as to assert that, where the artistic appreciation is absent, the photographic operator can never produce really superior or truly meritorious results. Of course, all men are not endowed equally by Nature with what I have described as artistic appreciation, and only a few have it in the higher degrees; but most people have it in some modified sense, and no operator should, in my opinion, bring his camera into requisition without recognising the importance of its application in everything that he does.

It may be asked: "How and in what way may such artistic appreciation be expected to manifest itself in the practical use of the camera?" Obviously, the first consideration has respect to the selection of the subject. A photographer, with the slightest artistic appreciation, would, for instance, refrain from wasting his time or his plates upon the reproduction of some of the objects and subjects which, with apparent expectation of praise, are occasionally submitted for our critical approbation, with no better claim than that the outlines of the picture are sharply defined, the toning excellent, and the surface as exquisitely glazed as a newly starched and carefully ironed shirt front. As specimens of mechanical photography, such productions may, and, in fact, do, attribute manipulative merit to the operator, nor is it my design to undervalue the importance of proficiency in execution; without such proficiency artistic appreciation would be of no avail. Without extraordinary and facile skill in the use of his paints and his pigments, his pencil and his brush, and the other instrumentalities of his grand craft, not all the powers of a Rubens or a Michael Angelo could have given to mankind the magnificent creations of his transcendant genius. And so no one, without proficiency in the use of his camera, and with a perfect knowledge of all the accessory processes, though the flame of art may burn brightly within him, can hope to excel in photography, or offer anything to the public worthy of taking a conspicuous place in the gallery of its proudest achievements. I do not, however, agree with some who have gone farther, and have insisted that the photographer should make himself quite familiar with the scientific value of all the elements brought into service in connexion with the production of the photographic picture. To begin with, it would be to place too heavy a burden upon the shoulders of the photographer, because light is essential, to require from him a solution of problems with regard to that substance—by the way, is it a substance?—which are yet undetermined, and may remain so for centuries to come. Nevertheless, it is desirable, though not absolutely necessary, that the photographer should know, not only the effects produced by the elements he employs, but also some of the reasons why such effects are brought about.

But to return. I repeat that the initial link which binds photography in its relation to art is in the selection of a suitable subject—that is to say, a subject which presents those features which please the eye and content the mind—features that, as with a seraph's finger, strike the golden strings in our inmost being, and awaken to exquisite vibration the poetical and artistic emotions of the soul. At the recent Exhibition of our Society I noticed a number of very admirable photographs, the subjects of which, in my opinion, testify to the existence of much artistic appreciation in their selection.

The experienced photographer, when he goes afield with his camera, fully equipped, is like a veteran soldier when in action, who does not waste his ammunition. In like manner, he uses his camera with cautious discrimination, and patiently holds himself in reserve for something worth taking. Nothing should escape his vigilant observation, and, when he meets—as he not unfrequently does, quite unexpectedly—with some choice "bit" of scenery, or with some attractive and pretty phase of rural or urban life, he loses no time in adding it to his collection.

Here, again, artistic appreciation is of consequence. A subject may have artistic value, but much will depend on the point of view from which it is regarded. Many a truly artistic subject has been virtually despoiled of its beauty by lack of artistic appreciation or inattention to this primary, I had almost said elementary, precaution. The best point of view is by no means evident at a mere casual glance. I am speaking in the presence of experienced photographers, and I am sure that they will not dissent from this. Another matter is material, namely, to exclude, as much as possible, from the picture all inartistic surroundings.

We have now a subject artistically selected, taken from its most artistic and effective point of view. But the relation of art to photography is not ended here. It follows the evolution of the picture throughout all its progressive stages until completion, and a comparison of the perfected production with the first print from the negative will often show us in how large a degree the technique of photography has been made subservient to artistic requisition. A good photograph should be well mounted and framed. The artistic temperament finds further opportunity of demonstration in the choice of materials harmonising in colour, and form, and decoration with the character of the subject. This is not so insignificant a thing as some people might imagine. There would be, for example, evident incongruity in placing a picture representing some scene associated with solemn and sombre memories in a brightly gilded frame.

I have not attempted to institute any comparison between the photographer and the painter. This has already been done by Mr. A. C. Payne, in an interesting paper read by him before this Society some time ago. The photographer and the painter move in their several orbits, and, without desiring to provoke controversy, I may be permitted to add, that each can claim for his own art points of superior excellence. In painting much is left to the imagination. Much is suggested rather than expressed. In photography, on the contrary, there is a microscopic fidelity to detail which leaves little to the imagination, and the only allocation of emphasis is that which, within narrow limits, can be procured by focal adjustments. The photographer is chained in fetters—but fetters of light—to the physical and the visible. Not so the painter. His thoughts may soar, on the wings of inspiration, into realms beyond the faculty of vision, and his greatest triumphs are often the intangible and ethereal creation of his own genius.

From an artistic point of view photography suffers from the absence of colour. The forms of Nature can be reproduced and fixed in the photographic picture, but the varied tints which grace and beautify them are wanting. Here the painter has an advantage, the importance and value of which it would be difficult to exaggerate. Whether it will be allowed to remain only time can determine. Certain it is that efforts have been made, and are still being made, to endow the photographic picture with the very colours and tints of the original. Something in this direction has been already accomplished, and several of the cardinal colours have, I understand, been reproduced, but it is objected that they soon fade and become obliterated. Nevertheless, so persistent are the investigations and experiments to achieve this object that, if attainable, this grand result will eventually be compassed. In such case, photography will prefer a new claim upon mankind. As a sort of make-shift—though a very good one—the crystoleum process has been invented, by

means of which coloured photographs are produced, some of them of highly meritorious character. At our recent Exhibition several most excellent examples were shown, though not for competition, and attracted considerable attention. Here we have "photography in relation to art" more closely united than previously had been possible, and it must be conceded that, in the development and application of this system, there is wider scope for the utilisation of the artistic faculties. A crystoleum photograph, when well and carefully—above all, when artistically executed—affords the nearest approach we yet have to a reproduction of the effects of Nature as she is, dight in the varied hues that make us love her so.

It has not been my purpose to-night to make a long discourse, or to burden what I had to say to you by technical details. Rather, it has been my object to submit to you the views of one who, without claiming himself to have deeply studied the science of photography, has a genuine admiration of the grand work it has achieved, with a sincere conviction that it has before it a noble future. I know of no occupation which presents so many attractions to the lover of the open country. The practice of photography invites its votaries to health-giving and agreeable excursions from smoke-begrimed cities and towns into those more pleasant and brighter scenes, where the air is pure, and the eye is refreshed by the thousand-and-one aspects of loveliness which speak so softly and wooingly to the heart and the enthusiasm of the lover of Nature. In search of the picturesque and beautiful, with his camera as a companion, the photographer enjoys communion with her, not only where she submits herself to the gaze of every casual observer, but in those places where she seeks retirement from the common inspection, and not unfrequently presents herself arrayed in her choicest charms. Rightly regarded, photography is undoubtedly one of the most innocent, refining, and salutary of pursuits, and, when it is invested with the halo of art, it may fairly claim to receive the recognition and approval of the whole world.

CHARLES DUNLOP.

The Inquirer.

*** In this column we from time to time print questions that may be addressed to individual contributors to our pages, or such as are sent to us with the view of eliciting information from a variety of sources. We invite the co-operation of our readers in rendering this feature of the* JOURNAL *useful and instructive.*

PITS.—A. LEVY writes: "In answer to Inquirer, 'Pits in Gelatine Films,' p. 810: They can be very easily cured (see last paragraph, p. 654 in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1897). It is the quickest and safest remedy, and cheapest."

WARM-TONED LANTERN SLIDES.—An experiment of my own seems to afford evidence that the deposit produced by the usual process of prolonged exposure and slow development with a developer containing ammonium chloride is, even after fixation, *still sensitive to light*. A red-toned slide, during prolonged exposure to daylight, changed first to a lilac tone, and finally to purple; it behaved, in fact, very similarly to an image formed in chloride of silver. Can any one throw any light upon this subject, or give references to the researches of any well-known authorities?—C. W. P.

ACTION OF SALT. (To "Cum Grano").—With regard to the action of a bath of salt in removing stain, if the so-called stain is really surface fog, due either to the use of an unsafe light during development or to the employment of too powerful a developer, then I see no reason to doubt the inaccuracy of your friend's statement. If a little developer is retained in the film, such fog is removed to a great extent by a bath of bromide applied before fixation (though at the expense of some of the finer shadow details), and also by a solution of iodide; a chloride probably has a similar effect, though I have not tried it. If hydrochloric acid is added to sodium sulphite, sodium chloride is formed, and, if the mixture is added to the hypo solution, a fixing bath is produced, which acts as a powerful reducer of density, and also removes surface fog. A plain solution of salt added to the hypo will probably have the same effect, and so also may a solution of bromide. Iodide has a powerful effect. The explanation is probably as follows: Metallic silver is reduced from a subhaloid salt of silver, either by the developer, or by the fixing bath. If a bath of a haloid salt is applied before fixation, the slight amount of developer retained in the film continues to reduce metal, which, by interacting with the soluble haloid while in a nascent state, is converted into an irreducible normal haloid silver salt, soluble in hypo. If the soluble haloid is added to the hypo, a similar effect takes place, the nascent silver being in this case produced by the action of the hypo. Stain, if co-existent with surface fog, may possibly be rendered colourless, or perhaps removed, by interaction with the alkali produced by the decomposition of the soluble haloid.

THE effect of salt in hardening the gelatine is probably more apparent than real. Possibly it prevents frilling, but the manner in which it does so cannot be satisfactorily explained. As is well known, it prevents the appearance of blisters in albumen paper. I have used bromides for removing surface fog before fixation, but cannot recommend them, excepting under special circumstances, as they undoubtedly have a deleterious effect on the details. Chlorides may be less objectionable in this respect. —C. WELBORNE PIPER.

Our Editorial Table.

PHOTOGRAPHIC MOSAICS, 1897.

Edited by E. L. WILSON. New York: Edward & Wilson.

Mosaics for 1897 does Mr. Wilson very great credit in several respects. It is beautifully printed, and the illustrations, of which there are nearly forty, are mostly half-tone blocks of good quality, made from good originals. American portraiture of the commercial kind would appear, from the examples here reproduced, to be quite the equal of British work. The Editor prefaces the book with an able and lengthy review of practical photography in 1896, and there are many original articles by, among others, Falk, Dr. J. Nicol, W. H. Sherman, Victor Schumann, Dresser, Eder, Jas. F. Ryder, C. W. Motes, G. L. Hurd, and W. T. Wilkinson. We have turned over the pages of *Photographic Mosaics* with genuine pleasure. It is an elegant book.

WYNNE'S INFALLIBLE PRINT METER.

The Infallible Exposure Meter Company, Wrexham.

THIS little instrument utilises the principle that a series of numerals graduated in density can be used in conjunction with sensitive silver paper to arrive at the time requisite to produce prints by the carbon, platinum, and other processes. It consists of a neat little metal case glazed with opal, at the back of which is a plate on which the numerals and letters are impressed. Contact is made with a piece of print-out paper, which is placed in the back of the meter. It is a handy system for arriving at the exact time of printing required in carbon, platinum, and ferro-prussiate paper work. The Infallible Print Meter should be found in the printing room of the amateur and professional.

THE "TEAR-OFF" TOURISTS' CALENDARS.

T. C. König & Ebhardt, 14, Billiter-street, E.C.

MESSRS. KÖNIG have sent us specimens of their daily "tear-off" tourists' calendars. Each leaf, besides the date, bears a pleasing view in half-tone. Being attractively got up, the calendars are ornamental as well as useful, and are therefore assured of a double welcome.

RÖNTGEN RAYS AND PHENOMENA OF THE ANODE AND CATHODE.

By E. P. THOMPSON, M.E. London: E. & F. N. Spon, 125, Strand.

DR. THOMPSON, in his preface to this painstaking volume, thus outlines its objects: "In addition to the illustrated feature for exhibiting the nature and practical application of the X rays, and for simplifying the descriptions, the book involves the disclosure of the facts and principles relating to the phenomena occurring between and around charged electrodes, separated by different gaseous media at various pressures. The specific aim is the treatment of the radiant energy developed within and from a discharge tube, the only source of X rays." The first six chapters of the work detail what was known of these interesting phenomena prior to the publication of Röntgen's paper. The subsequent record of experimental work published in the scientific papers since January last is very complete. Terseness characterises the compilation, which is in paragraphic form, with cross references. There are many excellent illustrations. The book is perhaps the most trustworthy record of the phenomena of anode and cathode rays that has appeared, and its value will, doubtless, be admitted by scientific men.

Convention Photographs.

By A. W. Westrop, Camden Lodge, Bridgnorth.

Many of our readers, who are also frequenters of the Convention meetings, are kind enough from time to time to send us photographic mementoes of these plensant annual reunions. Naturally, we attach a special valne to them. The most recent addition to this pleasing list is Mr. A. W. Westrop, a very able stereoscopic worker, who is good enough to send us some binocular photographs taken at Shrewsbury and Leeds. Some fine hoar-frost studies are also included. Mr. Westrop is *facile princeps* in this branch of work.

News and Notes.

Photographic Club.—The next weekly meeting of the Club will be held in the Club-room at Anderton's Hotel, Fleet-street, E.C., at eight o'clock on Wednesday evening, December 30. Travellers' Night. The subject will be *Woodland Studies*, with lantern illustrations by Mr. Fred H. Evans. Visitors are welcome.

The Camera in the Camp.—In the course of a speech delivered to officers of the Royal West Surrey Regiment, on the 12th inst., Mr. Hector Maclean dwelt upon the growing utility of the camera in military reconnaissance, and suggested that a short lecture, followed by a brief course of instruction, directed, not to enabling them to amuse themselves with a camera, but teaching them to apply photography to their military duties connected with reconnoitring, would be advantageous. The suggestion elicited loud applause, and there is considerable chance that early in the new year some such a course of study as above sketched will be initiated.

Borough Polytechnic Photographic Society.—The Second Annual Exhibition will be held at the Borough Polytechnic Institute, 103, Borough-road, S.E., on Tuesday, Wednesday, Thursday, Friday, and Saturday, December 29, 30, 31, 1896, and January 1 and 2, 1897, from 7 to 10.30 p.m. Lantern entertainments every evening at 8.30 o'clock. Tuesday, "English Lakes," Mr. John A. Hodges, F.R.P.S.; Wednesday, "Some Applications of Photography," Mr. E. J. Wall, F.R.P.S.; Thursday, a set of slides from negatives taken by members of the Society during the last summer outings; Friday, "Under the Broad Skies," Lieut.-Col. J. Gale; Saturday, a set of slides illustrating "Jameson's Dash to the Transvaal." Animated photographs and demonstrations of Radiography (Röntgen's X rays) will also be shown each evening.

The Salon.—The following extract from the *Journal of the Photographic Society of India* is not without interest in connexion with recent correspondence in our pages:—"The most noticeable and least pleasant feature of the catalogues, however, is the egotism of the 'Ring.' Just observe these figures, and consider which institution, by its modesty and patriotism combined, deserves to be the National Society. At the Royal Photographic Society there are 354 frames altogether. These are made up of: 338 frames sent in by 143 British exhibitors; 18 frames sent in by 18 foreign exhibitors. At the Salon there are 342 frames altogether, and these are contributed as follows: 249 frames by 94 British exhibitors; 93 frames by 34 foreign exhibitors. Looking further into the lists, we find that comparatively little distinction can be observed between members and non-members as to their acceptability at the Pall Mall Gallery (in fact, non-members head the list of the most favoured exhibitors), while at the Salon *all* the most favoured names in the catalogue, judging by the number of frames accepted, are members, not only of the Linked Ring, but of the general committee thereof. It is a pity; but, of course, what are the poor young gentlemen to do when they are themselves the only people who *can* produce pictures?"

"Dagonet" on Recent Photographic Advances.—The progress made during the last quarter of a century has been remarkable enough. It is certain that, if any one who died before 1850 could come back to life as it is now, it would be a case of *Alice in Wonderland*. I can imagine a middle-aged man fetching his grandfather and his grandmother from the tomb, and taking them for a day's outing and showing them the telephone, the electric light, the phonograph, the cinematograph, the Röntgen ray, and the female population careering madly through the traffic on bicycles. The chances are ten to one that the respectable elderly couple, after a day's experience of life in London in 1896, would gasp out a request to be allowed to retire again with all possible speed to the calm seclusion of the family vault. If they exhibited the slightest hesitancy, and their descendant and his wife thought it would not be advisable to introduce a couple of elderly ghosts into the family circle in these days of difficulty with domestic servants, their departure could be hastened. "The Master" might whisper in the old lady's ear that within a very short space of time we shall be able to speak to the ends of the earth without any connecting lines or cables, and that probably within the next twelve months it will be possible for any one who wishes it to see the Derby run at Epsom, or a cricket match played at Lord's, without leaving the easy-chair by the library fire. All that will be necessary is to have a properly prepared sheet of paper spread on the wall, and ring up the company who undertake to flash photographs of everything worth seeing to the private residences of its subscribers.—*Referee.*

Compressed Gases and Acetylene.—This subject formed the theme of a lecture recently delivered by Mr. Thomas Maben before the North British Branch of the Pharmaceutical Society of Great Britain. Speaking of the compression of acetylene, Mr. Maben said that the gas could be condensed at 32° F. under a pressure of 323 lbs., and at a temperature of 60° F. by a pressure of 570 lbs. on the square inch, so that the liquid gas could be easily stored in steel cylinders. The process of compression was, however, a dangerous operation, for this reason, that the critical point—that was the point at which acetylene could no longer exist in a liquid form—was the very low temperature of from 90° to 100° F. If, therefore, from any cause, such, for example, as the heating of a spindle in the process of screwing up or opening a cylinder, a heat of 100° F. were developed, it might at once pass from the liquid to the gaseous condition and cause explosion; but it was a mistake to suppose that the danger from explosion from a leakage was greater with acetylene than with coal-gas. If the leak was from a burner left open by mistake, the quantity of acetylene that escaped would be very much less than that of coal gas, owing to the smallness of the burner employed. Coal gas had a specific gravity of 0·4, whilst that of acetylene was 0·9, so that the rate of diffusion through a crack in a pipe would be three of the coal gas to two of acetylene. Consequently the latter could not be looked upon as more dangerous to property than the former. With regard to cost, it was calculated that illumination by acetylene would cost the same as sixteen-candle coal gas at six shillings per 1000 cubic feet.

Water.—Water is composed of nitron and carbogen half and half, and is known in aljebrer as O.H.²M.S. Its chief use is to put out fire with and to fish in and to make rain with. To much water is a blizzud and not enough is a famin we don't have no famins nor blizzuds in london. When you want water to sale a steamer in you has a river if its sslt its the seaside and called southend. plants what grow at the bottom of the s a is called watercreeces, there flowers is called water lilies and if you Leave 'em under the warter long enough in hot countries the warter lilies turn into water melons. Water mellons is a penny a slice but I like pine appel. Drinks are made of water such as tea and corfee. water has different tastes accordin to color. when its brown its ail when its black its ink or else stout. You tells by the bottles. If its red green and yeller its a Kemmists. if its sticky and thickish its gum or paste. Warter tastes very funny after eating peppermints. If it boils to hard it busts the engine-boiler and the machines can't work and the magazine don't get printed and the Editor makes a beano of a row and evryone gets inter hot warter. water what's froze is ice its a treat mashed with rasberrys and costs a hapenny, but when its just warter froze ordinary like it makes the whether so awful cold that the gas Can't burn even and you can't drink it. It's all froze at the north Pole and that's why lyingchaug had to come back to England cos when he got to the north pole their wernt a drop nowhere and his men all died of thurst till a ship came sailing along to the windward and found 'em. A water fall is a fall er water cept when its called a fraud, and a fountin is a thing made of water that grows beside a shoeblack boy so as he can wet his blacking. people is found of drowndin theirselves in water whenever they wantter kermit sueside. Water that comes down from the sky is called rain, water what comes up from the ground and fills up the road till The people can't get across means that the drains choked and a pleceman comes and theres no end of a lark. In wet wether they have 2 much water so they spread it on the roads. when the rodes is dry and dusty they arnt sech mugs. men that live on land have to carry umberellers men that live in the water are divers and mermades. It is a bally newsance when you upset the water-bottle Over the editor's papers he does make such a song of it though its fairly clean as a rule. Water is useful for cleaning things with thats how men have a fresh coller on of a monday. water is a thing what some people washes theirselves sometimes, but wheres the good? You gets dirty agin direckly. *I* aint sech a idjut.—"Our Office Boy," in the *Windsor Magazine.*

Concarneau.—Old photographers are not likely to forget the enthusiastic delight caused by Colonel Gale's *Brixham Trawlers*, which was exhibited in the days when instantaneous effects were by no means common. No better place for just such an effect as that in the picture just referred to can be found than Concarneau. There is a stateliness in the long procession of sardine boats that cannot fail to move even the most indifferent beholder. When the boats are back in their haven, and their silvery cargo discharged, there is a striking effect produced by the hanging out of the nets to dry, which is more available for the painter than the photographer, for colour plays an important part in the scene. The nets are dyed a variety of colours, but the most prevailing one is an indescribable blue—it is not turquoise, nor is it aqua-marine; and yet it is a little of both. A large slice of the blue of the sky mixed with just the right proportion of the green of the sea would come somewhat near it. The meshes of the nets are so fine that, when they are festooned from the masts, the boats look as though they had been decorated by rare-coloured weeds, culled from Neptune's garden, to do duty for some eventful festive occasion. Alas! how frequently the photographer is made to sigh when he finds that colour is absolutely necessary for the greater part of the effects most striking to his eye. If the artistic eyes are near companions of a fastidious nose, let not the owner come to Concarneau. It is true there is not the variety of Cologne; but, for the mightiness of its one great stink, this fishiest of places might challenge the world. The old town of Concarneau is a toy specimen of feudal times. It is nearly surrounded by water, and completely walled in, and towers and drawbridge protect the entrance from the quay. To modern eyes it is difficult to see the need for all these precautions for there seems nothing to protect except abject poverty. All the life and motion is in the new town, which has grown up outside the fortifications and along the quays. A striking feature of the country lanes in the neighbourhood is produced by metal hedges! Let not the reader lift his eyes in incredulity, for it is a sober fact. All the fragments of tin left over in the manufacture of the sardine boxes are carted away to make hedges, and, without doubt, they are more effective for this purpose than either briar or bramble. Where newly deposited, this refuse dazzles the eye with its silvery glitter; but, where age has crept in and time has put on his touches of colour, the effect in the distance is most striking, for yellow, bright orange, and russet brighten the scene in every direction, and make the whole district gay with its metallic floriculture.—Valentine Blanchard in *Autotype Notes.*

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

December.	Name of Society.	Subject.
28-31	Borough Polytechnic	Second Annual Exhibition.
29	Bradford	Children's Night.
28	North Middlesex	Technical, and Nomination of Officers for ensuing year.
28	Oxford Camera Club	Lecture: *Enlarging.*
28	Richmond	Open Evening.
29	Hackney	*With a Hand Camera in Venice and Lucerne.* W. Fenton-Jones.
29	Munster	*Emulsion-making and Plate coating.* H. Schröter.
30	Croydon Camera Club	Formal Inauguration of the New Rooms.
30	Halifax Camera Club	Prize Slides.
30	Leeds Camera Club	Lantern Exhibition. The Members.
30	Leytonstone	Members' Lantern Evening.
30	Photographic Club	*Woodland Studies.* Fred H. Evans.
31	London and Provincial	Lantern Night.
January.		
1	Bromley	Lantern Evening.
1	Nottingham	Prize Slides.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

DECEMBER 17,—Mr. W. D. Welford in the chair.

The HON. SECRETARY said the members were indebted to the Chairman for the large number of periodicals relating to photography upon the table. He wished it to be known that they could rely always upon finding the current issues of the principal journals of the Continent and America, besides those of the colonies and Japan and the more familiar home papers, in all numbering from fifty to sixty.

Mr. E. H. BAYSTON remarked that owners of pocket Kodaks, no doubt, sometimes wished to get a little larger image than the regulation size allowed by these cameras, and he passed round a negative of a head produced by placing a spectacle lens close up against the camera front before the existing lens, resulting in an appreciable enlargement of the image. It involved the same principle as the Frena magnifiers.

Mr. T. BEDDING read a paper entitled

A NOTE ON REFRACTION AND DISPERSION.

Mr. E. W. PARFITT inquired as to what effect a lens which was not corrected for the whole of the spectrum would have on the image.

Mr. BAYSTON asked if there was any practical and popular means of distinguishing between crown and flint glass.

Mr. H. C. RAPSON remarked on the softness of some of the new glasses, and asked whether lenses made of such glass were liable to deterioration.

Mr. A. HADDON wished to learn whether the new lenses were unattacked by sulphur compounds, and whether they suffered more from abrasion than those made of the old glass.

Mr. BAYSTON inquired whether it would be harmful to a lens of the new Jena glass if used for enlarging with a strong light.

Mr. PAUL MARTIN asked how the rapidity of the old and new glasses compared.

Mr. BEDDING, in reply, said the definition would most likely be degraded by a lens improperly corrected. He did not think an inexperienced person could hope to distinguish between crown and flint glass at sight, or to be able to pick out one from another by other than very careful examination, though the colour might be a guide. If the softening action had any influence on the density of the glass, it would alter its refractive index. As to the action of sulphur compounds on the Jena glasses, some were and some were not liable to this influence; for instance, one special glass was invariably sandwiched between combinations of other glass on account of its liability to attack. Limelight, or any of the ordinary illuminants, should have no bad effect on these lenses, although the great heat of an electric are possibly might. He could not state definitely the comparative rapidities of the new and old glass in lenses, but it was inappreciable in practical work, and could be ignored.

Mr. T. E. H. BULLEN showed the two plates described at the last meeting, one of which was developed with a pyro-metol solution, and the other with a further pyro-soda solution after both had been developed for ten minutes in a pyro-soda developer, in order to see which brought out the most.

The CHAIRMAN admitted that the advantage in favour of the metol and pyro was sufficient to render unnecessary a print on paper being taken, but remarked on the absence of fog, which generally accompanied pyro soda, in the negative so developed, and he ascribed this to the strength of the bromide in the solution. He thought the results would have been much alike if the soda developer had not been so restrained.

Mr. PARFITT expected that, had the plate been left longer in the soda bath, the negatives would have been very similar.

Mr. BULLEN added that the pyro-metol developer should be very useful for studio work where time was an object on account of its greater energy.

Mr. HADDON said it was recognised that, by developing first with one developer, washing and then treating by one of a different nature, much more could be got out of a plate than with a single solution.

PHOTOGRAPHIC CLUB.

DECEMBER 16,—Mr. W. D. Welford in the chair.

The Editor of THE BRITISH JOURNAL OF PHOTOGRAPHY presented the Club with a copy of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1897, for which the meeting thanked him.

Mr. FOXLEE showed several sets of views of Buenos Ayres. These views were printed in collotype by Mr. Witcomb, a professional photographer located in that country. The quality, both of the photography and the collotype printing, was excellent in every way. Mr. Foxlee also showed some interesting examples of the Eburneum process. These photographs were made some twenty-five years since, and Mr. Foxlee thought they were quite unaltered. The process consisted of a transferred collodion film upon a gelatine base, with which a colouring material—*e.g.*, oxide of zinc—was incorporated, the object being to simulate ivory.

Mr. MACKIE showed a coloured Daguerreotype made in about 1856. This was a good example of the process, and was in an excellent state of preservation.

Mr. RHEINBERG showed a novel instrument for "dropping" exact quantities of liquids from bottles. The apparatus consists of an ordinary glass enema syringe, the nozzle of which is inserted into a rubber cork, which has two holes, and the body of the syringe is marked to indicate its fluid contents. Into the second cork hole is inserted a bent glass tube, which serves to allow any liquid to pass from the bottle. By pressure upon the piston of the syringe in the usual way any quantities of liquid can be passed out. The invention includes the use of a rubber stop fitted to the piston, in order to regulate the output, as required.

Mr. Dallmeyer gave the Club his promised

CHAT ON PHOTOGRAPHIC LENSES.

He discussed the pros and cons. of flat *versus* curved fields, and said that photographers were still to be found who preferred the latter. Mathematical opticians, however, were all endeavouring to make lenses with a flat field, because that was the scientific goal. Andrew Ross made lenses free from astigmatism, but the field was curved. Petzval improved upon this, and the speaker believed that he had such a grasp of his subject that, had he possessed present-day advantages in the way of materials, he would have done all that had been done by latter-day opticians. The great object to be aimed at in lens construction was to obtain a perfect image throughout a plane, if for no other reason than that photographers had to use a plane surface to record their results upon. His late father made lenses giving a flatter field than Petzval's, but he achieved the result by means of a compromise between curvature of the field and astigmatism. He (the speaker) had been asked by an acquaintance if he could not do something to make an old Petzval lens more useful. As the result of this appeal, he had made a negative attachment which could be added to any lens of the Petzval type, and would give it a flat field. He called it the astigmatic corrector. The field of a lens so added to becomes perfectly flat, and at the same time free from astigmatism. A diaphragm of *f*-7 must be used, however, to remove some residual spherical aberration. Mr. Dallmeyer also described and showed his new stigmatic lens. This lens is free from spherical and astigmatic aberrations, and has a perfectly flat field. At *f*-6 it will cover absolutely and crucially a base of rather more than the focal length; at *f*-16 it will cover an angle of 80° and a base of double its focal length. It is no use to stop this lens down beyond *f*-16, except to obtain additional depth of focus and greater equality of illumination. He pointed out that this last obtained with all lenses, absolute equality of illumination of the plate being theoretically impossible of achievement.

An interesting conversation followed, in which Messrs. Foxlee, Parfitt, Bridge, Gotz, Hana, and Mackie took part, and the meeting heartily thanked Mr. Dallmeyer for his most interesting and instructive "chat."

Brixton and Clapham Camera Club.—December 15, Mr. J. W. Coade (President) in the chair.—A series of slides,

A HOLIDAY IN NORTH WALES,

were shown and described by Mr. A. E. ALLEN (South London Photographic Society). Views of Snowdon, Bala, Ruabon, Beaumaris, &c., were shown, and also views of places with less easily pronounceable names, Mr. Allen remarking that he had avoided the beaten track of the tourist as far as possible, and searched out for less known and frequented spots. Judging from the slides thrown on the screen, he had no reason to regret the experiment, having succeeded in finding some of the most lovely scenery in the country. Some fine slides of the working of slate quarries concluded Mr. Allen's series. Mr. E. Dockree had a curious exhibit in some coloured slides made over ninety years ago. Two (cathedral interiors) were specially beautiful, and it is doubtful if photography could give better results even at the present day. Slides made on Edwards's and Cadett lantern plates recently given to members were afterwards shown.

Hackney Photographic Society.—December 5, Mr. W. Rawlings in the chair.—The Hon. Secretary showed Wynne's actinometer for timing exposures of printing papers, &c. He also showed the pneumatic lantern-carrier from Mr. E. W. Hudlas, of Stockport. This is a contrivance by which a slide is eclipsed and changed with one pressure of a pneumatic ball. Members' work was shown by Mr. Hudson and Mr. Dunkley. Mr. A. HORSLEY HINTON then read his paper on

PICTORIAL PHOTOGRAPHY,

and succeeded in making a powerful argument in favour of this special subject as opposed to work of a merely topographic character. A long discussion followed, in which general agreement with Mr. Hinton's remarks was shown.

Putney Photographic Society.—December 17, Mr. H. Faulkner in the chair.—A demonstration on

PHOTO-MICROGRAPHY

was given by Messrs. BERTRAM H. JONES and WILLIAM MARTIN, followed by *Flashlight photography* by G. E. Martin. In opening up the subject, Mr. Martin mentioned that photo-micrography was far easier than many people imagined. Any one possessing a microscope, camera (with or without lens), and an ordinary paraffin lamp, need not hesitate to attempt this very fascinating scientific branch of photography. Those who had an oil, or, better still, limelight lantern, had an advantage in being able to give much shorter exposures. Two or three points were mentioned as being most important to observe in order to be successful, viz., the tube of the microscope should always be lined with black velvet to prevent reflected light, as, without this,

glare spots would result in the photographs; and when using an ocular, this should also be replaced with velvet. The object, microscope, and sensitive plate must be parallel with each other; also the optical axis of the light, lenses, and camera should all be central to one another, otherwise complete failure by uneven illumination, bad definition, or distortion, will result. After going into certain details connected with the microscope and its working, some photo-micro slides were passed through the lantern, and Messrs. Jones and Martin proceeded to give a practical demonstration, and, using an ordinary oxyhydrogen limelight lantern as an illuminant, a microscope provided with a two-inch objective, and an "A" ocular, slow plates, and medium stops, the respective exposures of 35, 30, 20, and 20 seconds were given by transmitted light on the claw of a spider, section of root of madder, section of root of white thorn, and hairs of a caterpillar, which were successfully developed with pyro ammonia. The flashlight apparatus was then placed in position, and some of the members availed themselves of the opportunity of procuring photographs of the microscopical apparatus as set up with the lantern and camera in working position. Three Todd-Forrett flash lamps were employed, producing a most brilliant light each time.

Aintree Photographic Society.—The subject on Friday evening, December 18, was a lecture on

PICTORIAL PHOTOGRAPHY,

by Mr. A. HORSLEY HINTON. Each picture and diagram was freely discussed, Messrs. Inston, Adkins, Lloyd, Heron, Lockier, and Jackson entering chiefly into the question of composition, &c. The evening was certainly a very instructive one and will prove of great benefit to the members who were present. Another lecture is announced for January 15, the subject being *Norway*, by one of the members, Mr. William Lockier, who spent a photographic holiday there recently, and who obtained two silver medals for his Norwegian pictures at the recent Exhibition.

Bradford Photographic Society.—December 14, the President (Mr. Alexander Keighley) in the chair.—Mr. H. J. DOBSON, R.S.W., gave a most interesting and instructive lecture on

THE COMPOSITION OF A PICTURE.

The lecturer illustrated his remarks with photographs and engravings. He said that the knack of composing a picture was, to some extent, a gift from Nature. It could, however, to a certain degree, be cultivated by practice, like public speaking, and become comparatively easy. A great change in the treatment of composition had taken place within the last thirty or forty years. Conventionalism had, to a great extent, been abandoned, and newer methods had been adopted. Mr. Dobson compared the works of Constable and Cox with the mechanical compositions of Richard Wilson and the earlier painters of the English School. Gainsborough, he said, was an exception, and broke away from conventionalism even in his day, and his influence had been felt on British art during this century. In some of the figure pictures the change was even more noticeable. The hard and mechanical arrangements of Benjamin West, Maclise, E. M. Ward, and others, were improved upon by the modern schools. The works of Munkacsy, Israels, Orchardson, Luke Fildes, and others of the present day, were far more truthful to nature. We had lost some of the finest artists in this century within the past few years. Cecil Lawson, Fred Walker, George Mason, and J. E. Milla's would rank amongst the greatest of the English School. The lecturer commended the study of their works to all students of art or photography. An earnest student would gain most knowledge in composition from observation and continued practice. Intelligence applied to hard work would succeed eventually with patience. No definite rules on composition could be fixed, experience only could teach. Mr. Dobson's own knowledge had been acquired by continued practice for the last sixteen years. His method was only imperfect as yet, and could be improved upon; but he gave it, such as it was. In choosing a subject it was important to select the best point of view. Much time, and even expense, would be saved by securing this. The student should not attempt too much. Beginners were apt to overlook this, and show too much in their pictures. This proceeded from want of knowledge. Simplicity of design should be aimed at, and the principal object made prominent to the rest of the picture. There were many difficulties to contend with, but the young student would gradually overcome them. Mr. Dobson, when a student at the Royal Scottish Academy, went out on one occasion to sketch with two student companions. He was the youngest, and felt a little nervous when a crowd of boys and girls collected. The critics persisted that his was the best picture, but he knew that this could not be, and saw that both his friends' work was too advanced for these children to understand. The people who knew most about pictures were the most sparing with their criticism. In the work of a great master there was a balance in the composition. The eye travelled instinctively to the central object. Mr. Dobson mentioned Orchardson's great picture of *Napoleon on Board the Bellerophon* as a fine example of good composition, and also Luke Fildes' *Doctor*, but he considered the latter's popular picture of *The Village Wedding* an example of crowded composition, and wanting in simplicity. The lecturer exhibited reproductions of these pictures, which were kindly lent by Messrs. Matthews & Brooke, and Mrs. Megson. Mr. Dobson went on to say that the balance of light and shade was also very important to success in a picture. The founder of the Dutch School (Rembrandt) had carried this to greater perfection than any other artist. No other master appealed to him so much as Rembrandt, and he (the lecturer) placed him head and shoulders above any other painter the world had yet produced. His influence was felt in every school but was more evident amongst the modern French and Dutch. The modern Impressionist School could be traced to his influence, and it depended solely on "values" in light and shade. The modern schools, he thought, would compare favourably with the old masters, but it was for posterity to decide. Never in the history of art had there been more striving after truth, and he had no doubt that many of the masterpieces of the nineteenth century would take place amongst the greatest of the world. The lecture was listened to with great interest by a large and appreciative audience after which a vote of thanks was unanimously passed to the lecturer, proposed by Mr. George Thistlethwaite, and seconded by Mr. Oliver Nicholson.

Cardiff Photographic Society.—Mr. WM. BOOTH entertained the members on the 18th inst. with a paper on the pictorial attractions of this neighbourhood. By means of many very charming lantern slides the lecturer showed that the locality abounded in subjects, which, if handled with discrimination and taste, could be turned to much account in the hunt for pictures. That this production of really artistic results from, apparently, the most unlikely sources, is probably known only to a few of the "knowing ones" is rather prominently shewn sometimes in the attempts that are made, for example, in figure studies with impossible accessories. The wise appear to be content with simple materials, and are, as a rule, rewarded with better success. Some of Mr. Booth's pictures had been secured in, generally speaking, most uninviting spots. The lecturer showed an extensive acquaintance with the town's history, and has been very greatly interested in the local photographic survey. A large number of his contributions are stored in the Free Library, where, by the courtesy of Mr. Ballinger, the librarian, the lecture was given, and form part of a valuable collection of records of the ancient monuments of the district. Large as the collection now is, it is hoped that no opportunity may be lost by those interested in these matters to contribute any prints they may be able to secure. The meeting closed with a hearty vote of thanks to Mr. Booth for the interesting paper he had given.

Hawke's Bay Camera Club.—At the Annual Meeting of the Hawke's Bay Camera Club the report and balance-sheet showed the Club to be in a flourishing condition. The number of members has increased to sixty-five, and a comfortably furnished club-room, with dark room attached, is now available for members and their friends. Papers have been read, and practical demonstrations have been given at the monthly meetings. Reference was made to the successful Exhibition recently held by the Club, and members were urged to contribute to the Dunedin Club's Exhibition, which opened on December 2. The following officers were elected for the ensuing year:—*President:* Mr. H. A. Banner.—*Vice-President:* Dr. A. Milne-Thompson.—*Committee:* Messrs. T. Bear, S. E. Cooper, G. F. Green, J. K. Newton, and H. Owen.—*Treasurer:* Mr. G. H. Pierce.—*Secretary:* Mr. W. Beswick, Post-office.

Leeds Camera Club.—December 16.—A goodly number of members followed, with intense interest, a description of

THE PREPARATION OF PLATES FOR COLLOTYPE PRINTING,

given by Mr. W. T. WILKINSON, the author of several works on this and kindred subjects. During the course of his lecture, Mr. Wilkinson mentioned a few important points to be observed; amongst others, the necessity of avoiding damp and maintaining throughout a uniform temperature. Very thick plate glass is carefully ground upon one side by rubbing with fine flour emery for some minutes. It is then coated with a substratum consisting of 4 ounces each four-ale and porter, 4 to 12 drops of ammonia, ·880, to which is added 1 ounce of silicate of soda just before using. After drying, the plates are rinsed under the tap for a few moments, and again dried, when they can be kept indefinitely. For the sensitising process an oven will be required, and kept at a temperature of not more than 120°. A stock solution is made of—Methylated spirits, 1 pint; tincture of tolu, 1 ounce; chromic acid, 5 grains; and the sensitising mixture consists of collotype gelatine (Swiss), 150 grains; water, 2 ounces; potassium bichromate, 37 grains; above stock solution, 1 ounce. The spirits must be added gradually, and the solution well stirred. Of this solution 4 to 5 minims will be required per square inch of plate for coating. The plate is then placed in an oven and "cooked" for forty-five minutes. A reversed negative is required for printing, the margin of which must be "blocked out" with tinfoil. The prepared plates should be kept from one to fourteen days face to face before printing. Mr. Wilkinson recommends an open-back printing frame, in which an average exposure of thirty minutes to good (but not sun) light, or several hours in dull weather, will be necessary. After exposure the plate must be washed for a few hours to remove the free bichromate. A continuation of this lecture will be given by Mr. Wilkinson on February 17, 1897, when a practical demonstration with the collotype press will be given. December 30: Annual Lantern-slide Exhibition at Fairburn's Athenæum Restaurant, 7, Park-lane. Members can have tickets for friends on application to the Secretary.

Oxford Camera Club.—December 14, the members were specially fortunate in having the opportunity of seeing over a hundred of

CAPTAIN ABNEY'S FAMOUS SLIDES OF SWISS SCENERY,

which he had kindly lent for the occasion at the instance of Miss Venables. The slides were wonderfully successful in their rendering of the ice and snow, which forms so large a portion of Swiss scenery at high altitudes. There were also some very fine cloud effects. A good many pictures were specially noticeable, as having been taken in winter by moonlight, this being necessary owing to the sun's altitude being too low during the winter for many of the best effects. A very hearty vote of thanks to Captain Abney for the loan of the slides, and to Miss Venables for procuring it, was passed with acclamation, as well as to Mr. Joyce for lending and working the lantern.

Wolverhampton Photographic Society.—December 18.—Some Welsh views by Mr. E. L. Coulthurst were much admired, but his statuary was marred by faulty outlines in blocking out. The architectural views proved interesting. The slides, on the whole, were considered excellent and gave much pleasure, and a hearty vote of thanks was accorded for the loan of them. With the view of showing the desirability of more care in the use of the slides, it may be well to note that eight broken ones were withdrawn and returned for replacement, and there is one slide missing.

FORTHCOMING EXHIBITIONS.

1896.

December 29–Jan. 2. Borough Polytechnic Photographic Society. P. C. Cornford, 103, Borough-road, S.E.

Dec. 1896–Jan. 1897 Bristol International. Hon. Secretary, 20, Berkeley-square, Clifton, Bristol.

1897.
January 14, 15 ..... Weymouth and District Camera Club. E. C. Bennett, 10, Newberry-terrace, Weymouth.
February 1–27 ..... Glasgow *Evening Times* Camera Club. The Secretaries, *Evening Times* Camera Club, 46, Gordon-street, Glasgow.
March 6–13 ..... South London Photographic Society. Charles H. Oakden, 30, Henslowe-road, East Dulwich, S.E.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

RESIDUES.

To the EDITORS.

GENTLEMEN,—In a recent issue you state, in reply to a correspondent, that, after reducing silver residues in a crucible, it is necessary to break the crucible in order to remove the ingot. In my own practice I have not found this to be the case, as I have used one half a dozen times, and it is still whole. Many photographers, I believe, avoid attempting the reduction of their residues under the mistaken impression that it is a very difficult process, and that a specially constructed furnace is a necessity, whereas the kitchen fire will serve the purpose quite well, at any rate in the case of small quantities. My usual plan is first to see that the fire is in good trim and free from flame. Place the crucible containing the residues in the midst of the red coals, and cover over the front of the fire with a large sheet of paper so as to cause a good roaring draught. Soon the residues will begin to boil and become white hot. Then remove the crucible, and, as soon as it is judged that the silver has set (while still red-hot), knock out the contents into a flag, and there you have a bright, clean lump of silver, the whole process only occupying about ten minutes. It is very simple, and certainly interesting and profitable without a doubt. Many professionals pour pounds of silver down the sink in the course of a year.—I am yours, &c.,

29, *Chapel-street, Leigh, Lancashire.* THOS. HADDOCK.

SCIENTIFIC INSTRUCTION AND THE PHOTOGRAPHIC PROFESSION.

To the EDITORS.

GENTLEMEN,—Mr. D. J. O'Neill, in answer to my letter of December 5, shirks the plain issues I put forward, and intrenches himself behind the Socratic platitude, "Knowledge is power." I admit it, but the immediate question for us to consider is, What exact knowledge is power at this particular moment to the photographic profession? This question Mr. O'Neill has not squarely faced. He prefers to seek refuge behind general statements, which convey no meaning or exact knowledge. I think the people of this country have a right to ask—and they are beginning to ask—to what definite end are the 50,000*l.*, 100,000*l.*, and other large sums of money being applied through the medium of polytechnics?

In my article on "Polytechnics and Photography" I questioned the utility of instructing photographic apprentices and assistants in the theory of the latent image, photographing the sun's corona, stannotype, and astigmatism. To these I added in my last, Abney on "The Law of Error," Hurter & Driffield on "Logarithms and Deposits," Lord Rayleigh on "Pinhole Images," and Meldola on "Silver Sub-chloride." To the general intelligence these are the "scientific parts thereof." It seems I misunderstand Mr. O'Neill. To him the "scientific parts thereof" needing to be taught are: "Knowledge of the nature and uses of the materials he employs," "study of chemistry," "study of 'Art' pure and simple," "photographer who turned out the best work in the town," item, "not wise in his own conceit," "not 'theory' but practice," and "something higher than rule of thumb." In all this I agree with Mr. O'Neill, and have been insisting throughout that such limited instruction is enough for the practical work of commercial photography. In addition, I maintain that such instruction does not call for the enormous buildings and large sums of money devoted to it, and that it is totally inadequate to enable English manufacturers to hold their own against French and German competitors. Hence I insisted, as a remedy, upon the endowment of research, the establishment of well-equipped laboratories, and the importance of experts, men of ability and men of genius, being in them. This harmless proposal raised the ire of Mr. O'Neill. It is such specialisation as this that has enabled Germany to capture so many of the newer industries, experts like Röntgen actually creating by simple experiments vast industries.

With regard to profits, prices, and wages, I observe that Mr. O'Neill has forgotten to mention the latter; this is significant, for it indicates the reason that induced him to reply to my letter of November 21. In that letter I asserted that polytechnics caused assistants to be supplied at a greater rate than the trade demanded, hence this operated to the advantage of employers by keeping wages at a low level. Now we see by his last that Mr. O'Neill will not admit that polytechnic teaching has proved beneficial to assistants; but why not if he advocates it? Because he saw that I should immediately ask, Why, then, does not the N.A.P.P. pay an increased wage to assistants having a polytechnic certificate? Of course, in spite of Mr. O'Neill, they do nothing of the kind, but act precisely as I say, that is, they take advantage of this stress of competition to obtain cheap assistants. Cheap assistants, we thus see, account for the admiration of the N.A.P.P. for polytechnic teaching. I having had the audacity to point this out, and expose the dodge, Mr. O'Neill imagined a letter in the JOURNAL would snuff me out. In this he was mistaken. He was also mistaken in supposing that this red herring, in the interests of employers, would draw me off the main scent, *i.e.*, the low wages of assistants caused partially by the action of polytechnics. I have also not the slightest doubt that the N.A.P.P. will support him in this laudable action of kicking the photographic assistant into his "proper station."

Mr. O'Neill names several employers, and, with a flourish, exclaims, "These are the people!" I fail to see how the top prices certain employers obtain improve the condition of the thousands of employers outside the N.A.P.P. who are obtaining bottom prices, neither does it show that assistants are receiving top wages; it being notorious that top-price firms usually pay bottom-price wages, *i.e.*, the competition wage. Why should they do otherwise? Whether these employers will maintain their prices is the crux of the matter. I hope they will. I am certain they will not unless they pay sufficient wage to induce men of ability to work for them. When wages were higher, the complaints of bad workmen were fewer; now, wages being low, employers are constantly complaining of bad workmen.—I am, yours, &c.,

JOHN. A. RANDALL.

42, *Tonsley-hill, East-hill, Wandsworth, S.W., December* 19, 1896.

To the EDITORS.

GENTLEMEN,—Mr. D. J. O'Neill quotes my name in his letter of last week. I admit in good company; at the same time, I am entirely opposed to his argument from beginning to end as applied to photography, and am in much sympathy in every way with his opponent, and may say, "Them are my sentiments."—I am, yours, &c.,

THOMAS FALL.

9, *Baker-street, Portman-square, W., December* 20, 1896.

A HARDSHIP.

To the EDITORS.

GENTLEMEN,—In your valuable JOURNAL of the 11th inst. you advise "Hard Lines" that he "has no remedy" against his late employers, on the ground that "the arrangement was only verbal."

May I point out what I believe to be an error in your otherwise sound judgment? In my own opinion, which I submit humbly, if "Hard Lines" was definitely engaged for a year certain, although verbally, the engagement cannot legally be determined until the twelve months have elapsed, as a contract, so far as I am aware, need not be in writing if intended to subsist for one year only. If, as I take it, he was to be paid by the week, month, or quarter, and not *so much for the whole year's service*, then he can maintain an action for damages for wrongful dismissal (although he cannot sue for wages not then due), unless there has been gross or wilful neglect or misconduct on his part or some other special circumstance to justify his employer's action in dismissing him. Anticipating the favour of your kind indulgence, I am, yours, &c., NIL DESPERANDUM.

EXHIBITIONS—A SUGGESTION.

To the EDITORS.

GENTLEMEN,—We are probably all agreed that the present arrangements for the photographic exhibitions in London are unsatisfactory. If the lantern slides are also to be seen, it is necessary to make three expeditions and pay half-a-crown in admissions.

The spacious halls of the Royal Academy are in the autumn, as far as is known, in disuse. Do you think the Academy would lend them to a combination of the societies for the lesser arts?

The Royal Photographic might have three rooms, one for pictures, one for the lantern, and one for technical exhibits; our good friends of the Salon one; and the other rooms, which perhaps should be the best rooms, used for etchings, engravings, and architectural designs.

The Academy would probably not refuse on theoretical grounds, for the improvement and cheapening of the methods of reproduction is for the interests of art, and the transfer to an autumn exhibition of some or all of the engravings and designs would give more room in summer for painting and sculpture.—I am, yours, &c., JOHN SMITH.

A CORRECTION AND THE LINKED RING DISCUSSION.

To the EDITORS.

GENTLEMEN,—"Dogberry," in your last issue, makes a definite assertion concerning myself, which he must allow me to correct. I approve of much that he writes; but, when he says that "'H. P. R.' went through the drudgery, and mastered *photography*, before he attempted art," I am bound to tell him the facts are precisely the reverse. I went through at least fifteen years' art training before I began photography. If "Dogberry" will take the trouble to consult the Royal Academy Catalogue for 1852, he will find my name in it as an exhibitor. This could not have happened without training. I did not take to photography till later, and not seriously until 1857. I hold that the camera is the *last* tool that a pictorial photographer should take up, and chemicals the last materials he should study.

May I mention that, if "Dogberry" kindly reads the "Autobiographical Sketches" I am writing for the *Practical Photographer*, he will find that I particularly congratulate myself on escaping the camera for so long a time, and show how the first twenty-seven years of my life were almost every minute of them nothing but a preparation for taking up the camera. I believe, if my early technique was as good as "Dogberry" flatteringly says it was, it was because I studied just sufficient technique for my purpose, studied it well, but took good care not to confuse myself with any more than was necessary. There is no necessity for even that much now, but there is for that higher technique of which the ordinary photographer never seems to think.

Now I am writing, I may perhaps refer to the many curious attacks on the members of the Linked Ring and the Salon that have recently appeared, and from replying to which I have kept aloof, for reasons which may be gathered from Mr. Maskell's letter in your last; but, as a sample of how low down they condescend (beyond even the self-respect of the very lowest), will you allow me to transfer a paragraph which has somehow crept into the ALMANAC.

"Certain illiterate tradesmen, who had tried art but failed, began to pose as 'artist photographers,' and to write the merest drivel upon art. Then followed a host of amateurs who, with a camera, could easily produce (by fluke, as a rule) a 'pictorial' transcript of nature, and they, too, joined the babble, and finally embalmed themselves for ever in a ridiculous brotherhood of children called the Linked Ring—the latest sickly flower of a morbid body."

On second thoughts, I do *not* give this paragraph as a sample of the others. Goodness forbid that I should accuse any man of being so venomous. I am proud of the success of the Salon and the Linked Ring, but I am sorry that our success should have such a disastrous effect on the mind of any man. Here we have again our scurrilous Greek, and our modern Thersites of a few years ago; he seems to forget that he is dead, and that his anonymous ghost is not even amusing.

It is not perhaps surprising such stuff is written; envy, hatred, malice, *the sense of failure*, will often induce irresponsible insanity; the wonder is that it ever gets printed. It is very rough on the unfortunate writer.—I am, yours, &c.,

H. P. ROBINSON.

Tunbridge Wells, December 19, 1896.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries, must be addressed to* "THE EDITORS, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post. Questions are not answered unless the names and addresses of the writers are given.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2, *York-street, Covent Garden, London.*

PHOTOGRAPH REGISTERED:—

David Whyte, 57, Church-street, Inverness.—*Photograph of the Rev. Dr. Aird*, Rossshire.

LENS.—ABER. The lens, from the reputation of the firm, is probably a good one.

PROCESS SCHOOL.—C. L. F. The address of the school you mean is Bolt-court, Fleet-street, E.C.

LENS NOMENCLATURE.—P. T. R. "Anastigmat" and "orthostigmat" are convertible terms, signifying absence of astigmatism from lenses.

POSITIVE PROCESS.—J. BENNETT. The picture appears to be a Daguerreotype. We do not think the portion of the image that has been removed can be restored.

HELIOS.—A train of prisms is usually employed for the purpose, and will give you the result you want. The arrangement is sketched at page 407 of our volume for 1894.

PRINTING PROCESS.—S. REANY. The prints are produced on Nikko paper, which is a gelatino-bromide paper, the high surface being imparted to them by squeegeeing down.

BOOK ON STUDIOS.—UP-TO-DATE STUDIO asks for a book on studio construction.—In reply: Messrs. Marion & Co., Soho-square, publish an excellent work on the subject by Mr. Thomas Bolas.

HAMLET.—The price of the *Lantern Slide Manual* is 1*s*. It is published by Warne & Co., Bedford-street, London. For the other information you had better address Mr. Chadwick direct at St. Mary's-street, Manchester.

LENS.—E. R. F. We are somewhat sceptical of your statement that the lens, although a cheap French one, has not its visual and actinic foci coincident. However, we advise you to communicate with the firm of whom you obtained it.

COPYRIGHT.—ONE IN DOUBT. We cannot here give the space required to answer your queries. In the 1897 ALMANAC, just published, you will find the full text of the Copyright Act, the perusal of which will give you the information you seek.

CHLORIDE OF GOLD.—T. C. Sorry we are at present unable to help. If you can give us the title of the article, and that of your reply, and also a more definite date than "about thirty-six years ago," we will endeavour to look the subject up for you.

SHEET GELATINE.—A. T. F. says: "Will you kindly give me the name of some place in London, preferably in the E.C. district, where I can obtain, at a reasonable rate, sheets of coloured gelatine for use in a lime-light box?"—In reply: Cornelissen, of Great Queen-street, Holborn.

DISPUTE WITH EMPLOYER. — B. COOPER. The case appears to be so intricate that we cannot offer any advice likely to be of service. It is entirely a matter for legal advice. Why not consult the magistrates at the local Police-court? This is often a cheap way of obtaining valuable advice.

WINTER SNAP-SHOTTING.—B. OSBORNE. Instantaneous pictures can, of course, be taken of winter scenes, and without much difficulty. The conditions are: plates of great rapidity, and a lens working with a large angular aperture, say, *f*-6. Under these conditions good negatives can be secured in a fair winter light. Of course, the most must be made of the exposure in the development of the image.

HIDING VIEW.—W. A. writes: "I am going to build a studio for professional work, and the outlook from the side from which I must get my working light is very unsightly—a mews, a small cottage, chimneypots, &c. Is there any means of hiding the scene without stopping out light? I do not wish to use ground glass or stippled glass, as I have it in my present studio, and the smoke of this place necessitates continual washing of the former and renewing of the latter?"—We should advise the side in question to be glazed with plated glass. That will completely stop out the view, while the light will not be at all obstructed.

COPYRIGHT.—ALPHA. On comparing your photograph with the illustration in the paper, we have little hesitation in saying that the latter was taken from your picture; but, from what you say, although you have registered the copyright, we are very much afraid you cannot maintain it if becomes a question of legal proceedings. You see you did not take the photograph yourself, and you were paid for taking it, the work being actually done by an *employé*. However, if you write to the paper, asking a moderate fee, you will probably get it. We should certainly not recommend legal proceedings. If it be refused, you have no legal copyright in the work.

RESIDUES.—B. B. B. writes: "I am, as usual at this time, collecting my year's waste, which consists mostly of gelatine paper ashes and the sulphide from the fixing baths—paper and negatives, with a very little ash from albumen paper. Last year I had about the same lot from similar sources, and I was very much dissatisfied with the return made for them. Do you think I should do better if I tried to reduce the waste myself?"—No. You must not expect the same returns from gelatine papers that you got from albumenised. They contain less silver. Furthermore, the silver, when recovered, is not worth nearly so much as it used to be.

STUDIO.—N. says: "I am building a studio 36 feet long, north and south, by 26 feet wide; space is quite open on the north, blocked in on the south, open about the same upon east and west sides. 1. As studio is wide enough for considerable ordinary work, would it not be advisable to glaze north end and work by this generally; also to glaze one side about two-thirds, and work this when greater length is required? 2. Which side would you advise being glazed, east or west? 3. Would you have roof of equal pitch under these circumstances, or a greater 'rake' the side it is glazed? 4. Opaque blind to cut off light would be available over most of the glazed portions. From which end would you think it would be best to work from, with studio in the position? 5. Do you know of a new system of fixing blinds more artistic than the usual running blinds on rollers? 6. Could you name me two or three good firms making the fixing of electric lamps to studios a speciality?"—In reply: 1 and 2. The north end might be glazed, and the major part of the work done with that light quite well. Then either the east or west sides may be glazed for special work, groups, &c. The side chosen should be governed by the time of day most business is done. If that is in the morning, the west side should be glazed, and if in the afternoon the other side. Or a certain portion of each side may be glazed and used as desired, morning or afternoon, and the north end left opaque. 3. Equal. 4. When working lengthwise, work with the camera at the north end, as the sun will be hidden by the house. If working with the north light, either end to suit the features of the sitter. 5. No, not for utility. 6. Messrs. Gwynne & Co., Brook-street, Holborn. Watford Engineering Works, Watford for arc light.

MONTHLY SUPPLEMENT

TO THE "BRITISH JOURNAL OF PHOTOGRAPHY."] [*January* 3, 1896.

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

By the time this is in the press the old year will be gone, and 1896 duly ushered in. At such a time as this it is usual to review the work of the past twelve months, and, although from a lanternist's point of view one cannot say the year has been fruitful in inventions, yet it has not been barren as regards improvements and general progress.

* * * * *

ONE cannot call to mind any invention that is a complete departure or perfectly original in principle, but many useful modifications and variations of existing apparatus or previously known principles have been designed and introduced, the majority of which have some distinctive merit, and, what with science lanterns, mechanical lanterns, automatic lanterns, magazine and cycloramic apparatus for projection, besides the regular and irregular forms of optical lanterns, there should be no excuse, on the score of lack of variety, for the non-purchase of a lantern, while illuminants of every character are now available for lanternist purposes.

* * * * *

THE boom in oxy-ether saturators that set in the year before continued through 1895, and, although personally I am not an advocate for the indiscriminate sale of them, I cannot but admire the light produced from a well-constructed ether apparatus, or fail to recognise the advantage, under some conditions, of having only one gas to convey or manufacture. Jets, again, have had added to the list the ejector and injector, a species of mixed gas jet with only the oxygen under high pressure.

* * * * *

THE general distribution of electricity throughout England has stimulated the employment of the electric light for optical projection, and, as a consequence, a number of arc lamps have been designed and constructed, which have been the means of showing the lantern world that an electric arc lamp is not the fearful and wonderful thing it was supposed to be, for, by following certain well-defined rules and regulations, and working to the simplest possible directions for use, the light obtainable for lantern purposes is brilliant, simple, certain, and economical.

* * * * *

IF the photographic and lantern public realise the simplicity and safety of the electric arc lamp, it is evident that the lay public do not, and, from what I recently learnt, some of the electrical engineers and general lighting contractors require a little tuition in what has been accomplished in the way of electric arc regulators and hand-fed arc lamps for the optical lantern, or they would never recommend incandescent lamps for projection purposes where arc lamps are available, or hint that the latter are attended with a certain amount of danger.

* * * * *

ANY photographer or lanternist that is in doubt about this source of illumination should attend at one of the meetings of the Royal Photographic Society, the Society of Arts, or the Camera Club, and have the lamp and light explained by the demonstrator or honorary lanternist, who, no doubt, would be pleased to do so; or visit the establishment of the makers of the various arc lamps placed on the market, and see for themselves the satisfactory nature of the light, and the simplicity or otherwise of its adjustment and use.

* * * * *

NEW carriers have found their way into the market, and, in this very necessary part of the optical lantern apparatus, it is astonishing how much ingenuity has been spent. What with rolling curtain carriers, obscuring carriers of the Eclipse and Uno-Mano type, and modified quick-changing carriers, with slide-raising adjustments, there should be no difficulty in finding a carrier suitable to one's purpose. The number of little accessories in connexion with the lanternist and slide-producer's outfit makes quite a long list.

* * * * *

ONE cannot help regretting, as month after month goes by, which are so important to the lantern and gas industries, that no publication is made of the Home Office Committee's report on the gas-cylinder question and the restrictions concerning the use of the lime-light and conveyance of cylinders imposed by certain County Councils and the railway companies, and it is to be hoped that something will be definitely announced at once, for, with January and February as the busiest months, it is as well that trade should be encouraged, for, from what can be learnt generally, the lantern season up to now has not been very flourishing.

* * * * *

IF ignorance of the laws of the country and by-laws of railway companies were accepted as a plea in cases of transgression, no doubt a good many lanternists would conveniently forget these unpleasant restrictions and prohibitions. Certain it is, if a little bird whispers truly, that now and then a small-size cylinder goes into a fairly large hand bag and is conveyed to its destination. As there is a very heavy fine for taking by rail a charged gas cylinder without duly declaring it and passing it through the parcels office, it is as well that this should be known.

* * * * *

WHAT will 1896 bring forth in the way of lantern novelties? Already we have in the air rumours of projection in colours much in advance of anything done before, also a projection kinetoscope or

something of that order to show lifelike movements; then, at an early date, a modified lantern stereoscope is to be shown, and no doubt, with popular science as a subject in all schools, there will be many interesting pieces of apparatus designed for use with the lantern. These in due course I hope to have the pleasure of referring to. G. R. Baker.

ACETYLENE.

The widespread interest which was excited in both the scientific and commercial worlds, by the recent announcement of the discovery of a ready and cheap method of making acetyleue, as yet shows no signa of flagging.

As I have had the light from this gas in fairly constant use for a period of some three months, and have subjected it to a series of comparative and careful tests against other illuminants in ordinary use for photographic work, I am induced to add one more contribution to the many which have already appeared in your pages. A brilliant light, second only to the lime or electric light, but which is so easily and economically produced with the simplest of appliances, must prove of the utmost importance.

Although acetylene is usually spoken of as the "new gas," it is by no means a new discovery, for it has been well known to the chemist for many years. It was first of all mentioned by Edmund Davy, who obtained it by the action of water upon the greyish masa which remained after an attempt to obtain potassium from calcined tartar and charcoal. He described it as a new hydrocarbon, to which he gave the name of klumene, but did not follow up his investigations, and the matter was forgotten, until Bertholet rediscovered it and gave it its present name of acetylene or ethine. He obtained it by causing the vapours of wood spirit, ether, or alcohol, to pass through a red-hot tube, and subjected the gas so produced to a searching investigation. It was also obtained by many other methods, the best of which was perhaps the most interesting, because it was the first instance of the production of a hydrocarbon by direct synthesis. The cylindrical carbon rods of an electric arc lamp were drilled through their entire length so as to form tubes. The ends were enclosed in an air-tight glass globe, and, whilst the light was burning, a stream of hydrogen was passed through the carbon rods, when there was a direct union of the elements of carbon and hydrogen at the temperature of incandescent carbon. The resulting gas was caused to pass through an ammoniacal solution of cuprous chloride, which formed a precipitate of cuprous acetylide, whilst any uncombined hydrogen escaped. From this precipitate the acetylene was liberated in a state of purity by hydrochloric acid.

It will, however, be readily perceived that none of these methods rendered the gas practically available for commercial use. Thus the announcement of the accidental discovery of calcium carbide made from cheap and plentiful materials, and that it liberated pure acetylene gas in great abundance by the mere application of water, was hailed as a discovery which was one of the most important of modern times.

The rapid advance and extension of the use of the electric current which has taken place during the last ten years has placed in the hands of the investigating chemist powers which were hardly dreamt of a generation ago. By the intense heat which is generated between the carbon poles he is enabled to melt the most refractory substances, even those which had defied the heat of the oxyhydrogen blowpipe; and, as the heat is generated inside the crucible itself, and directly upon the substances to be operated upon, instead of, as in the furnace, outside, and so having first to penetrate through the substaunce of the refractory clay, there is a great saving in energy, and comparatively little risk from breakages. The story of the discovery of calcium carbide has already been told. An American chemist, Wilson, whilst endeavouring to obtain metallic calcium from lime, employing the electric furnace and the usual reaction of carbon, failed in what he was attempting, but succeeded in obtaining, in a cheap manner, a compound of calcium with two atoms of carbon, which, upon being thrown into water, was decomposed with great violence, liberating acetylene in a nearly pure condition.

How to Make Acetylene.

Already the inventive genius of many individuals has been exercised, and patents applied for, for generators of a more or less complex character. But nothing of an elaborate nature is at all necessary or advisable for use in the photographer's laboratory. I do not mean to imply that the apparatus I employ could not be improved upon, but for simplicity it would be difficult to beat, and, although in constant use, it has never given any cause for complaint, and is entirely automatic in its action. It aimply consists of a tank of galvanised iron to hold water, and a reservoir working in this like a gasometer. This is fitted with a tap at the top as an outlet for the gas, which is generated within the reservoir itself, and, as a matter of precaution against any explosion, this outlet has two or three thicknesses of fine wire gauze over it. Inside this reservoir, at the top, is a hook, from which is suspended by a wire a common flower-pot, which has also a piece of fine wire gauze inside it at the bottom, the use of which is to keep the residue of calcium hydrate formed from falling into the water. A pound of calcium carbide is put in the flower-pot as a charge, the reservoir placed in the tank, and the tap turned on to allow the air to escape, and as this takes place the reservoir gradually sinks down into the water. This necessarily causes the flower-pot to dip into the water, which, passing through the hole in the bottom, instantly generates a quantity of gas, and the meter at once rises, lifting the charge out of the water and stopping the action of the water until the gas is used up. This goes on continually until the whole of the calcium carbide is exhausted.

The inside meter is of about one cubic foot capacity, and a charge of one pound will give a continuous steady light from eight to ten hours with a pressure of one inch. The burner I use is a No. 0000 Bray's special, which consumes less than half a foot per hour. The question of a suitable burner was a difficult one. I first tried a No. 1 Bray, but the flame was so large and gave so much smoke that I had to abandon it. I next tried No. 0, and then No. 00, which was the smallest obtainable at the time, but still the smoke was great and the flame too large. With the burner above mentioned, however, the light is perfection, being perfectly free from smoke, of comparatively small area in the flame, and very brilliant. These are all points which render it of great use for enlargement or lantern work.

Testing the Light.

The method I adopted in making comparative tests of the light for photographic work was as follows: The light was placed upon a table, and, at a measured distance of four feet, a board was placed to receive a quarter-plate printing frame. Instead of a negative, a graduated quarter-plate actinometer screen was employed, consisting of a series of square apertures with increasing number of thicknesses of thin coloured gelatine films upon them, numbered from 1 to 25. No. 1 was clear glass, and No. 25 appeared nearly opaque, with all grades between. Selecting a good brand of commercial plates, one was placed in the frame behind the screen, and exposed to the acetylene light for three seconds, when the plate was changed, and another exposed to the three-wick oil lamp commonly used in lantern work, and yet another to the limelight blow-through jet, giving the same distance and exposure in each case. All three plates were then developed together in one dish. The experiment was repeated several times with varying exposures, but the comparative results were about the same. In the case described, the triplexicon oil lamp ranked far away the lowest, only just rendering No. 5; the acetylene came next with No. 16, and the limelight gave No. 21. As the light of the limelight appeared to the eye far the most brilliant, this result of the acetylene was a surprise, and showed that the light is exceedingly rich in actinic rays. I have not had an opportunity of comparing it with the incandescent gas burner, but I should judge it will be at least double the power.

Employed as an illuminant in the lantern, the result was at first disappointing, until I obtained the small burner, when a good five-feet disc was given, and one which would be admirably adapted for parlours or small rooms. By the use of two burners suitably placed, copying can be readily done without the aid of daylight, and, by increasing the number of burners to seven or eight, portraits could be taken at any time quite as quickly as by ordinary studio light. It will thus be seen that there is probably a useful future before acety-

lene in the photographer's every-day work. Into its more extended commercial use I do not propose to enter, that being outside the province of a photographic article; but, viewed from a chemical standpoint, acetylene has many points of interest.

The Chemistry of Acetylene.

Its constitutional formation is simple enough. Common chalk, and shale coal, or any other convenient form of carbon, are heated together. The carbonic acid first escapes, leaving calcium oxide, CaO. The oxygen unites with an atom of carbon and in turn passes off as carbon monoxide CO, thus reducing the chalk to metallic calcium, which, however, immediately combines with two atoms of carbon to form calcium carbide, CaC_2. The acetylene reactions have been well investigated by chemists, and many of them are of special interest to photographers. By passing through cuprous chloride and ammonia solution, copper acetylide is formed as a red precipitate, which, however, should not be allowed to dry, as it is an explosive. The washed precipitate, treated with granulated zinc and dilute ammonia, is decomposed into ethylene by taking up two more atoms of hydrogen, $C_2H_2+H_2=C_2H_4$. This ethylene burns with a brilliant light, but of less than half the power of acetylene. Passed through a warm solution of chromic acid, ethylene is converted into aldehyde, or aldehyde may be obtained directly from acetylene, by passing through a hot solution of mercuric bromide. This action is curious and not thoroughly understood; but, the acetylene so treated unites with a molecule of water $C_2H_2+H_2O=CH_2:CHOH$. This aldehyde forms a good starting point for producing the salts of hydrazine (H_2N-NH_2), or it is easily reduced to alcohol by nascent hydrogen. Acetylene mixed with an excess of hydrogen in the presence of platinum, black takes up four atoms of H and ethine is the result, $C_2H_2+2H_2=C_2H_6$. The oxide of ethine is sulphuric ether. A mixture of acetylene and phosgene, passed through a tube at a dull red heat, is polymerised to C_6H_6 or benzine. If acetylene is mixed with nitrogen and a series of electric sparks be passed through it, hydrocyanic acid is formed, $C_2H_2+N_2=2HCN$. Thus the cyanides may be synthetically constructed. By oxidation with potassium permanganate or chromic acid, acetic acid, oxalic acid, and formic acid are formed. Thus it will be seen that the possible uses of acetylene are almost endless. A specially interesting reaction, however, is the formation of one of the NH_2 groups by a simple operation. If calcium carbide is placed in absolute alcohol, no action takes place; but if water is present, the alcohol is dehydrated with the liberation of acetylene, which dissolves in the alcohol, but may be driven off by heat. If to the alcohol and calcium carbide a solution of ammonium chloride is added drop by drop, the acetylene is given off and the ammonium chloride at the same time is decomposed by the calcium hydrate, to form ammonia, NH_3. The two unite, but the ammonia is split up into H and NH_2. The result is a gas, ethylene diamide, $C_2H_2+2NH_3=C_2H_4(NH_2)_2$. This gas unites readily with various acids to form well-defined crystals, and would be a good addition to the list of our NH_2 developers.

I have hitherto said nothing as to the price of calcium carbide or the cost of the light. It is yet too soon to predict what it will be. The demand will, no doubt, speedily produce an increased supply, and consequently cheapen the price. At present, calcium carbide may be obtained retail at about 1s. per pound. Statements have appeared in the papers that it could be purchased now at $2\frac{3}{4}d.$ per pound. Such statements, however, are misleading. Upon inquiry at the makers', it will be found that, to get it at that price, not less than a ton will be supplied. To this must be added the cost of metallic cases and packing, with carriage from either Germany or America, and railway transit here. The railway companies, I understand, also refuse to carry it except as an explosive under special conditions and charges, so that the price at which it is at present supplied by our dealers is not by any means exorbitant. Whenever our own manufacturers see their way to make it at home, the cost will be considerably reduced. Even at its present price, however, it is a cheap light for photographic purposes. One pound of calcium carbide makes about five cubic feet of acetylene, and this, with a No. 0000 burner, will last from eight to ten hours consecutively.

Edwin Banks.

EXPERIMENTAL WORK WITH A LANTERN.

It is somewhat surprising to find how seldom the lantern is used for experimental work at society meetings, and evenings devoted to this work might well form a welcome change to the ever-recurring lantern-slide exhibition. The necessary apparatus is by no means costly, and can even be made at very little cost.

For many purposes a special optical front is required, but this can be constructed, using the ordinary lens mount, and with very little extra outlay. The front combination of the lens should be removed altogether, as also the concave lens of the back combination. A piece of stout millboard, just large enough to fit into the lens tube, should be obtained, or it may be fitted like an ordinary cap, on to the front of the tube. In the centre of this card should be cut an aperture large enough to take a piece of postal tube of about one inch diameter, which should be well glued into the hole.

Into the tube, which should be about two inches long, is inserted a plano-concave lens to parallelise the light. The best way is to provide three or four concave lenses of varying foci, so that beams of different diameter may be obtained.

Another piece of apparatus, which is always useful, is a slit, and this can also be made very reasonably. A sheet of glass coated with black varnish, and a narrow streak of the varnish can be scratched off with a small piece of wood cut square across. Such a slit cannot, of course, be adjusted as regards width, but its length can be altered by using a piece of black card. A brass slit may easily be made, and it is almost as easy to make it adjustable as of fixed size. A slit one inch long is quite long enough; it is therefore necessary to obtain two pieces of brass plate about two inches long and one inch wide. They should be bound firmly together with the ends even, and supported on a block of wood, and with a rather fine file sloped off at one end at an angle of about 45°. When this has been done, the pieces should be separated and turned back to back, so that the two edges slope away from the centre, and should be firmly bound together in this position, and fastened either in a vice or to a block of wood, so that they cannot shift and will keep level. Now, with a piece of snakestone, which can be obtained from almost any dealer in process materials, polish down the sharp edges slightly, not much, but just sufficient to take off the knifelike edge. Great care is required at this stage to keep the edges parallel, and not to polish more off one end than the other, or else the slit will not close. Commercial slits are usually made entirely of brass, but this is not actually necessary; all that we want is a block of wood about 4×3 and $\frac{3}{8}$ of an inch thick, with a hole one inch square cut out of the centre.

One of the pieces of brass should now either be fastened by shellac, or else screwed down to the wood, so that its polished edge just projects half way over the opening in the wood. The other slit must be adjustable, and this may be effected either by means of a screw, which is, of course, preferable, or else by merely sliding between guides: this is by far the simpler plan. Lay the brass on to the wood so that its polished edge just touches that of the other plate, then, either by brads or stout ordinary pins cut in pieces, make a guide way: the pins being round are preferable to brads. A pin should be driven in at every half inch, both top and bottom, close up to the brass, leaving just sufficient room for it to move freely. Two pieces of stout copper wire, with the ends bent over, may be driven into the wood to prevent the slip from falling off. This little piece of homemade apparatus works very efficiently, and for any one with a taste for such things is not much trouble to make.

For showing a spectrum it is usual to employ a bisulphide bottle prism, and, as these are some trouble to make properly, it is advisable to purchase one. The disadvantage of such a prism is, however, that the lantern must be slewed round at an angle to the screen on which the spectrum is to be projected, or else the screen placed at one side of the room. A direct-vision lantern prism, constructed of glass, is a somewhat costly affair; but this difficulty may easily be got over by a very simple and ingenious dodge, suggested some time ago by Mr. A. Haddon, and this actually is to construct a water prism, in which is placed the bisulphide bottle, the result being that the refraction, but not the dispersion, of the light is destroyed. The water prism consists of an open box, the base of which is about three times

the length of the base of the bisulphide prism. Its sides are planed off at an angle of 60°, and colourless plate cemented on to them. The width of the box need be no more than just sufficient to take the bisulphide prism, the depth being, of course, determined in the same way.

The wood of the box may be mahogany, teak, pitch pine, or any other wood, but it will be necessary to make it thoroughly watertight inside, and this can be done by using a compound of—

Asphalt	4 ounces.
Mineral naphtha	10 „
Indiarubber	30 grains.

This, applied once or twice, will make almost all wood watertight, and the only precaution necessary is to avoid the near proximity of a light whilst applying it. To cement the glass on to the ends there is nothing better than stick lac. This is difficult to obtain of good quality, but round Hatton-garden many little oil-shops, dirty in appearance, will be found where good lac can be obtained.

The prism having been constructed, it is only necessary to place the bisulphide bottle in the box, with the apex in the middle of the base of box, and then fill it up with water to complete it. The dispersion with such a prism is not very great, the length of the spectrum at about twenty-five feet being only about three feet, but this is quite long enough for all experimental purposes, and, in fact, too long in some cases. If greater dispersion is required, it will be necessary to use two bisulphide bottles, and to double the length of the water prism, but this is attended with so much loss of light that experiments are robbed of much of their value.

To obtain a spectrum on a screen it is only necessary to place the homemade optical front on the lantern, the slit in the ordinary slide; stage and focus the slit sharply on the screen, and then place the prism in the path of the rays. With an ordinary bisulphide it is necessary to find the angle of minimum deviation, and this can be done by merely turning the prism on its stand, and, as it is turned, the spectrum will be seen to shift, as it were, from side to side of an image of the slit, and the position when it does not shift is the correct one. Actually the brightest spectrum is formed when the prism is in such a position that it gives the spectrum comparatively short and at the least distance from the straight line drawn from the lens to screen. With the compound water prism the base of the prism requires practically to be in a straight line with the axis of the lens.

There is only one point with regard to the use of bisulphide. Its smell is not very pleasant, but the purer the sample the less objectionable it is, and, if the stopper of the prism bottle is just luted down with a little bichromated gelatine, and exposed to the light, the evaporation of the bisulphide may be almost, if not entirely, prevented.

It is, of course, well known that an incandescent solid like a lime gives a continuous spectrum, and it is therefore impossible to show the Frauenhofer lines existent in the colour spectrum. It is better to use an ordinary lantern slide of the solar spectrum coloured by hand, and explain the formation, although there is no very great difficulty in showing the formation of the lines with a lantern, particularly if one is not particular as to absolute accuracy.

There are so many experiments, however, which can be performed with the lantern to demonstrate the formation of colour that must defer notice of these till a future note. PHAROS.

THE OXYHYDROGEN INCANDESCENT GASLIGHT.

[Edinburgh Photographic Society.]

I HAVE much pleasure in communicating the result of a few experiments I have made in order to adapt the use of the Welsbach lamp for optical lamp enlargement work in place of the oil pattern, and I hope to demonstrate to the meeting some decided advantages possessed by this lamp.

Before I begin, will you permit me to remark, that I do not wish to claim for this light when burning ordinary house gas, or even when aided by other means explained in this paper, that for *intensity* it can approach the limelight, but it is rather in the direction of showing slides to a small audience, and making photo enlargements, that I have hitherto worked?

To my mind there are three pretty sharply defined classes of photographers in these days. Firstly, the "button-presser;" secondly, the "half-plate carrier;" and, thirdly, the "studio man." Claiming myself to be one of the second class, I have to confess that this communication, while intended to interest all, will, I hope, commend itself to this great and growing class, amateur as well as semi-professional. Let me define it more sharply. It contains those who, having produced a good negative and a good print, have sufficient knowledge of their photograph to cause them either to attempt a lantern transparency or make a bromide enlargement of the picture; but, unfortunately, it also contains those who can produce the perfect negative with its charming print, who have to stop short for want of an easily worked and comfortable projection light.

You ask me what I mean by an easy and comfortable light? At this stage you will pardon me replying in the negative form—(1) A light requiring no preliminary trouble before lighting; (2) no trouble or adjusting after lighting; (3) no smoke or smell; (4) a minimum of heat; and (5) a sufficient intensity with great actinism and pleasing colour.

Now, Mr. President and gentlemen, in these specifications you will, doubtless, think I strike for a very high standard, but, when we remember some of the great objections which pertain to the oil lamp, on the one hand, and the limelight on the other, I venture to say that the elaborate drying, trimming of wicks, and cleaning with oily rags, which precede the use of an optical oil lantern, not to mention the smoke, smell, and great heat, are sufficient to make one hesitate before starting an enlargement in the dark room, or venturing into a drawing-room full of ladies. In both cases the final "blow-out" is a relief to all concerned.

Turning now to the use of the limelight, with its great brilliancy and immense power, there can be no doubt that to the vast majority of those I now particularly address it would prove a needless waste of energy. In the first place, for dark-room work its heat is intense, it requires almost constant attention while at work, and the flame is, after all, not so steady as one would wish. Taken into the drawing-room, the hissing is objectionable to the audience, while the small innocent explosions which sometimes occur within the lamp are very unpleasant if it is doubted that the lamp is in careful hands.

Possessed as I have been for the last six or seven years of one of these "paraffin oil optical furnaces," which I generally used in a very harmless way for micro projections, and throwing a six or seven-feet disc comic slide on the screen now and again, to amuse my children, I kept an open mind, as Mr. Gladstone used to put it, for any reasonable improvement short of increase in "furnace" power. Over a year ago I began to turn my attention to the Welsbach incandescent gaslight, which was making electric-light promoters feel rather uncomfortable in many quarters, and about the same time a writer in one of our journals "wondered whether this light would give a better colour than that of oil in the magic lantern." Having procured from the Incandescent Gaslight Company one of their burners, I had it fitted to a stand to go into my lantern, and made so that the centre of the illuminant would coincide with the axis of my condensers.

As some of those present may not have studied the construction of the Incandescent Company's lamp, I would like to describe it generally. It consists of a Bunsen burner, with its tube widened out at the top, into which is fitted a wire grating with a circular stop in the centre, which does the double duty of dispersing the flame equally round the burner and serving as a stand for supporting the porcelain stick, to the top of which the mantle is suspended. As the mantle forms the subject of patent, and, not being a chemist, I can tell you little about its components, but I believe it to be constructed of material resembling the cotton from which ordinary wicks are made, and which is dipped into a liquid consisting mainly of thorium after being woven. From what I saw at a kiosk at the Amsterdam Exhibition this summer, where a large working exhibit in mantle-making was going on, I can quite understand that the manufacture of these articles must be a very remunerative business, and possibly well deserving of the most jealous protection against competition. Although personally I have not the slightest interest in the Incandescent Gas Company's concern, I think it may interest the meeting to quote from the printed report by the manager of the Leith Gas Works, which states that, for the cost of 1000 feet of gas, viz. 3*s.* 6*d.*, the incandescent electric gives 1540 candle power; common gas, in a five feet per hour jet, 5000 candle power; and gas in the incandescent Welsbach burner, 18,440.

Returning to the subject-matter of my paper, viz., the adaptation of the Welsbach light for ordinary lantern work, I find in it all the superior convenience which gas always possesses over oil lighting—

minimum of trouble, absence of smell, and almost complete safety. A few yards of rubber tube attachable to any convenient jet is the only requisite. The tap gives the power of instant regulation, and the lamp in the lantern may be left burning by purpose or accident any length of time without attention or danger greater than that of neglecting to turn out the "lobby gas before retiring." In connexion, I may here confide that, although I seldom, "hardly ever," forget to turn out a jet before locking up, I did so on one occasion with this lamp. I was admiring a new slide which I had that day purchased, when I was called from my dark room, and forgot to return. Next evening, on entering the room, my classic statuary figure burst forth in full view, to my astonishment, and, knowing the joke only cost me about a penny, I think I can afford to tell you it in confidence, at my own expense.

Considering this light from an optical point of view, I find its colour, compared with an oil lamp, a great improvement, resembling as it does that of the lime and electric arc lights, a purity and crispness is at once discernible, and, what is much more valuable to us, its actinic power is very much greater than that of oil; and, as we well know shortening of exposure in enlarging means prevention of fog, this attribute alone should be sufficient to commend it to your consideration.

You will observe, the lantern is provided with a circular hooded chimney to take the ordinary funnel of the lamp, and, although I have found no serious tendency to breakage, I have adopted the mica chimney in preference to glass. This chimney costs only 1*s.* 4*d.*, and with care will last many years. The confinement of this lamp in a lantern has absolutely no deteriorating effect upon its burning, even when a focussing cloth is thrown over to prevent stray rays reaching the bromide paper when enlarging; and, in connexion with this, I may say that, so far from this light approaching what I have called a furnace, I find it possible to use the focussing cloth in this way during a pretty long exposure without singeing the cloth, and there is certainly no need of the alum tank.

I am now about to throw a picture of seven-feet disc upon the screen, and you will note the purity of colour and steadiness of light. Note also a property which may be useful in the dark room, viz., that the light may be turned completely out for two or three seconds and burn up again when turned on.

In order to shorten exposures, and at the same time be enabled to give a lantern demonstration to a moderately sized audience, such as this, I commenced to experiment by feeding oxygen into the lamp, in the hope that an improvement would result. But I soon found that by mixing the gases in a Bunsen where air is present forms an explosive mixture, and is an experiment not likely to be repeated by any one who tries. I then determined to burn the oxygen outside of the lamp proper, and designed a burner for the purpose, which has been found to work well and safely. If you will kindly refer to the drawings, I will endeavour to explain its simple construction. The drawing is a semi-sectional elevation of the lamp, and the red lines show the general construction of the oxygen attachment. The oxygen comes from the cylinder, per regulator, in the usual way. After passing the check stop cock, it passes through perforations in the end of the tube, which spread the gas within the burner, and finally the gas emerges through very fine perforations on the top of the burner at a low pressure, and acts by stimulation of the incandescence on the part of the mantle next the condensers. The burner and a portion of the supply pipe is fitted to the top of the lamp by an annular ring, and may be removed by unscrewing the union joint should the remaining part of the fitting require to continue fixed. The whole apparatus, however, may be removed by unscrewing the pinching screw which secures it to the foot of the lamp, so that, by means of these arrangements, the oxygen part can be added or dispensed with as occasion requires. When in position, the top of the oxygen and hydrogen burners should be about the same level, with a space of from one-sixteenth to one-eighth of an inch between them, into which the foot of the mantle slips.

During my first experiments with oxygen in this way, I was troubled by finding that the most brilliant part of the mantle sometimes faced the back or a side of the lantern, away from the condenser, with the consequent darkened field upon the screen. To meet this erratic habit, I thought of fitting a turntable on the Welsbach fitting. After repeated experiments, however, I found the best way to cure this is to block out the rear portion of the mantle by means of a hood of platinum foil placed inside the mantle, and held in position by the ring which supports the oxygen-burner. This is a "perfect cure," as it not only concentrates the light to the front, but enhances its illuminating value, and also helps to steady the mantle without doing it injury. I may here say that this is a most essential part of the apparatus, and one which I claim as quite novel. When we come to consider the photometric values later on, you will be better able to appreciate what I have just described.

It is needless to deny that the fragile nature of these mantles is very much discounted by the public generally, and especially those who have not tried or given them fair play. For instance, the mantle sold by the Company is, as a rule, too long, or, as the ladies say, too "deep in the skirt;" but, in order to adapt it for this lamp, I usually clip fully half an inch off the bottom, which has the effect of preventing splitting and fraying, so common in ordinary lamps.

One of the chief fears I had for the success of the oxygen fitting was the interference with the air passage between funnel and mantle, but I find no deterioration whatever. In fact, in course of my experiments, I have disturbed and upset all the air currents at one time or another, and have not been able to detect any reduction of intensity, or even unsteadiness of light. An oil lamp, if treated as I sometimes treat the one before you, would nearly suffocate the operator with smoke, or go out altogether.

Before leaving the subject of the mantle, allow me to state that up to the present I have found that no injury whatever is done to the mantle by burning oxygen as I describe, neither can I detect any lessening of its durability. Under ordinary care in moving the lamp about, even from one room to another, there is no reason why a mantle should not last an operator a whole season: indeed, I have had one in frequent use during three months which is as good as when first lit.

With your permission, I will now show you the effect of the oxygen on a picture through a lantern plate of ordinary density. In order intelligently to express in figures the actual value of this light, I asked Mr. Ivison Macadam to make some careful photometric tests, which he was good enough to carry out at the expense of considerable time and trouble, extending over several evenings, at my own house, and also in his laboratory: and, on considering these figures, you will be good enough to bear in mind that they are comparative tests, inasmuch as, where gases were used, the hydrogen consumpt was in all cases kept the same, namely, to the low quantity of three cubic feet per hour.

1. Four-wick paraffin-oil lamp.—Open light, 37 candles; in lantern, 23 candles.

2. Incandescent burner.—Without author's fittings, 40·25 candles.

3. Incandescent burner (with author's fittings).—(*a*) *Without oxygen*—Open, 47·10 candles: in lantern, 28·12 candles. (*b*) *With oxygen*—Open, 71·50 candles; in lantern, 40·50 candles.

4. Limelight burner.—Open, 80·50 candles; in lantern, 50·31 candles.

Calculating the effective discs available comparatively from these figures, we have—

40·50 c.p. + oxy.
28·12 c.p. − oxy.

12·38 of increase.

Then, for a distance of 12 feet and a 7-feet disc—

$$\frac{28{\cdot}12}{40{\cdot}50} = \frac{12^2}{x^2}$$

and $28{\cdot}12\ x^2 = 5832$

$x^2 = 207$

$x = 14{\cdot}4 = 14'\ 5'' =$ distance from lamp, at which the oxygen light would act with equal power to that of the plain incandescent gas at 12 feet; then

$$\frac{12}{7} = \frac{14{\cdot}4}{x}$$

and $12\ x = 100{\cdot}8$

$x = 8{\cdot}4 = 8'\ 5''$, the size of disc which would be obtained with illumination equal to the plain incandescent light upon a 7-feet disc.

You will please observe that the standard disc of seven feet was adopted, owing to the small room in which the experiments were made, and by no means fixes this as the limit performance of the lamp *minus* oxygen.

If the screen, sizes, and distances obtainable from the other two illuminants are calculated, we may collect the following, viz:—

	Distance.	Disc.
1. Four-wick oil	10' 9"	6' 4"
2. Incandescent ordinary	12' 0"	7' 0"
3. Incandescent author's	14' 5"	8' 5"
4. Limelight	16' 0"	9' 4"

The diagram shows very clearly these comparative proportions drawn to scale, which you will readily understand.

Referring again to the figures of the analysis, and comparing the open incandescent *without* author's fittings as against the same

burner with author's fittings, but *minus* oxygen, where we get 40·25 as against 47·10, you will appreciate the importance of the introduction of the platinum foil as a concentrator of light.

We come now to consider what I look upon as the most valuable property of this new light, viz., its photographic power, or, as we term it, *actinism*. With the view of determining a comparison with that of a four-wick W oil lamp, I proceeded to photograph one of my best and most plucky 8 × 10 negatives by transmitted light from my lantern upon a quarter-plate through a 5-inch Cooke lens working at *f*-6, but stopped down to *f*-8. A well-known member of this Society assisted me, and developed the negatives. Our tests were:—

1. Oxygen	6 seconds	.....	*under-exposed.*
2. Do.	12 „	.....	*normal.*
3. Four-wick.....	14 „	.....	*greatlyunder-exposed.*
4. Do.	60 „	.....	*almost normal.*

Decided that other 12 seconds, viz., 72 seconds, would give normal. Comparing the two normals, we have the proportions 12 is to 72, or as 1 is to 6.

Assuming now the fact, which I have no reason to doubt, that the oxygen does not improve the incandescent ordinary light with regard to colour, I conclude, referring again to Mr. Macadam's comparative tests, that what is got in the way of an exposure for, say, 40·5 seconds by the ordinary would be reduced to 28·12 seconds by the oxygen, which means roughly that in working this lamp without oxygen it becomes necessary to increase the exposure by one and a half times. This is, of course, assuming that the exposure is in the direct inverse ratio to the candle powers of the two systems.

Our friend, Mr. Balmain, has very kindly agreed to assist me in making a couple of bromide enlargements to demonstrate to the meeting the relative "speeds" of the four-wick oil and the incandescent oxygen Welsbach lamps, and during the few words that remain in my closing remarks, I would ask him to make the necessary arrangements for the exposures.

In conclusion, Mr. President and gentlemen, I would most respectfully commend this light to the practical consideration of this Society. During the last twelve months, I have found it a most convenient and comfortable mode of lighting either plate, paper, or screen, and I feel certain that when this light comes into the market, which I trust will be in a few weeks, it will meet the requirements of first-class amateurs as well as many professional photographers. There need be absolutely no fear of danger, as the fact of the oxygen being separated from the hydrogen in the act of burning by means of the mantle affects the gases in the same way as the Davy lamp already referred to. When we consider the combustion system in its order, as (1) the furnace, viz., the Bunsen; (2) the fuel, viz., the hydrogen; (3) the mantle heating, viz., the work; and (4) the atmosphere, viz., the oxygen, there is a sequence of natural elements naturally treated which at once commends itself to those who are aware of the importance of the prevention of explosive mixtures, especially in a lamp used in studios or dark rooms.

William Penman, C.E.

THE RISE AND FALL OF THE OPTICAL LANTERN.

The majority of writers about matters connected with the optical lantern have so steeped their souls in the creed which takes for its continual boast the promotion of their favourite from the realm of toydom to the status of an optical instrument, that they never pause to inquire whether or no the elevation is still going on. They say that the advent of photography has been the means of making the lantern—which before was a mere plaything—into one of the most powerful instruments of instruction and entertainment which an enlightened nation can possess. So it has, there can be no doubt about that; but are we right in assuming that there is to be no reaction?—indeed, that the reaction has not already commenced? The pendulum of popularity has swung a long way; it may swing back again. Photography it was that first made the stereoscope possible, and then photography gave it its marvellous popularity; but where is the stereoscope now?

Depend upon it, photography is a fickle goddess. When she was young, she gave of her best to the lantern, and nursed the feeble baby till it grew to be strong. But, now that she is older (and some say wiser), and has far choicer gifts in store, she showers them elsewhere, and the poor lantern's slides, by contrast, "must needs seem horrible." Or, perchance, our magic lantern is the victim of that "vaulting ambition which o'erleaps itself and falls on the other." Certain it is that it has lured to their destruction many men who would otherwise never have dreamed of lecturing, and who have flared up brightly for a moment upon the uncertain footing of a flowery poster—they will generally give their services provided they are well advertised—and then sink for ever into well-deserved oblivion, whence they would never have emerged but for the blandishments of unscrupulous lecture agents or flattering friends.

No one would grudge them their short-lived scintillation, if it give them pleasure, were it not that, in the fall which is the certain sequence, they drag down with them to a certain extent the whole art of popular lecturing. When will the secretaries of literary institutions and the like awake to the fact that the ability to write a book does not necessarily confer upon the author the power to read it in public? When will they come to see that, because a man has been most successful in cutting off other people's heads (for their misdeeds), he may yet not be able to lecture? Even Mauger had his limits, and there is a vast deal of difference between public execution and public elocution. It is quite possible that the deftest wielder of the axe or the noose may do sad havoc among an audience—with the jaw-bone of an ass.

It is, perhaps, more excusable in a secretary to suppose that a man possesses the "gift of the gab" who has succeeded in persuading somebody else's mamma that he is her son (to say nothing of sundry others who believed the story); but why, in the name of all that's awful, should an artist be considered capable of lecturing on no other recommendation than that of his pictures? Until the secretaries and others who are responsible for the choice of lantern lecturers begin to realise that lecturing is as much an art as any other form of public entertainment, and requires, not only the original gift (which is seldom given), but also a long apprenticeship and course of study, audiences will continue to be disgusted by the vain sputterings of duffers, and the illustrated lecture will never be freed from the stigma which is fast descending upon it. But, as the Romans of old used to say, "Experientia does it," and, before long, entertainment providera must come to see what is the real cause of their diminished audiences. Meanwhile there is, unfortunately, but little room for doubt that the lantern as an illustrator of high-class lectures is falling into disfavour.

Some say that it is owing to a temporary scare regarding the safety of the limelight that lantern entertainments are now so poorly attended, and that as soon as the scare subsides, audiences will return with whetted appetites.

That there has been a limelight scare there is, of course, no doubt, but all appearances point to the fact that it has existed, and does still exist, only with the lantern users—amateurs mostly—and audiences are quite unaffected by it. Several dozen cases are on record of the owners of gas cylinders sending them away immediately upon hearing of the Fenchurch-street accident, and one reverend gentleman has taken the precaution of having his gas cylinders buried several feet deep in the earth at a sufficiently safe distance from the parochial lecture-hall, whither the gases are conveyed by iron tubing. Truly it is better to "bury the bottle" than that the parishioners should come to an untimely interment, and it has the extra advantage of supplying a most excellent simile and object-lesson for the use of generationa of tee-total talkers.

And this mention of temperance meetings—where the talk is usually anything but temperate—brings us round easily and smoothly enough to a consideration of quite a different phase of the subject; for, though we are fain to admit that the optical lantern as an illustrator does not now possess that popularity which of itself it undoubtedly deserves, yet, as a temperance tout and Christian converter, it is most decidedly in the ascendant, for, to bring cash to the Christian coffers, and "tin" to the teetotal till, there is nothing like it under the sun.

Let it not be for a moment supposed that any disparagement is implied regarding the employment of the lantern for such purposes, for it is but meet and right that the best of all we have should be devoted to the service of religion, and surely the lantern need not be ashamed to join issues with the king of musical instruments in such a cause, It is against the ghastly examples of the "art" of that fell destroyer of human peace, the commercial producer and colourer of lantern slides, that the strongest protest must be entered, for, among his very vilest productions—and is not their name legion?—there are none so bad that they will not do for temperance orations, while the "religious" figure subjects, though they are not worse, because that is impossible, are, from their nature, even more shocking to the sensibilities of the sensible.

It is proverbially useless to grumble unless a remedy be suggested for the state of things objected to. A few ideas are therefore submitted in all humility for the criticism of those whom this subject may concern, and it is hoped that, humble as they are, they may possibly serve as a basis upon which something more practical may ultimately be reared.

In the first place, it seems most desirable that there should be some kind of combination between the secretaries of the various institutes and

lecture-halls throughout the country, in order that they might compare notes and assist one another in the choice of lecturers. And why should the lecturer not be asked to furnish references as to capability? Such a course would save a deal of trouble and annoyance to the secretaries, though it would, of course, have the somewhat doubtful disadvantage of being an obstacle to the youthful and untried lecturer's progress. Such a one might, however, be allowed to spout for a given time before a meeting of delegates from the various institutes, and, having once passed successfully through that ordeal, he would have no more trouble.

To refer to the secretary of an institute where the lecturer had had a previous engagement would be a far more satisfactory manner of judging of his ability to lecture than to ask to see—if he be an artist—his pictures, or an executioner, his scalps; for such trophies, beautiful as they undoubtedly are in themselves, and excellent evidences of the artist's ability in his own particular line, are quite valueless as indices to his power to even briefly describe a set of lantern slides.

Again, would it not be possible to start a kind of inter-secretarial black list, whereon to write the names of those lecturers who "didn't oughter?" Or perhaps something a little more elaborate might be compiled in order to show the reasons of the lecturer's failure, and this would be fairer, because audiences in different places vary so much, that an entertainment which has fallen flat in, say, London, may, although given in a precisely similar manner in the Midlands, prove most attractive to the denizens of those parts. It may be urged, of course, that any lecturer who knows his business will be able to judge, directly he steps upon the platform, what kind of audience it is to whom he is speaking, and that he will be able to modify his discourse to suit his hearers. But it is also true, as all public speakers know to their cost, that there are audiences that care for no more intellectual entertainment than "niggers," and before whom no lecturer stands a chance of making his entertainment "go," unless he is prepared to black his face, take a banjo or auto-harp upon the platform with him, and to colour his lecture to match his countenance.

But, regarding the semi-religious form of entertainment, it is to be feared there is no remedy for the terrible state of affairs into which our poor lantern is here fallen; for it is one of the inexorable laws of Nature that those who have the bump of the knowledge of good and evil so abnormally developed in one particular direction should be quite unable to discern the quality of anything so mundane as a lantern or its slides. They are Salvation specialists, so to speak; they know and care nothing about the instruments they use, except perhaps their price; and, whatever else the religious lantern may be, it is always cheap.

And so, alas! it must continue to be the fanatic's faithful friend, the teetotaller's tout, and the collection cadger for all sects. And, if occasionally we hear of one unable to contain itself, as it were, which bursts itself and scatters dismay and perhaps death, around, let us not be too hard upon it, for a fellow feeling should always make us kind.

CECIL M. HEPWORTH.

POSSIBILITIES OF THE CARBON PROCESS FOR LANTERN-SLIDE MAKING.

[Autotype Notes.]

INQUIRIES are sometimes made as to the suitability of the carbon process for making lantern slides.

Seeing that the carbon process will give the most beautiful transparencies that can be produced by any process, it may fairly claim to give the best lantern slides if properly worked. Lantern slides are only transparencies that have to be highly magnified.

The weak point in the process is want of contrast, and therefore it is always directed to print only from negatives having strong contrasts.

When the carbon process was first introduced, it was claimed that, by increasing the amount of pigment in the tissue, almost any amount of strength in the shadows could be obtained. This is practically true for prints on paper, which are seen by reflected light; but any increase in the amount of pigment, over a certain quantity, is useless, as this increase would render the tissue obstructive to light, and therefore, would defeat the purpose for which it was intended.

It may be accepted as fact that only negatives having a good amount of contrast are suitable for lantern-slide making by the carbon process; it is, however, possible to improve most lantern slides that have been already made by this process. I shall refer to this later on, but will first, however, make a few remarks on the method of working the process for making lantern slides, and therefore advise those who intend trying it to adopt the following directions, which can be relied upon.

Procure ready-sensitised transparency tissue in sheets, 13×10 inches (each sheet will make one dozen slides), *and on the day the tissue is to be used* turn up the edges of each piece, so as to form a shallow tray, pin to a flat board, and coat with collodion. Dry in a warm room quickly. After trimming the edges with a pair of scissors, each piece must be laid, face up, on a zinc plate, and, with a zinc template, exactly 3¼ inches square, and a sharp knife, cut it into twelve pieces, and put them in a flat tin box. They are then ready for use. Mask the negatives with tinfoil on the film side, exactly three inches square.

Thin clear glasses, 3¼ inches square, are necessary for the final support; and the following solution will be required as a substratum, in order to ensure success:—

Water	1 pint.
Gelatine	300 grains.
Bichromate of potash	30 „

Dissolve and filter through paper or cotton-wool while hot, coat the plates in the usual way, and dry in daylight, taking every precaution possible against dust.

These plates may be prepared weeks in advance, but should be kept in a grooved box, and the greatest care must be taken that no rubbing or marking of the surface takes place to mar the beauty of the final result.

Print for about three times the length of time required for a paper print, with the same tissue, and, when ready to mount, place the exposed pieces of tissue, one or two at a time, in clean cold water (about 60° in summer and 70° in winter), till just flaccid; and remember that the time of immersion will be proportionately longer on account of the front being collodionised, and that absorption can only take place from the back of the tissue. At the same time place the 3¼-inch glasses in the water, and lift out with the tissue upon them, adjust position on glass, and squeegee. Lay between blotting boards for fifteen to twenty minutes, and then develop thoroughly; finish off with a jug of water at 120° to 150°. Dip again into the developing water, and then into cold water. Dry in a place free from dust, and in a fairly warm room.

If the exposures have been properly timed, the slides, when laid face down on white paper, will be quite white in the high lights; if, however, the white paper is degraded in those parts, the best effects cannot be expected, and such results will not fairly represent the suitability of the process for this class of work. Supposing that negatives having good contrasts have been used, no further treatment will be required, unless it be desired to modify the tone. This may be done by simply dyeing them in a solution of alizarine in dilute ammonia, followed by a dilute alum solution, or with sulphate of indigo for cool tones.

The best method known to me for giving great vigour and fine colour was published by me, ten or more years ago, in one of the photographic almanacs.

Prepare three solutions:—

A.

Distilled water	1 pint.
Silver nitrate	5 grains.

Dilute ammonia, just sufficient to give a clear solution.

Avoid a large excess.

B.

Distilled water	1 pint.
Citric acid	5 grains.
Pyrogallic acid	1 grain.

C.

Distilled water	1 pint.
Silver nitrate	10 grains.

Proceed as follows: Place the dry transparency to be treated in solution A for half a minute, and wash. Take sufficient of B in a glass measure, and add to it half a dozen drops of C, and at once flow over the slide; the effect is very rapid, and if washed off at once the colour will be warm, but, if the action is allowed to go on, the colour will become cooler. If the negatives used have a fair amount of contrast, this treatment will give the slides great richness when thrown upon the screen.

It has been supposed that the carbon process would not give sharp results, but that is a mistake. Some of the best slides ever made were by the Woodbury process, which gave results similar in character to the carbon process.

The method here recommended for making transparencies is certain in results, and, after over twenty years' daily working, I have no hesitation in saying it is the best possible process. I am well aware that substratums can be dispensed with, and so can collodion—*sometimes!* H. J. BURTON.

A NEW INCANDESCENT LAMP.

THE recent attempts to replace the ordinary oil lamp by the incandescent gas has but one drawback to amateurs, especially those who live in the country, where frequently gas is not obtainable, or of very poor quality. In France a new form of incandescent lamp has just been introduced, which is provided with a mantle like the Welsbach, but is not dependent on gas, but may be used with paraffin, or, better still, with methylated spirit, and a beautiful white, clear light is obtained at a cost of from a halfpenny to a penny per hour. We hope to be able to give a fuller description next month, with illustrations.

A HOME-MADE FLASH LAMP.

HAVING profited by the descriptions of devices and contrivances for increasing the capabilities, says Mr. F. J. Burnett in *The Photographic Times* and therefore the happiness, of the amateur of limited means, that have appeared in previous numbers of the *Times*, I am moved to give the readers of this number a chapter of my own experiences in evolving accessories, trusting the same may be of benefit to some of them who are obliged to look at both sides of their dollars before letting them go.

I do not suppose my flash lamp is unique, but I never saw one like it and never showed it to any one who had; it represents an outlay of thirty cents, and this is how it was made:—

A common clay pipe, of which I purchased two "fur a nickel" in Omaha, but which I believe can be had for a penny each east of the Mississippi, I stuck through a cork, which should be large enough so that a hole of sufficient size to admit the pipe stem will not weaken it seriously (the cork is the connecting link between the lamp and the handle or standard). Around the bowl of the pipe I wound a piece of lamp wick long enough to go three times around; this I held in place by winding a short piece of wire once around it and twisting the ends together. Over the end of the stem I pulled a piece of rubber tubing three feet long. This length is not necessary, but it is sometimes convenient to be able to hold the lamp at some distance from you. The cork I now stuck on the point of an iron office spindle; the other end of the rubber tube I attached to a bulb which I had; this, however, may be dispensed with, and the air supplied from one's lungs by blowing through a pipe, a convenient mouthpiece for which purpose can be made from a section of a rubber penholder, or the ferrule of a penholder or any similar tube. The manner of using this lamp is apparent: Put two or three pinches of powdered magnesium in the bowl, touch a match to the wick, upon which a little alcohol must previously have been poured, blow through the tube, and there is your flash.

The rubber tubing, which cost twenty-five cents, and the clay pipe are the only things I had to purchase. The cork and the lamp wick I got from the kitchen, the wire from the wood shed, the spindle I had; I believe a similar one costs five or ten cents.

Of course, the lamp must be reloaded for every flash, but a single flash I have found sufficient for an ordinary interior, or a group of ten or a dozen persons.

There are a number of ways by which it might be supported in place of using the cork and spindle, but they make a light and convenient handle and standard; the spindle is easily detached, permitting the lamp to be packed in a small space, and by unscrewing the base of the spindle the lamp may be tied to a cane or stick, and held above one's head for lofty interiors.

Of course, it should be extinguished immediately after each flash, else the flame, having consumed the alcohol, will burn the wick.

A "DANGEROUS" PRACTICE.

WE subjoin the account of a case in which it was alleged that a lad struck a lady with an oxygen cylinder that he was carrying. The reported remarks of the witness and of the magistrate as to the "danger" of carrying cylinders of compressed oxygen are, to say the least of it, of an unwarrantably alarmist character:—

"William Mordy, a young man of respectable appearance, was charged with assaulting Miss E. S. Gladman. Prosecutrix stated that between seven and eight o'clock the previous evening, as she was walking along Waterloo-road towards home, a man slipped down immediately in front of her. Prisoner appeared to come up hastily, and, after making use of a filthy expression, struck her on the face with an oxygen gas cylinder which he was carrying. As a result, both her eyes were blackened and her nose bruised. He threatened to serve her sister in the same manner, and, a constable coming up at this juncture, she gave prisoner into custody. He appeared to be sober. Prisoner stated that the assault was quite an accident. He heard a disturbance behind, and, on turning round to ascertain the cause, the cylinder came in contact with the lady's face. He called a witness, who stated that the cylinder was five feet in length and six inches in diameter, and contained eighty cubic feet of gas. It was very dangerous to carry these cylinders through the streets, because, if they were dropped to the ground, an explosion would take place which would have fatal results. A man threatened to strike prisoner on the nose. Had he done so, accused would in all probability have dropped the cylinder, and he, with all the surrounding people, would have been blown into the air. Mr. Slade said the assault was very serious, and he would inflict upon prisoner the highest penalty, viz. 5*l.*, or one month in default. The magistrate directed the attention of the inspector on duty in the Court to the dangerous practice of carrying these cylinders through the streets, and requested him to report to the proper authorities."

We hope the "proper authorities" to whom Mr. Slade allndes will seek expert advice before taking the worthy magistrate's recommendation into consideration. If the public has a right to be protected from possible dangers, it has an equal claim to freedom from the thoughtless disturbances of panic-mongers.

SOUTH AUSTRALIAN PHOTOGRAPHIC SOCIETY.

AT the October meeting Mr. R. W. Chapman, M.A., B.C.E., of the University, delivered a lecture on "The Composition of Colours."

He first drew attention to the composition of ordinary white light, by resolving a beam from the limelight into its component colours by passing it through a prism, thus obtaining a brilliant band of colours on the screen. He stated that colour bears the same relation to light that the pitch of a note does to sound, but proceeded to show that the effect of compounding colours was very different to the effect of compounding musical notes. The trained musical ear could distinguish every note of a chord, but the eye had no suspicion of the component colours that go to make up a mixed tint, as the same tint apparently might be composed in very many different ways. The effect of compounding coloured lights by reflecting beams from various portions of the spectrum was then shown, and by analysing the light passing through coloured glasses the nature of colours by transmitted light was exhibited. The difference between the colours obtained by mixing the lights that had passed through coloured glasses and by superposing one glass on the other was then shown by a series of striking experiments. Further experiments proved that white light may be produced by a mixture of two colours only, and that the eye could not distinguish the white light so produced from ordinary white light, The modern theory that the eye possesses only three separate colour sensations was then explained, all our notions of colour being due to the mixture of the three primary sensations in different proportions. Experiments on the compounding of colours by means of the colour top were shown, and the lecturer explained the practical application of the theory of three-colour sensations in Dr. Joly's new method of colour photography. He concluded by exhibiting some curious electrical effects produced on photographic plates.

PHOTOGRAPHIC LANTERN SLIDES IN CHURCH.—The optical lantern is growing in popularity as an aid to pulpit exposition. At the old London City church of St. Mary at Hill, the Rev. W. Carlisle has used the optical lantern every Sunday evening for some years, and has by no means confined the slides to scenes from Scriptural lands. Current events and scenes, especially those which may serve to awaken a sense of Christian duty, are shown frequently, slum life being frequently illustrated and contrasted with life in the palaces of the rich.—*Thomas Bolas in the "Photographic Times."*

ACETYLENE FOR ILLUMINATING PURPOSES.—We have in several issues of the *Bulletin* alluded to the new illuminant, acetylene. By the courtesy of Mr. E. N. Dickerson, we were able to see the practical application of this gas to ordinary illuminating purposes. The gas, in the liquefied form, was stored in an iron cylinder which was connected to a gas pipe, and the ordinary burners were used. The light given was simply superb, making the ordinary gas, burning at the same pressure, look ridiculous. The enormous advantages of this form of illumination are evident. Street mains are unnecessary, gas companies can no longer extort high prices for a miserable product, with a meter that does not measure, and a light of extraordinary power is thus placed at the disposal of any one in any locality. An acetylene torch was an interesting application of the gas. The price will, we believe, be considerably less than that of ordinary gas. We predict a revolution in house illumination.—*Anthony's Bulletin.*

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*February 7, 1896.*

THE LANTERN RECORD.

CONTENTS.

THE SEARCH LIGHT.

I have duly received a beautifully engraved document which affords Sir H. Trueman Wood and Mr. Chapman Jones the opportunity of certifying that I have been elected a Fellow of the Royal Photographic Society. The certificate has a large red seal stuck in the left-hand bottom corner of it, and the total effect produced is as awe-inspiring as that given by similar examples of the engraver's art, patronised by the "Perseceutical"—I mean Pharmaceutical—Society, which you see in chemists' shops. If I were a professional photographer, I should frame my Royal Photographic Society certificate, and hang it prominently in my reception room; it might help me to get better prices and prompter payments. As it is, the document has found a place on the walls of my study, and is the admiration of all who are privileged to behold it. I have not spent £2 2*s.* for nothing.

* * * * *

I have been favoured with the first five copies of the reformed and rejuvenated *Photographic News*, now reduced in price to a penny, and appealing to amateur photographers. I search its pages in vain for the hand of the cynical and flamboyant "Ignotus," from whom last autumn I had the honour of occasionally differing, for he and the other features of the old *News* have disappeared, and in their place we have a bright, chatty, workmanlike little paper, judiciously edited, prettily got up, and supplying a capital pennyworth for amateur photographers.

* * * * *

The usual annual excitement about the Council election of the Royal Photographic Society, which takes place next Tuesday, has broken out among those members who are interested in the matter, Last year an attempt, happily defeated, was made to draft on to the Council a number of gentlemen whose qualifications for the position were that they were the nominees of a small group of worshippers of the Golden Calf; this year three or four old members are in danger of being displaced by new and untried men. On the whole, it is a pity that this agitation has arisen, for the good that is likely to issue from it is very doubtful, while the creation of some amount of bad blood and ill feeling is probable.

* * * * *

By the way, "Lictor," a reporter to an amateur contemporary, referring to the Council election, says: "It is a little difficult to appreciate the advice of our contemporary, The British Journal of Photography, though given *ex cathedrâ*, when in one paragraph we are warned against the machinations of a caucus, 'which in the cause of progress is trying to exclude from the Council a few of the older members,' and in another, immediately following, the hope is expressed 'that members will vote solid for the old Council.'"

* * * * *

The difficulty experienced by "Lictor" is one for which he alone is responsible. I turn to the passage in this Journal to which he first refers, and find it runs as follows:—"A self-elected caucus, however, has taken upon itself not only to run a candidate for the chair, but also, in the cause of 'progress,' is trying to exclude from the Council a few of the older members, *who have been re-elected for a good many years, but whose further presence on that body is supposed, in some mysterious way, to interfere with the progress of the Society—and photography.*" "Lictor" not merely omits the quotation marks given to the term "progress," but, in suppressing the words I have italicised, lays himself open to the accusation of not being able to understand what is aimed at in the Editor's remarks, viz., that it is doubtful if the "progress" of the Society is prevented by the presence on its Council of a few old members. Again, if "Lictor" is anxious to publish to the world the uninteresting fact that he is a stupid person, and unable to read, he is under no obligation to demonstrate that he is also poor-spirited enough, in order to secure a point, to mutilate his quotations, and draw therefrom dishonest and indefensible deductions.

* * * * *

By the way, a rumour reaches me that there is a secret plot, having for its object the endeavour to prevent the re-election of members of the Press, "as it is undesirable to have them on the Council on account of their connexion with the photographic journals." My information comes from a trustworthy source, and, as a similar, but abortive, attempt was made last year to boycott those who were suspected of an ambition to prevent the Society from becoming the mere plaything of a few gentlemen from South Kensington and other aristocratic parts of London, I have little difficulty in crediting the rumour, extraordinary as it is.

* * * * *

On what grounds a representative of the Press is an "undesirable" person to be on the Council of the Royal Photographic Society I am at a loss to understand. Assuming for argument's sake, however, that some valid objection can be advanced against the presence of the fourth estate on the Council, let us see, from the composition of the outgoing body, against whom the agitation is directed. The following members of the old Council are "connected with the photographic journals:" Captain W. de W. Abney, C.B., Mr. Chapman Jones, Mr. Andrew Pringle (all three being editorial contributors to *Photography*), Mr. Thomas Bolas (connected with *The Photogram* and *The Amateur Photographer*), Mr. Thomas Bedding, Mr. T. C. Hepworth, Mr. E. J. Wall; while at least *four* other gentlemen, whose names I withhold, have, to my knowledge, a more or less

direct connexion with the photographic press, which brings them under the ban of the conspirators. The movement, therefore, is, *or should be*, levelled against ten candidates for re-election.

* * * * *

But, as a matter of fact, out of ten journalists, only two are aimed at by this truly heroic and consistent clique. It is a graceless and paltry agitation, inspired by ungenerous motives, buttressed by narrow-mindedness, and crowned with ingratitude. The present prosperous condition of the Society is not inappreciably traceable to the personal and professional efforts of some of the photographic press, who have given much of their spare time and energies to forward its interests. This Journal in particular, during the past four years, has backed up the Society through thick and thin. I am quite sure that anybody connected with it who happened to have a seat on the Council would "stand down" if it could be shown that such a course would benefit the Society and it was the wish of the members; but I am equally sure that the Society would not benefit thereby, if such a result was brought about by underhanded means, and that the great majority of the members will not approve the tactics I have referred to, whether they are successful or not. Radiant.

LANTERN MEMS.

Parliament is to reassemble on the 11th inst., and then, among other items of interest to be made known, even though it should not find a place in the Queen's Speech, will be one of marked importance to the lantern world, viz., the publication of the report of the Home Office Committee on the gas-cylinder question, and the use and conveyance of compressed gases. I understand this is already printed, but, according to custom, cannot be published except it passes through the recognised channels. Verily, official ways are wonderful.

* * * * *

It is just a year since the trouble to the lantern world and gas-compression industry was caused by the deplorable accident at Fenchurch-street Railway Station, and it has taken all this time for officialdom to arrive at a decision as to how, when, and where compressed gas may be used and conveyed, and what kind of cylinders can be employed for the purpose. I venture to think that any commercial concern would have fully investigated the matter and arrived at logical and practical conclusions in two months at the longest, with the aid of experts in engineering and chemistry, which are likewise available to the Government.

* * * * *

The havoc played with the lantern trade during this season must be largely attributed to the delay in the publication of the official report on the compressed-gas question, for, although the precautions taken by the gas-compression companies are such that those who have gone into the matter recognise as sound and satisfactory, yet the general public are slow to forget a matter that affects their safety, and consequently many who thought of purchasing limelight apparatus deferred doing so until some authoritative statement was made. The season, unfortunately, is best part over before any announcement is made, and manufacturers suffer in consequence.

* * * * *

I don't think I am wrong in saying that, notwithstanding the "boom" in jets, high pressure of wonderful candle power, injector jets, and oxy-ether saturator jets, the number made this season will not at all compare with those made last. Many lanternists may, of course, be content to use the incandescent gaslight, and others be fortunate enough to have electricity laid on, and so avail themselves of the electric arc light; but, even putting a fair number down for these two classes of lanternists, there is still a big deficit in trade.

* * * * *

The mention of the incandescent gaslight reminds me of an American patent taken out and published for the manufacture of indestructible mantles, or at any rate, if not indestructible, so made that they can be handled. It consists of oxide of thorium, oxide of didymium, and oxide of lanthanun. They are mixed into a dough consistency with liquid glue, and then forced into threads and woven. These are duly supported on a platinum or fire-clay mould, dried, and incinerated. The yellow light desired by some users of gas in preference to the light of the Welsbach light is obtained by didymia, but not more than five per cent. must be used, or the light will be too yellow.

* * * * *

According to decisions on patents in connexion with mantles for incandescent gas lighting, it appears that Auer Von Welsbach was not the inventor of the incandescent gaslight, but he so far improved the method of producing it, that, while he uses the salts from the earth metals only, his patent remains good. A final appeal is, however, to be made to the Imperial Court to see if the decision of the Patent Office will be upheld. Another patent has been allowed by the Board of Appeals of the Patent Office, and this is for a hood formed by an electrolyte of the nitrates or sulphates of earth metals. It appears a finely woven platinum conical hood has deposited on it by electricity a mixture of these nitrates and basic earth salts, and this is then converted into oxides by calcination. The resultant is a hood that gives a splendid light when used over a Bunsen burner, and, moreover, can be handled, and, if pressed out of shape, easily reshaped.

* * * * *

This looks as if the future of incandescent gaslighting would be a grand one, for with a platinum base there should be practical indestructibility, and the cost of production is said to be such that they can be sold quite as low, if not lower in price, than the present ones. For lanternists it may lend itself to being supplied with oxygen gas, and thus a greatly improved light obtained for special work. Our old friend the limelight will want a lot of beating for projection work, especially now the "injector" type of jets permits of such powerful light being obtained with the ordinary house gas as supplied at low pressure, and oxygen gas at high pressure from a cylinder. It will be found that the best results are obtained with these jets by leaving the taps of jet fully open, and regulating the supply of gas by means of a fine screw-down valve on the cylinder.

* * * * *

The "New Light" is on all sides the feature of the hour, and the lanternist, if he wishes to be "up to date" must have some slides of the wonderful shadowgraphs produced by the X rays discovered by Professor Röntgen. I noticed the other evening at the Royal Institution the negatives and prints on view in the library, as well as the lantern slides taken from subjects of a similar class to those experimented on by the originator, were the subject of much comment and interest. The results clearly show that there are few things in nature really opaque, and, just as coal, stone, and wood, if the section is thin, can be seen through when placed under the microscope, and ordinary daylight or limelight used, so flesh, leather, wood, vulcanite, and aluminium can be penetrated by these mysterious rays, and, given a certain time and a limit of thickness, an impression can be made on a sensitive plate. As ordinary simple spark apparatus can be used for this work, the numbers of experimenters in this direction will be legion, and the results will be anxiously awaited by the scientific and lay world.

* * * * *

Among the many interesting things in the reprint of the first number of the *Daily News*, published on the occasion of its jubilee on January 21, is an advertisement of the Royal Polytechnic Institution. It runs as follows: "The lectures selected for this period of the year by Dr. Ryan and Professor Bachhoffner in chemistry and natural philosophy will be illustrated by interesting and brilliant experiments. A lecture on the prevalent disease in potatoes will be delivered by Dr. Ryan and also on the atmospheric railway by Professor Bachhoffner, a working model of which, carrying several persons is exhausted daily. The additions to the opaque microscope, dissolving views and chromatrope are very effective. The physioscope" . . . .

To read this after fifty years causes one to reflect, and, in analysing the above, that which stands out prominently, or appeals most strongly to a lanternist, is the part referring to the opaque microscope. How often is a projection microscope shown in public at all now, and especially an opaque microscope! I feel, however, that there is a large percentage of the present generation who would be as much entertained now by a good microscope and popular living and other objects, as their parents were before them in 1846.

* * * * *

Such lectures as have lately been given by Professor Stewart at the Royal Institution will do much to popularise the microscope, and I am glad to see the newspapers are reporting them in an interesting manner, especially the *Daily Graphic*, its heading of "Armour of Flint," and "Jaws in the Stomach," being very *apropos* and catchy, and likely to cause lay readers to take to microscopy.

G. E. R. Baker.

THE LUMIÈRE KINEMATOGRAPH.

[Photo-Gazette.]

We have on several occasions brought chronophotography under the notice of our readers, and have successively described in these pages M. Marey's apparatus for studying objects in motion, M. Demeny's for projecting living scenes, and, more recently, the same inventor's hand camera, bringing chronophotography within the scope of the amateur; and, lastly, Edison's kinetoscope, which is now seen to some extent everywhere.

Messrs. Lumière, the well-known plate-makers, have just made an

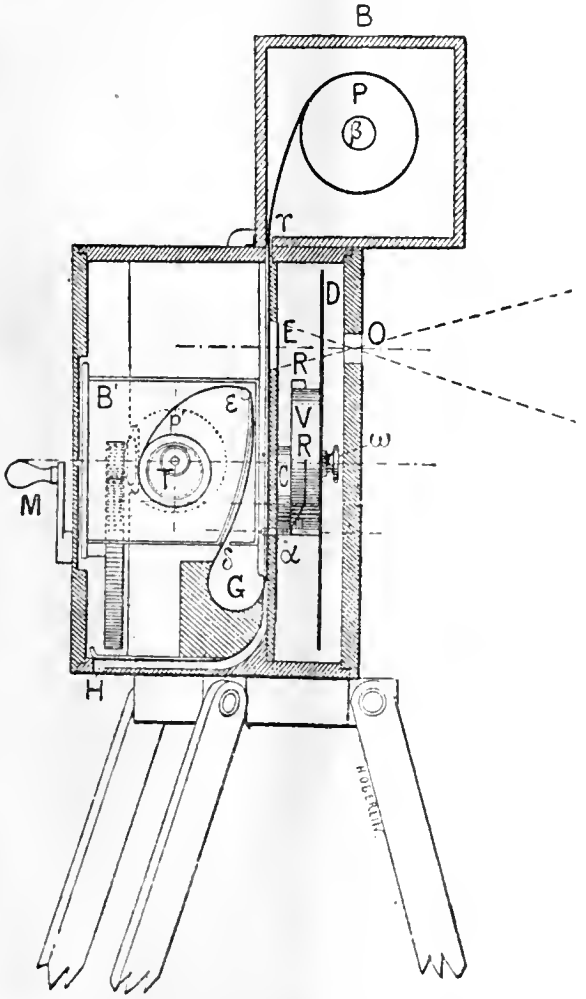


Fig. 1.

instrument founded upon the same principles as these different inventions, but which has the peculiarity of being reversible; that is to say, 600 to 800 exposures may be made upon a band of film, and, after a positive has been made upon another similar band, the scene in motion may be projected upon a screen and exhibited to a large assembly.

During the last few days a series of photographs, thus projected, have been shown in Paris with great success. The first picture is thrown upon the screen for a moment; then, suddenly, the figures begin to move—carriages, a tramcar crossing a large square, &c.; nothing could be more striking, more unexpected than this sudden transition into life of the photographic image.

Our friend, M. L. Oliver, editor of the *Revue Générale des Sciences Pures et Appliquées*, has kindly lent us the drawings, which he has

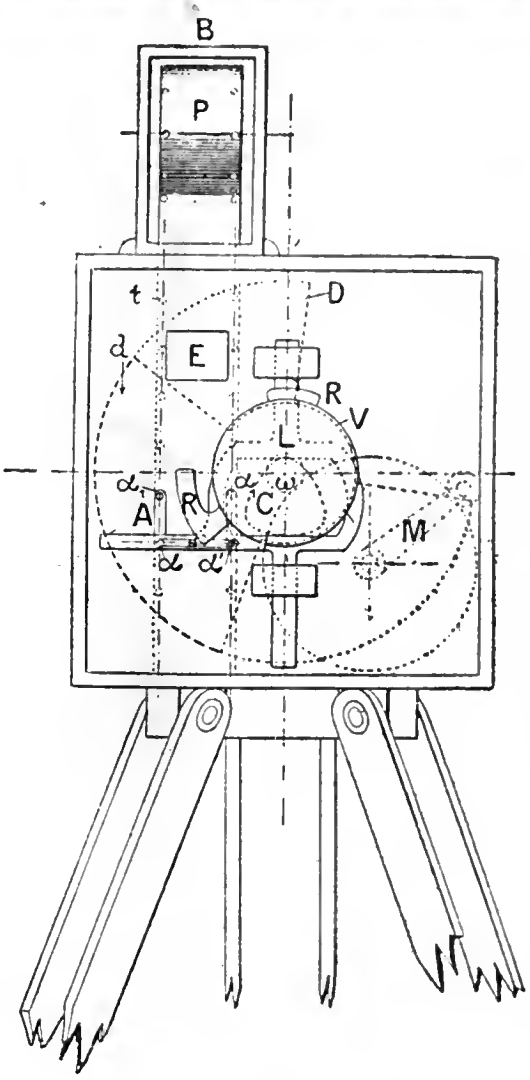

Fig. 2.

had prepared, of the apparatus, and which we shall now use for giving a description in detail.

The band of film follows the same path, whether it be a sensitive band for making a negative or a positive band used for projection; in the latter case the back of the apparatus is removed, and a strong beam of light is thrown upon the band.

Only one description is, therefore, necessary to make both functions of the apparatus understood, either as kinematograph or kinematoscope.

The band of film enclosed in B (figs. 1 and 2) is fifteen metres long and three centimetres wide; it is perforated near both edges with equidistant holes situate at the extremity of each image; the pictures taken at intervals of one-fifteenth of a second are exactly similar, that is to say, if two pictures be superposed, those parts representing stationary objects will exactly coincide, and the parts

representing moving objects will be so situate that they represent the change that has occurred by movement in the interval between the exposures.

This band, P, rolled on a spool (figs. 1 and 2), passes through an opening, *y*, descends vertically, then passes an aperture, E, in front of the lens situated at O; thence it goes into the recess, G, to pass upwards over a small rod, E, to be carried on to a spool, P′, rotating on the axis, T.

The handle, M, turned by hand, rotates the spool by a system of cogs, and at the same time turns the arbor, *w*, of an eccentric, C (shown alone, fig. 3), and imparts a go-and-return movement to the frame, L, vertically.

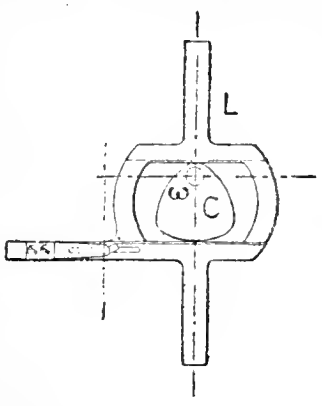

FIG. 3.

From the form of this eccentric it will be seen that a regularly increasing speed is imparted to the frame, and that it decreases in like manner, and that there is a rest at each end of the track. This rest is necessary to allow two small hooks, X and A′, carried by the frame, to pass through, and return from, the holes along the edges of the band. The hooks are attached to the springs, A and C; two inclined planes, R, upon which they slide, remove them from the film when the frame, L, is at the lower extremity of its path, and they allow them to approach and engage with the holes when the frame is up. It follows that the band is drawn along the path of the frame in equal sections, and that it remains stationary whilst the frame returns. The length of the picture is, therefore, exactly that of the path of the frame.

The moment the film is at rest a shutter of a disc, D, also moved by the same handle, presents its open section to the lens and effects the exposure. The light passes in either direction, whether for photographing or for projection. The opening in the disc may be regulated at will to diminish or increase the exposure as may be found necessary. In order that the film may be rolled up continuously on the spool, P′, which receives it, the film at E passes over a rod mounted on a light spring, by which sufficient elasticity is imparted to compensate for the intervals of rest caused by the eccentric. But this arrangement, which is quite indispensable for making exposures, because the film, must then be perfectly guarded from light, may be dispensed with when transparencies are projected. In practice one may dispense with the drum, P′, in the latter case, and allow the film to pass out of the apparatus. The periods of rest are indispensable for exposure in making the negatives in order that the pictures shall be sharp; it is not, however, necessary that the lens be uncovered by the shutter during the whole period of rest, and the aperture in the disc may be regulated and reduced even to a narrow slit. The pauses are none the less necessary for projection, to enable sufficient light to pass. One cannot use too much, and the aperture of the shutter may be opened to its fullest extent. It suffices if the pictures follow each other at intervals of one-tenth of a second; they will then unite and give the idea of movement, owing to the persistence of vision.

SMASHED LANTERN CONDENSERS.

Now that the electric light is being so commonly employed for lantern projection, we may expect to hear of more cracked condensers than of yore. Some lanternists seem to be most unlucky with regard to accidents of this nature, while others enjoy perfect imunity from them. We suspect that care in lighting up, and in avoiding draughts of air after the jets have been turned off, may be the secret of this freedom from breakage. But other precautions may, with advantage, be taken by those who wish to preserve their condensers, one of which consists in having a flannel cushion to place against the glass after use, so that it shall not cool too quickly. We need hardly mention that the glasses should be loose enough to rattle in their cells when cold, and then there is no fear of their breaking by their own expansion when hot. When using the arc light the condensers should be protected by a curved screen, with its concave surface towards the light, for the carbons have a tiresome way of spitting out particles of incandescent matter which, if they do not break the condenser outright, will pitt and roughen its surface.

We may mention, in this connexion, that Mr. Ives, who has devoted much attention to lantern matters, supports the back glass of his condenser at three points only by means of brass catches attached to springs. He lately told us that before he adopted this plan he lost many condensers by breakage, but that since he has used these spring clutches he has been quite free from such vexatious disasters.

COMBINATION PRINTING OF LANTERN SLIDES.

THE combining of two or more views into one lantern slide is an operation but seldom undertaken by amateur workers, and, in fact, is one which is more often passed on to the hands of professional slide-makers than any one else engaged in the ordinary practice of photography, the reason for this being, no doubt, that such an operation requires at least some amount of special experience at this particular work, which entails a fair amount of neat-handedness, combined with a supply of special apparatus, but seldom at the command of those who do not give particular study and attention to this class of work.

Among amateur workers, no doubt, many experienced slide-makers could be found who have never made a combined transparency, nor ever seen the operation performed either. Although at the same time such may have a perfect idea of how such pictures are produced, still, from, very possibly, a want of some piece of apparatus, they never care to undertake the making of combined lantern slides. Others, again, look upon the operation as one of great difficulty, entailing an amount of experience quite beyond the limits of amateur workmanship. In point of fact, however, such is not the case, and, in the remarks which I am about to offer on this subject to the readers of THE BRITISH JOURNAL OF PHOTOGRAPHY I hope to show how easily any one who has experience of making lantern slides by reduction through the camera, may produce combined slides also, provided they give a fair amount of close attention and bestow a little amount of neat-handedness when undertaking this class of work.

To make combined slides from two or more negatives, the first essential is suitable apparatus, but this need not be in any way an elaborate or costly outfit; as a rule, any ordinary copying box, capable of holding varying sizes of negatives *in situ* for the purpose of being reduced or enlarged, will be found amply sufficient for the work, and, no doubt, copying boxes of this description are now in the hands of nearly every amateur who aspires to the honour of being an expert slide-maker. To such, however, as may not have such a box beside them, perhaps a brief description of how any one can make such themselves, at a mere bagatelle in the way of cost, may be of interest.

A very useful size is one that will carry any dimension of negative up to 12 × 10 inches. Let this be a square box with top and bottom knocked out, at one of the open ends, nail strips of wood to act as a groove, so as to permit the largest size of negative, and also carriers, to slide easily into the grooves. A nest of carriers for each of the stock sizes of plates will complete the box, and such is easily produced at home by any one possessed of even the crudest ideas of carpentry.

Having provided a suitable copying box, the next requirement is a good copying board; this is of great service in permitting the camera and box being placed at proper distances from each other when the ever-varying sizes of reductions and enlargements are being registered exactly on the focussing screen of the camera. A very useful size is one of eight feet long by about twelve inches wide, and made in such a manner as not to warp or twist, otherwise the camera and box will not stand flat upon its surface. When such has been provided, at spaces of every six inches or so, rule or scrape across the top of the board lines at exactly the same distance, the same as a foot rule registers inches; this will be found of great service in permitting the camera to be placed square on to the negative in the box, and so prevent any distortion in the pictures.

The next essential is the preparing of the ground glass, or focussing screen of the camera, with a special set of guides for this particular class of work.

The first essential is to find out the exact centre of the dark slide of the camera it is intended to employ in this work. One and the same slide should be always used, and, when this slide is fitted with its carrier for

the lantern size of plate, attention should be given to see that the aperture of this cut out is not too large, but of the exact size to carry the 3¼×3¼, or lantern size of plate, without the same moving in any way when such is placed in the carrier; this is very important, for, upon the sensitive plate always occupying exactly the same position in the camera when the dark slide is inserted, depends the entire success of the operation. Any carrier that permits of the plate moving from one side to another should be discarded as quite unsuitable for the work, and, when such is found, it should immediately be doctored by gluing to its side small pieces of cardboard, until the lantern plate just sits snugly in its place. The springs of the dark slide should be firm enough to keep it from falling backwards, also a precaution necessary to observe when at times the copying board is pointing upwards to the sky.

Having selected a suitable slide, and fitted to the same a good carrier as described, the next step is to find the exact spot on the ground glass of the camera that exactly coincides with the true centre of the cut-out aperture of the carrier in the slide, and, until this has been discovered and truly marked upon the focussing screen, it is no use attempting to register correctly any combination of negatives on one and the same sensitive plate.

There are several methods of finding the exact centre of the sensitive plate when the same is contained in the carrier of the slide, and perhaps the simplest to describe is the following:—Place a sensitive plate in position, and then rule diagonally from top to bottom corners of the plate; where these two lines cross will be the exact centre of the plate, and some means must be found to find and mark the exact spot upon the focussing glass, that coincides with the centre of the plate, when the same is pushed home in the carrier for exposure of the plates. Once found, this is known for all time coming when the same slide and carrier is used; hence the desirability of allotting one slide specially for this work.

To find the exact spot on the ground glase that just coincides with the centre of the carrier, perhaps as sure a method as any to adopt is to rule diagonal lines also on the focussing screen, and then, by exposing a few trial plates, it will soon be found if the spot where the diagonals cross on the focussing screen exactly correspond with the diagonals on the sensitive plate; in practice it will be found that some slight allowance will requlre to be made from these points with most cameras, but, once the true spot is found, it is easy to keep to it for all future time.

From this true centre several circles of varying sizes or diameters should be rnled on the ground glass, commencing with a very small one, and terminating with a larger one the exact size of a cut-out round mask, which it is intended to adopt as the size for mounting and finishing the slide.

These centres will be found of the utmost use when varying sizes of images have to be printed in exact positions on the sensitive plate; in fact, they are indispensable for exact registration.

Having such apparatus at command, the production of combined lantern slides becomes a matter of ease, only requiring the exercise of a due amount of care when registering the various negatives on the ground glass, and the exercise of proper judgment in the exposure of the sensitive plate to the different densities of the negatives that are being used, so as the development of the various exposures will all come along together, and finish in something like the same manner, as regards detail and density.

In most lecture sets a good introductory slide is always appreciated by an audience, and a good start is of the utmost importance with most lecturers. As examples of combination slides and a description of how these introductory transparencies are produced will probably prove of interest to our readers, a detailed description of the method employed in making the same will be appreciated.

Individual taste must always be observed more or less as regards design; but in most instances, when furnishing introductory slides for lecture sets, some of the more interesting or particular view of the sets are generally selected to form the combination slide, with perhaps a bold titling describing the name of the lecture. Surrounding these various selected views, and in the remarks which I am about to offer, it shall be my aim to describe, as plainly as possible, how any one should set about making such a slide.

At the outset any lettering or printing which has to be included in the picture should be first produced on a clean white card; this may represent the name of the lecture, and may assume any shape or form according to taste, provided the design is such as will permit suitable spaces for the printing of the little views that have to be placed alongside such titling or lettering. As a general rule, the extreme edges of the slide carry these titles, the form of which may be either round, square, cushion or other shape according to taste; this will leave the centre clear and suitable for the reception of as many little pictures as may be desired to illustrate the coming lecture.

Let us suppose it is decided to adopt a round shape. In which case, let the operator pay a visit to his nearest ticket writer, and get him to describe a true circle in black ticketing ink on a pure white card; outside this circle get him to print, in good bold characters, the title of the lecture set; this provided, let a good negative from same be made—by a good negative I mean one absolutely opaque as regards the whites and almost clear glass as regards the black lettering. If an operator cannot do this, he should practise black-and-white working until he can. In some cases recourse may be had to absolutely blocking out all but the lettering, so as to provide a negative through which no light will pass on to the sensitive plate on those parts that must be reserved for other negatives. On the production of an absolutely opaque black-and-white negative for this purpose much of the success in results will depend.

Having provided a suitable titling negative, the next step is the selection of the illustrating negatives, and these may be of any size or density; in fact, just ordinary stock negatives may be utilised, provided a copying box, as previously referred to, has been supplied.

In my next I hope to refer to the various manipulations necessary so as to combine these negatives into one and the same slide.

T. N. Armstrong.

THE CAMERA IN NEW ZEALAND.

[Sharland's Trade Journal.]

Among Whales and Whalers.

The stranding of twenty-seven whales at Murewai, on the west coast of Auckland peninsula, just between Waitakerei and Kaipara, brought almost to our doors an unexpected opportunity for securing some great subjects for the camera; as in these dull times the demand for novelties is unabated, here was a splendid chance for adventure.

Although the railway runs along within about ten miles of the coast, the track to the stranded monsters was very rough, with no friendly shelter or food supply on the way. Yet some of the more hardy and determined of our Auckland camera men faced the trouble, and in heavy marching order, with a heavy *pikau* of gear and tucker, bravely attacked that muddy track. Fortunately they found some tents on the beach, and made themselves at home, roughing it with the whalers, who were making the most of the

Flotsam and Jetsam

on the beach.

Several very good negatives were secured of the novel scene. The stranded whales were half buried in the sand, and the work of saving the blubber, boiling down and filling casks with oil, gave life and interest to the pictures.

After the mid-winter season, the whales returning from a cruise in Antarctic waters coast along the shores of New Zealand, often quite close to the land, on their way to warmer seas, and these had probably been driven by bad weather out of their usual course.

On the east coast of the North Island the whales' homeward track has been observed to pass close under Cape Brett, and Messrs. Cook Bros. determined to attempt their capture here by means of nets stretched across the whales' line of progress, and we are pleased to say that the greatest success has crowned this bold and daring enterprise.

Whales Caught in Nets.

This seemed to promise an adventure with results even better than stranded whales as novelties in photography—at least so thought our friend, Mr. Tom Ryan, who, scenting here a rare kind of sport, not unmixed with hard work and no little danger, determined upon putting his aquatic experiences to the test, and, armed with a hand and a whole-plate camera, he made for the scene of action.

It was no good waiting for good boating weather, as the whales did not object to wind or rain; so, after a pretty rough experience of one of our winter storms, he reached the whaling ground, and was welcomed by the whalers with hearty hospitality.

Here is the log of his

First Day's Work,

in which our friend did his full share at the oars, exposed to wet and cold, with little food and no shelter, and on one occasion at least for sixteen hours at a stretch:—

"The first morning at 5 a.m. a terrible noise was heard. I woke up with a start, and thought that a bull fight was on. It was pitch dark, so I looked outside in some trepidation, and heard voices of natives shouting here and there. Knowing the Maori lingo, I soon ascertained it was only

'Charlie,' the cook, blowing the horn to call the boats' crews to breakfast—5 a.m., just fancy what an hour for a mid-winter breakfast! I tumbled up, however, and had breakfast, and then set off to the jetty to ship in the whale boats for the day's work. Our crew were all natives except Bert Cook and myself, and our boat was pretty full, for the nets were on board coiled up in a huge bundle fore and aft. We had three sections of net on board, with numerous twenty-gallon kegs for buoys. The sea was beautifully calm, and we rowed along swiftly under the frowning masses of cliff, which is characteristic of this wild part of coast. We arrived off a large rocky reef, and then proceeded to set the nets, which, by the way, are no small things. There are five sections, ten fathoms square in each section, which gives altogether a total length of 1000 fathoms of whale line. The mesh is a six feet square one, and, when one comes to weigh up the line and various appendages, it is no wonder the whale boats float very deeply.

"Setting the Nets.

"The mode of setting the net is thus:—A stout fixed line is made fast to the rocks, and it is then carried sixty fathoms, out to sea, where it is fastened to a large buoy moored to a half-ton mooring. The boats pick up this strong line, and then proceed to tie the net to it by means of stops, and pay it out. These sections are now temporarily lashed together with a piece of rope yarn, so that when a whale get meshed, he breaks away the section which has caught him from the other sections, leaving them intact. All the net being paid out, an inspection is made as far as possible to see if the net is hanging all clear and not tangled. An adjournment is then made shorewards to get a landing on the cliffs, which is managed with a bit of manœuvring, as the heavy ocean roll always makes a nasty surf here.

"Whilst we are having 'tucker' one of the Maoris cries out 'Blow!' and we are all in a buzz of excitement, as two whales are seen approaching not half a mile away. The boats are manned as rapidly as possible. The whales still keep on their course, heading well inside the net. If they keep on the same course, the capture of one is a certainty, so the line is bent on to the harpoon, and the boat steerers in both boats are standing up ready as the whales approach the nets, heading right into them. We now are filled with excitement, every eye being on the buoys.

"A Double Catch.

"The next minute two of them disappear below the surface of the water, then two more follow amidst a cheer from both boats' crews. 'Dubs?' exclaims Bert Cook, meaning that two whales were meshed. We now strain every muscle on the oars to pull up the whales, who are now lashing the sea all round into a fury of foam. The other boat singles out one and chases it, whilst we chase the other. A sharp spurt of half a mile brings us up to our whale, who is lashing out with his flukes in all directions. Under the skilful heading of Bert Cook we range up near the whale, getting smothered with spray through his kicking. 'Stand up, Warren!' shouts Bert to the native boat steerer in the bow, and our man is ready in an instant. 'Now, then, strike!' rings the cry again from Bert; then our boat steerer, a strong, athletic man, sends the harpoon deep into the side of the whale, who marks his disapproval by a most determined lashing of his flukes.

"'Come aft, Warren!' shouts Bert to the native, who, quick as a cat, hops from thwart to thwart and takes the steer oar from Bert, who now rushes forward to where the lances are kept.

"We 'peak' oars, and the whale sounding, the line runs out of the tub at an alarming rate round the loggerhead with an unmistakable smell of something burning. It is caused by the friction of the line round the loggerhead, so a bucket of water is thrown over the line to cool it. Down, down, he goes, 20, 25, and then 30 and 35 fathoms line out, when it eases up a bit.

"'He's coming up,' shouts Bert. 'Haul on the line,' is the order; so we start hauling on something different to a schnapper or hapuka.

"Now we commence to travel quicker, for the whale is rising rapidly, We haul every man for all he is worth, when up comes the whale about thirty yards ahead. We haul our hardest so as to be up close to him next rising, which we do. We get pretty close, when Bert, who has now the deadly lance unsheathed, standing erect, delivers a blow into the whale's side. The lance sinks deep into the flesh and out pours blood. The lance, being hauled out by means of the warp attached, is thrust in again and again, each thrust being the signal for renewed furious lashing of the flukes till he goes down. He now starts running, as the lance wounds have pricked him up a bit.

"Sixteen Miles an Hour.

"We hang on with the line round the logger, and away we go in tow of the whale, travelling about sixteen miles an hour, a great wave of spray being thrown out from each side of the boat, wetting us through. The truth of my friend's words as to the spice of danger was now dawning upon me. I had time to recover from the first burst of excitement, and here we were, fast behind a whale, travelling goodness knows where. On looking round we were well off the coast. We just could make out the other boat, still fighting their whale, all safe. Up comes our chap again, and we once more 'haul line.' We get up close to him again, and once more the deadly lance is at work, two more thrusts, and up shoots a column of deep red blood from the nostril of the whale. An expression of delight bursts from our crew, for a whale spouting with blood is an indication that he is mortally wounded by the lance. He seems now thoroughly flurried in his actions, and the succeeding lance thrusts make the huge carcase twitch and tremble from end to end. The whale shows no desire for 'further sounding,' preferring to remain just below the surface of the water.

"Death of the Whale.

"As he is spouting blood and not travelling, it is no use mincing his body with any more lance thrusts, so we have just to wait and see him die, which sometimes is a very slow process. We waited about half an hour, the whale just bobbing up and down, when all at once he makes a furious kick, and, raising his head clean out of water, rushes shorewards at an alarming rate for about half a mile, when he suddenly stops and lies quiet for a while. A few more small spasmodic kicks, and then the drama of the sea is finished as far as his whaleship is concerned. He turns over on his side with a fin partly out of water and dies, lying motionless just awash with the water. We haul up on the line right alongside and immediately cut the net away. It is an awful tangle round the body. After a good deal of labour we get it into the boat, and then we find the buoys are completely stove in, either with the great pressure below the water or through getting kicked by the whale.

"The next thing is to fasten a tow line, which is made fast to the two jaws, which are drawn together so as to prevent the mouth opening. Everything being ready, we start towing, which is slow work with one boat; but the other boat, having killed their whale close in shore, anchor it there and comes to our assistance. It is a good long way to the harbour, but, both crews being willing, we make rapid progress, eventually landing the whale at the wharf after a good tow of nearly six hours. On the way in we were followed by numbers of 'gonies,' 'stinkpots,' seagulls, and other birds, all intent on having a good feed off the blubber of the whale.

"Once on shore again, we are around the tea table in no time, with a very, very good appetite after the hard day's work. It was nine o'clock when we arrived at the wharf, sixteen hours in the boat with a little lunch and plenty of hard graft. Think of that, ye eight hours a day men! We were one and all soon asleep, only to be roused at 5 a.m. again by Charley's confounded horn-blowing for breakfast."

But the narrative as given in detail, with illustrations reproduced from the photographs, in the *N.Z. Graphic*, does not tell of the dangers of landing from a whale-boat on a slippery ledge of rock washed by the surging Pacific; of the perils to operator and apparatus, as riding in on the crest of one wave he leaps ashore, and with scarce a foothold scrambles up the wet and slippery steep. Then the boat draws away and comes in again on another wave, when the tripod is thrown up on to the rock. Next time the camera in its travelling case is thrown up—

A Good Catch!

in which our friend's experience as a football athlete comes in opportunely. Next, the package of dark slides is as well caught, and, as a whale is already in sight, it becomes very trying to one's nerves to fix up and get ready for a shot. Just when all is ready, drawing the slide shifts the legs and disarranges the focus, and there is no finder on the camera. To do it all over again in haste and steadily is very trying to one's patience, but, as our artist is nothing if not calm, he has everything soon fixed again, as in a moment of intense excitement off goes the shutter, just as the whale charges and takes the net away with him; again reverse the slide to get him as he comes up. Then "Hurry up, my lad, into the boat and after him." To get that camera packed again in less than a wink, and all snug on board before you could say Jack Robinson," without leaving even a stop behind, is itself a feat worthy of renown, but it had to be done, or our photographer would have been left on that rock till the boat's return.

Presently he gets a snap-shot with the hand camera, as the monster, lashing his enormous tail with terrible fury, dashes into the air its encumbering mass of cordage, floats, etc. Then again another shot just as the harpoon is thrown, and several other instances are snapped at, but just as a whale makes a clean breach out of water—like a mullet at play—the shutter sticks, and this, the only chance, is lost. Fortunately Mr. Ryan's artistic genius was equal to the occasion, and he easily made good

the deficiencies of the camera, and was also successful in getting many valuable negatives of the various subsequent operations. If any of our young enthusiasts wish for a week of rare sport, hard fare, long hours, plenty of real hard work, and the finest trial of patience, tact, and temper, we would recommend them to follow Mr. Ryan's example, only don't be afraid of getting wet, and be sure that your apparatus is waterproof; also be not disappointed if under the circumstances none of your negatives are perfect, and none of your pictures of any great commercial value. JOSIAH MARTIN.

THE ILLUSTRATED LECTURE.

[The Exhibitor.]

THE illustrated lecture has assumed a unique position in the entertainment world. With few exceptions, lectures illustrated by means of the stereopticon are more popular and draw larger audiences than those where this adjunct is not employed.

Pictures are an attraction to old and young and a description can be made much more satisfactory if accompanied by a view of the place or thing described. A double advantage is secured, as both eye and ear are addressed at the same time.

The use of the projecting lantern for the purpose of illustration has grown to large proportions within a few years, and is still increasing. In view of this fact, it may not be out of place to offer a few suggestions which may have some influence on those who contemplate entering upon this pleasant, and, if properly managed, profitable phase of public work.

In the first place, a matter of exceeding importance is the choice of a subject; and this, if possible, should have a catchy title, the quicker to arrest attention. Occasionally there are topics like the Columbian Exposition, the disaster at Johnstown, and those of a kindred nature, upon which popular attention is concentrated for a comparatively brief time, but these must be taken advantage of while the public enthusiasm maintains, and cannot be depended upon for more than a limited period. Those of more general interest, and which are applicable at any time, are the more desirable.

The subject having been selected, it is of much consequence that the matter be prepared with care, and that the most striking points be described in choice and appropriate language. Too much stress cannot be laid upon this essential feature, for the way in which this is done goes far towards inducing success or failure. A good plan is to write out the entire lecture from the best available sources, and then commit it to memory. If the lecturer have a fluency of speech which enables him to talk readily from notes, he is consequently fortunate; but comparatively few, even of so-called good speakers, possess this talent to any marked degree, but it is a good one to cultivate by any one who has the good fortune to be so gifted. The written lecture, however, possesses this advantage, that it enables the speaker and operator to work more in unison, and thereby acquire a smoothness and accuracy not otherwise so readily attained.

Another essential which cannot be too strongly emphasised is that none other than the best slides be employed. It is a matter of surprise that so many lecturers are satisfied with inferior productions, and many an otherwise interesting and effective lecture has been hampered by the miserable apologies for pictures used for the purpose of illustration. True, it is sometimes impossible to get just the view one wants, or as good as is desirable, but that can occur only in a very limited number of instances, and, with the present admirable facilities for making slides, very beautiful transparencies, which are attractive because of their intrinsic merit, can readily be procured. By all means get good slides.

Another important consideration is the lantern. A poor instrument is literally worse than none, for no satisfaction can be assured to either lecturer or audience if the apparatus be of an inferior grade. The cost of a good instrument is so little in advance of a poor one that there is no excuse for selecting the latter, and the applicant for popular favour will sooner acquire recognition if he have the proper utensils with which to do his work.

But, if it is necessary to have a good lantern, it is equally important to employ a first-class operator. Many an otherwise meritorious effort has been spoiled by the antics of a lantern manipulator who did not know enough to properly manage his light, to rightly adjust his lenses, or to even put his pictures in proper position. It is not so difficult a matter to operate a lantern that one cannot, by proper practice and attention, learn to do it well, and an audience should not be subjected to annoyance and injustice when the matter could so readily be obviated. See to it that you have an efficient operator.

The personality of the lecturer occupies a foremost place. There are certain requirements which he should unquestionably possess, and one of these is a properly trained voice. This effects not only its carrying quality but those other essentials of which the voice is so fully competent. It should be able not only to sustain itself for a long period, say, an hour or more, but should maintain its flexibility, so that tone and colour can be given to expression. There are speakers who start well enough, but soon show signs of weariness, which manifest themselves in disagreeable monotones and husky utterances that quickly tire their hearers.

The writer recalls two instances which serve as illustrations by way of contrast. In the first the speaker was hampered by an imperfect manner and an indifferent voice, although the subject-matter was most excellent. In the other, the lecturer who spoke for nearly an hour and a half, showed so little the effect of the exertion that he was congratulated upon his success by quite a number of his audience, who seemed to think the speaker possessed a remarkable gift. In explanation, the lecturer, whose physical proportions were by no means robust, stated that he had spent both time and money to acquire the skill he had evidenced, and that it was his teachers who were to be commended, whose methods had demonstrated their correctness and value. The voice is susceptible of such manifold variety that art can accomplish much under a skilful trainer even where nature has not been lavish with her gifts.

Dignity on the part of a public speaker is a desirable accompaniment. Ease of manner soon exerts an influence upon the audience and puts the listener in a more receptive mood. What is termed personal magnetism, that quality which places a speaker *en rapport* with his audience, goes far towards establishing a mutual sympathy that renders each attractive to the other. It is this power which gives the natural orator a decided prominence over his less gifted fellow. It is susceptible of development, however, and by proper cultivation can be enlarged and strengthened until it possesses some measure of force.

To the veteran in the lecture field these suggestions may possibly seem trite, but to the tyro they may be of service in helping him, in the outset of his career, to surmount difficulties which might otherwise be met only by annoying experiences. R. J. H.

CHADWICK'S PORTABLE OXYGEN GENERATOR.

W. I. CHADWICK, 2, ST. MARY'S-STREET, MANCHESTER.

THIS oxygen generator consists of a safety valve retort, in which small charges of chlorate of potash and manganese are heated by a Bunsen's burner. The oxygen is conveyed by a ⅜ rubber tube from the top of the generator to the floating bell of a portable gas-holder, and from this direct to the lime light jet. As the oxygen is used, the bell of the gas-holder sinks in the water, which is used as a luting. The generator is then to be recharged, and thus a continuous supply of oxygen can be maintained.

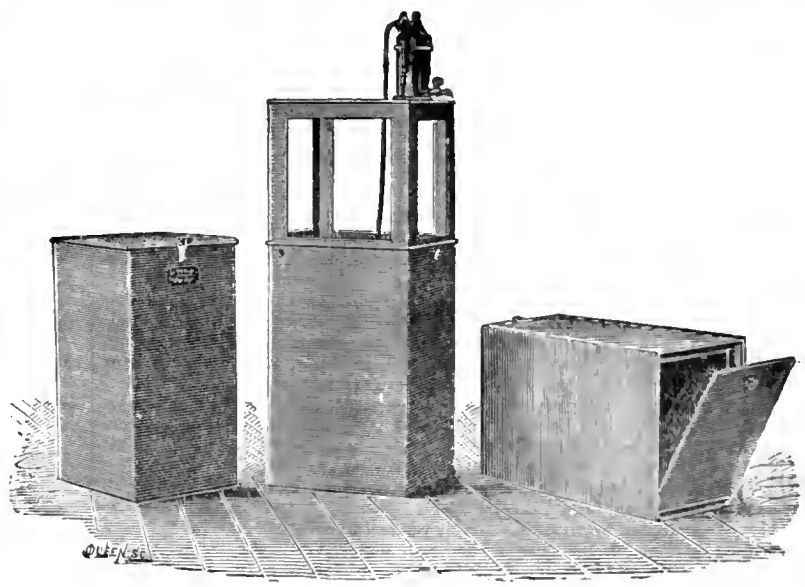

FIG. 1. FIG. 2. FIG. 3.

The general principles of the generator can be seen from fig. 4. It consists of a flat plate and a bell-shaped cap. These are turned and ground together, forming a gas-tight joint, and supported by a stand, in which is the Bunsen's burner. On the top of the cap is a bent tube, by which the oxygen is conveyed to the gas-holder, the fastening being effected by a bow, shown in the illustration, with a wooden handle on the top, and at the lower extremities are spiral springs, adjusted to maintain a pressure equal to 1½ lbs. per square inch, or, in other words, weighted to about 12 lbs. dead weight.

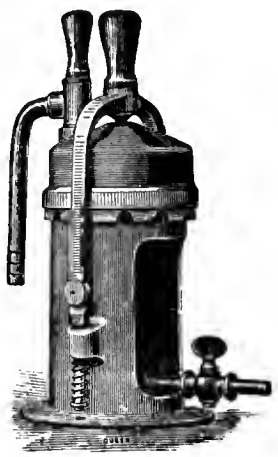

FIG. 4.

To charge the generator it is necessary to pull over the bow by the wooden handle, remove the cap by the other wooden handle, place a charge on the bottom of the generator, replace the cap, and push up the bow.

The gas-holder is made of metal, japanned inside and out. It is telescopic, for convenience and portability in travelling When closed, as in fig. 1, it measures 24 × 16 × 12 inches.

The following are the instructions for use:—To set up for work, draw out the upper part, as in fig. 2, and secure by three small brass bolts and wing nuts, place the generator on the top, as shown in the illustration, remove the screw cap on the top of the bell of gas-holder, and pour water from a bucket until the outside is full up to the top of the bell. The water is to make the luting, and for the bell to float when full of oxygen. By this time all the air has been expelled. Next replace the screw cap and connect the rubber tube from the generator to the bent metal tube of gas-holder, and by another rubber tube connect the tap on the top of the gas-holder direct with the lantern jet. Now fill the reservoir on top of the bell with water, to, say, 4 in. or 5 in. high (this is to apply the pressure). Charge the generator as described, light the burner, and in a very few minutes the oxygen will be generated, and in its passage through the water of the gas-holder it will be well washed and purified. The lantern may now be lighted, and, as the gas is used, the generator can be recharged as described, thus a continuous supply can be maintained.

The charges are made as follows:—To four parts of chlorate of potash and one part of manganese add sufficient water to moisten—not to make too wet. This should be mixed in something like a clean earthenware dish or basin, then fill the mould supplied with the generator, using a little pressure. Smooth off the surplus with an old table knife or spatula—do not use a piece of stick or wood for mixing or smoothing off. On turning the mould over, the cakes will leave entire. They must then be set to dry either spontaneously or by gentle heat, and when dry the bottoms of the charges are to be coated by dipping into a mixture of manganese and water, made to the consistency of cream, and after final drying they may be used at once, or stored away for use at any future time. The coating of plain manganese at the bottom of the charges is simply to prevent the spent charges sticking to the bottom of the generator.

EXPLOSION OF AN ETHER SATURATOR.

MR. W. HOWARD STABLES writes to the *Derby Express:* "The worst of having a slight mishap with a lantern is that the general public, being somewhat in the dark as to the apparatus used, is likely to feel an alarm which in many cases is quite unnecessary, and to imagine that, if the worst did not happen, it was due rather to chance than to the fact that with the apparatus in use at the moment no serious accident was possible. I was using on Wednesday last a cylinder of oxygen, an ether saturator, and a mixed gas jet, when early in the exhibition the light failed, and nearly went out, and, as I was endeavouring to adjust the taps of the jet so as to give a better light, one cylinder of the ether saturator blew up. As this apparatus is made of thin brass, such an explosion could hardly be attended with serious danger, as the thing simply was ripped open, and no portions of it were scattered. The worst that could have happened would have been that the operator and possibly one or two near him might have been burnt, perhaps severely. The Ilkeston disaster, to which the public naturally turn their mind on a seeming recurrence of this kind of accident, was occasioned by a totally different cause—one which, after that experience, no sane person would run the risk of incurring, There the supply of gases was contained in the old-fashioned leather bag—oxygen in one, hydrogen in the other. But, unfortunately, the half-filled oxygen bag had been filled up with hydrogen by mistake, and the result was a most deadly explosive mixture. That mistake can never occur with cylinders, as the oxygen cylinder is screwed on to the supply tap by a screw which turns the opposite way to the hydrogen screw. Thus the wrong cylinder simply will not go on the wrong supply tap. Your readers will see, therefore, that no such risk was run on Wednesday last, and to parallel my mishap with the Ilkeston disaster is to needlessly alarm the public. At the same time, I must confess that I am still in the dark as to the cause of my accident, and that such of my friends as understand the working of the lantern and have offered me explanations of the accident have indicated causes that might recur almost every time the saturator is used. I am in correspondence with the makers, and hope to get at the bottom of the matter in a day or so. I cannot close my letter without referring to the splendid behaviour of the company at the accident. A few women, who were too far off to see what had happened, were alarmed and screamed; but as, thanks to the electric light, which was promptly turned on, it was at once clear that no cause for alarm existed, and that no one was hurt—the company sang the National Anthem and quietly dispersed. Let me, in conclusion, offer the following advice to that section of the public who frequent lantern exhibitions:—

"1. If you see the ominous bellows-like form of the old-fashioned gas bags—*Flee ! !* It is never safe to use them; they are dangerous to all in the room.

"2. The ether saturator is risky to the operator and those near him

"3. Two cylinders, or one cylinder and common gas, is safe. Any accident from cylinders will occur before the lecture begins. The safest time is when the exhibition is going on and the gas is being released."

Apropos the foregoing Mr. E. C. Green writes us: "I was present at the exhibition and the behaviour of the crowd was beyond all praise, as the explosion was certainly very alarming.

"At the moment of explosion the operator was altering the pressure at the outlet of the oxygen cylinder. No regulator was used. The saturator had been charged with ether before the performance, sp. gr. ·720."

A DISCOMFITED SHOWMAN.—An applicant for popular favour secured one of the largest and best known halls in Philadelphia for a lantern exhibition, says *The Exhibitor*, and issued free tickets to those whom he thought might be impressed by his venture, hoping thereby to secure engagements. The views embraced a variety of scenes taken from the Old and New Testaments. When the entertainment was about to begin the exhibitor discovered that his pianist was not there, so another was secured from among the audience, suggested by some one to whom the lecturer had mentioned his dilemma. Hastily giving directions to the player to adapt himself, as far as possible to the illustration, the show began, and went on to the apparent satisfaction of the audience, until a very striking picture of the wise men journeying to Jerusalem was shown. The performer had, in the meanwhile, nearly exhausted his stock of pieces, some of which were a little incongruous; but the climax was reached when, as an accompaniment to the picture mentioned, he suddenly and vehemently pounded out *When Johnnie comes marching home.* The effect was pronounced. The audience began keeping time with their feet, but, in a moment more, broke out into loud laughter which swelled into a perfect howl. The demoralisation was so great that the manager's prospects were utterly ruined, and but one other of his exhibitions was given in the city, and the engagement for this was made in advance of the free entertainment.

A PHOTOMETRIC STANDARD WITH ACETYLENE.—Acetylene, in the author's model, issues from a small conical orifice carrying with it the necessary quantity of air. It then penetrates, by a narrow aperture, into a tube where the mixture is effected, and which terminates with a bat's-wing burner made of steatite. The entire flame corresponds to more than 100 candles under the pressure of 0·30 metre of water. The consumption of ethylene is 58 litres per hour. We see that the illuminating power of acetylene is more than twenty times that of coal-gas burning in a Bengel burner (giving 1 carcel = 9·6 candles for 105 litres), and at least 6 times that of the same coal gas for an Auer burner (giving 1 carcel for 30 litres).—J. VIOLLE in *Comptes Rendus.*

THE lantern-slide catalogue of Mr. A. H. Saunders, of Heath-street, Birmingham, for the current season, is to hand. Many popular sets are particularised.

WE have received the lantern-slide catalogue of Mr. T. T. Wing, Chatteris, Cambridgeshire. Mr. Wing makes a speciality of colouring lantern slides, and also supplies lanterns and their accessories.

A PHOTOGRAPHIC "NEW WOMAN."—Mrs. Mary Winslow is travelling through Western New York with a portable photograph gallery taking pictures, and doing it well. She is modest and unassuming, but carries a couple of revolvers for the "Rubes" who get too fresh. She makes no claims to "newness," tends strictly to business, and has more than she can do.—*American Journal of Photography.*

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*March* 6, 1896.

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

The projection of animated panoramas and lifelike motions of everyday life is now an accomplished fact, and, although several earnest workers have been experimenting for some time past in this direction, the honour at the time of writing of being the first to make in England a demonstration that approaches closely to perfection must be awarded to MM. Auguste and Louis Lumière, who have been, through their agent, exhibiting during the week in the Marlborough Room, Polytechnic, their apparatus, which is called Lumière's Cinematograph.

* * * * *

I say at present advisedly, for I learnt, only recently, that Mr. Birt Acres was to give a public exhibition of the results of his apparatus and methods of working in this direction on Monday, March 2, and, if the report I have received privately is confirmed, the results should be very good, in fact run the French instrument very close. Both, however, are thought to give better results than the apparatus exhibited at the Royal Institution on Friday; but then, on the other hand, the limited space and nearness of the audience, no doubt, made the vibration and noise of the Theatrograph more apparent.

* * * * *

To return to the Cinematograph, which, I am informed, will not be for sale for twelve months, and then will cost 60*l.* to 80*l.* complete, but will be worked under concessions in the various capitals of Europe with a view to money-making by charge for admission while it is a novelty. That there is money in the invention seems to be apparent from the fact that one financier offered one million francs for it. It certainly, in my opinion, wants a lot of resolution, backed up with confidence, to refuse 40,000*l.*; but, as during a few weeks in Paris, where the apparatus has been on show every half-hour during the latter part of the day to crowded houses, many thousand pounds' profit have already been made, the sanguineness of MM. Lumière may turn out to be justified.

* * * * *

The audience at Marlborough Hall or Room only see the results of the projection, for the apparatus is placed in a gallery and carefully concealed by curtains. I am, however, indebted to Mons. Trewey, who is the *concessionaire* for England, for certain particulars respecting the apparatus. Optically, it is an ordinary magic lantern supplied with an electric light, the regulator for same having 12 mm. carbons, and using 15 ampères of current. Each subject or picture, of which at present there are ten shown at each *séance*, consisting of 900 to 1000 exposures, and the film on which they are produced is fifteen yards long. The latter is propelled through the lantern front by hand motion, it having been found that more care could be taken of the films in that way than if electricity were employed.

* * * * *

And now for the subjects. Imagine yourself sitting in a nice-sized hall, and a small screen five or six feet square, or rather oblong, with a dark border, hanging in front of you, well above your head and level with the gallery, when presently, after a little introduction, a picture appears on the screen, at the same time as the electric lights are turned out in the hall. What is it? Well, we will take a typical one; and, as it is photographic in more senses than one, it shall have precedence. It is a steamboat pier, and there is a gangway in the mid distance. A little whirr is heard in the gallery above our heads, and the picture on the screen is all animation. Some one is walking up the gangway carrying a camera, and he is followed in quick succession by a hundred or so of others. Some turn to the left at the end of the gangway, and others to the right; every third or fourth person raises his hat, as if he recognised some one the audience cannot see; but, when two or three run across the intervening space, one concludes they wish to be quickly out of the field of view of the camera, and that the salutations are for M. Lumière, who is photographing this wonderful scene. It was stated that the gentlemen coming from the boat were those attending the Photographic Convention at Lyons (I think). Certainly the marvellous detail, even to the puffs of smoke from the cigarette, spoke volumes for the perfection of the apparatus employed.

* * * * *

The subjects are considerably varied, the first being a domestic scene, *The Family Tea Table*, in fact with father and mother and the little baby seated at the table; the child is in turn fed, and the lady sips her tea or coffee, and every movement is gone through with all the exactness of life. *The Railway Station* again forms another scene. The station is at first apparently empty when the train is seen approaching, and gradually gets nearer and larger until the engine passes where we are apparently standing, and the train stops, the guard comes along the platform, passengers get out and in, and all is *real*. *The Forge* again gives an opportunity of shewing that the apparatus can faithfully reproduce delicate objects, for, when the hot iron is plunged into the barrel of water, the steam rises in a most natural manner.

* * * * *

The scene outside a café of three gentlemen playing cards, and the waiter bringing in refreshments, drawing the corks pouring out the contents of the bottle, and each of the three toasting the other during an interval in the game, was rather "mouth-watering," and the hilarity of the garçon at the results of the game seemed almost bound to produce laughter among the audience. The photographic

reproduction of Monsieur Trewey's wonderful girations of a strip of long calico whipped round and round must be seen to be realised, for it baffles description.

* * * * *

THE same may be said of the *Street in Paris*, and, finally, the *pièce de resistance*, viz., *Sea Bathing in the Mediterranean*, for here we have the breaking waves on a shingly shore, a diving or jumping board, and the bathers in succession going down this board, jumping into the sea, battling with the breakers, climbing the rocks, and getting once more on the diving board, all so faithfully to life that one "longed to be there."

* * * * *

WHAT Edison has done with the kinetoscope for visual observation, MM. Lumière have done for projection, and if, as I was informed when I first saw the kinetoscope on its introduction to London, that they had already completed an apparatus of the same kind for projection, it is a great pity for Mr. Edison and the Kinetoscope Company's sake they delayed the introduction so long. The idea was to keep it in reserve until the novelty of the ordinary kinetoscope had worn off, but the moral to be drawn from the facts is, "Don't delay;" for over and over again it must have been realised by workers, that others, finding a want to be supplied, had introduced the *very thing* that they themselves had done, and been obliged, from force of circumstances or want of time, to put aside for a more favourable opportunity to make it known.

* * * * *

TALKING of kinetoscopes, I recently saw a circular giving particulars of a resolution, on the part of the Company running them, to supply a more popular-priced instrument, in fact, instead of a machine costing 65*l.*, they had, by making up larger numbers of each part of the instrument, been able to produce them so that they could be sold for about one-fourth of that sum. The next thing is to design, manufacture, and introduce an apparatus to produce the subject for both the kinetoscope and the Lumière Cinematograph cheaply.

* * * * *

MY advice to all lanternists is this, Take the first opportunity of going to the Marlborough Hall, to see the "living photographs" I have described, and country readers up for the day should time themselves to be in Regent-street (Oxford-street end) five or ten minutes before any of the hours between two and ten p.m. As this may sound something like an advertisement, I may add I have no interest whatever in this invention, but simply a desire to inform the lantern world of a novelty they ought not to miss, and to set manufacturers thinking, so that they can produce apparatus to give as good, if not better, results; for the lantern industry, without doubt, wants "waking up."

* * * * *

THE last news I had of the Home Office report on the gas-cylinder question was that it had been passed for the press, and would probably be a fortnight before it was ready for issue; it is therefore necessary to exercise a little more of the patience we have been reserving during the dull lantern season. I was very pleased to see the Editor exposing the foolishness of the lay press in speaking of the chemical experiments and explosion of a vessel as a gas-cylinder explosion in Holborn. It had not any more to do with oxygen gas than if one took a saucepan, filled it with water, then hermetically sealed the lid down, and put it on the fire and left it there until the steam could not be confined any longer, and so burst the pot to escape.

G. R. BAKER.

THE SEARCH LIGHT.

MY knowledge of Japan has been chiefly derived from books—and Gilbert and Sullivan's charming opera, *The Mikado*, but, unlike most of my fellow-countrymen similarly placed, I have had the further advantage of hearing from the lips of that eminent traveller, Mr. Drage, the Honorary Secretary of the Photographic Convention of the United Kingdom, a great deal on the subject of the England of the East, in which delightful country he not long since toured—and took photographs. So, primed with an extensive stock of first-hand Japanese information obtained from a reliable and graphic *raconteur*, which we all know friend Drage to be, my readers will easily understand with what lightness of heart and confidence of success it was that I undertook, in the cause of philanthropy, to deliver, a few months ago, a lantern lecture on Japan and the Japanese.

* * * * *

MY experiences on that eventful occasion were mixed, that is, entertaining and instructive in about equal proportions. The preliminaries of this particular lecture were mapped out with mathematical exactitude. My friend (a man of some eminence in the lantern world) undertook to officiate at the jet. Two-hundred-and-fifty slides, and sufficient reading matter about Japan and the Japanese to fill a large book were handed to me to arrange in proper order, and it was agreed between my friend and myself that I should call upon him early in the evening of the eventful night, dine with him and a gentleman under whose auspices the lecture was to be delivered by the eminent authority on Japanesia whose name (in large letters) footed, I was told, a bill that was to be circulated by thousands.

* * * * *

FOR two or three days before the lecture I was absent from town, and on my arrival home I found awaiting me a letter from my friend, asking me to meet him about two hours earlier than the time previously agreed upon. All my efforts to comply with his request only resulted in my reaching his establishment exactly at the hour originally fixed. I was met by the reproachful statement that Mr. X could not wait any longer, and that he had gone off to deliver the lecture without me. "But *there*," I excitedly rejoined, pointing to a box of slides and a parcel of MS. notes which I deposited before my puzzled informant—"there *is* the lecture! He can't give it without me; he has never addressed a public audience in his life; he's got to work the lantern; he hasn't any slides with him; h—— but stop, *where's* the lecture to be given?" In the hurry of making the appointment, I had forgotten to take the address of the lecture hall, and all I knew of its whereabouts was that it was somewhere—*somewhere*—on the south side of the Thames!

* * * * *

"WHERE, sir!" came the marrow-freezing reply. "*I* don't know, I'm sure; but perhaps they know at the other office. I'll telephone and ask." "Bless you for that happy inspiration," I murmured. Of *course* they'll know. Why need I have allowed myself to break out into that cold perspiration of fear? Why conjure up mocking visions of three or four-hundred expectant hungerers after Japanese knowledge frigidly receiving the statements that the individual who was billed (in large letters) to address them had not put in an appearance, that the slides and lecture were with him, and that their money would in all probability be returned to them? Why torture myself with contemplating the withering disgust of the wealthy Chairman, at whose dinner table I was to have sat; and, above all, the rage and mortification of my friend the lanternist, who, if he hunted up any slides of Japan, would be powerless to describe them, and, if he failed to find any, would be reduced to the terrible humiliation of throwing himself on the tender mercies of a disappointed audience? Why, I reflected, as I wiped my clammy brow, why bother about all this when they're sure to know at the other office where the lecture is to take place? There is plenty of time. I can follow at once, and—all will be well.

* * * * *

THEN the telephone bell stopped ringing, and—— They *didn't* know where the lecture was to be! Mr. X. had left in great excitement a quarter of an hour before. He had sent four telegrams after me. They were very sorry, they knew nothing about it. . . . Then a cold silence filled the room in which I stood; my companion looked at me with undisguised pity, and I gave myself up to mute, helpless despair. So I stood for several minutes, numbed and deaf, with the scene before me shrouded in a semi-opaque film. And then—the door was suddenly burst open, and, hatless, breathless, panting, and gasping, my friend, a fat man, rushed in from his other office, and sank into a chair, jerking out with difficulty the heartfelt ejacula-

tions, "Thank God I came back! thank God I've found you!" and then, when his excitement had partly subsided, and my own usual smile had returned, "You villain! you did this on purpose!"

* * * * *

In ten minutes we were in the train, bound for our destination. In vain I explained to my friend that our original appointment was for six o'clock, that I returned to town at five o'clock to find that in my absence he had altered it to four, and that *I* was not the man who would be likely to forget the hour at which I was expected at a millionaire's table. No; he would not be comforted. In the intervals of mopping his face and getting back his breath, he accused me of plotting his discomfiture, vowed he would never again "be had," said I ought to be ashamed of myself for sacrificing a magnificent dinner for a practical joke, doubted if we should get to the hall before the people got in, knew very well that the lantern and screen would have to be rigged up in full sight of the audience (a thing he abominated), and was *sure* that, now he had found *me*, the other villain (Smith, his man) would take the lantern and screen to the wrong place, after all! Misfortunes never came singly. Something *told* him things would go wrong. I ought to be ashamed of myself to treat an old friend like that. . . . Gentle reader, pity me, who, having to stand about twenty minutes of this sort of thing, was also conscious of a certain emptiness of stomach, which reminded me that the appetite I had specially prepared for a *recherché* dinner was thrown away.

* * * * *

Well, we reached the hall at last—that is at half-past seven, the time at which the doors were announced to open; Mr. Smith, of course, had preceded us. A surging mob of youths and children had to be kept outside the hall until Mr. X and Mr. Smith had erected the lantern, made the connexions, and placed the screen in position. The duty of quieting the young people was assigned to me. It was easily accomplished by the aid of all the good humour I could summon to my assistance. At a quarter to eight a map of Japan appeared on the screen, the doors were opened, the room quickly filled, and two hours afterwards my friend and I received "the usual vote of thanks" for our services, and everybody went home happy.

* * * * *

Everybody, that is, but my ungrateful friend, who topped the maledictions he had already heaped upon me by saying that he hoped I'd give him the chance to do as much for me as I had done for him that night. He has since explained that he bears me no malice, and that he didn't mean me to accept his aspiration in the dubious aspect it undoubtedly appeared to have at the time. Still, I don't think I'll give him the chance he asked for. Radiant.

EXPERIMENTAL WORK WITH A LANTERN.

In continuation of the notes in the January number of The Lantern Record, p. 3, we will proceed to the explanation of some of the more simple phenomena of colour.

The first experiment should be to prove that, although we have decomposed our white light, we have not altered it materially, and that every constituent ray existed there prior to passing through the prism, we have neither subtracted from nor added to it, but merely placed in regular order the conglomeration of rays of different colours, and we have merely to concentrate our coloured band into a narrow line again to obtain white light. For this purpose we require a lens which need not be achromatic. Single lenses of comparatively large diameter may be obtained at reasonable prices from most opticians, but the front lens of a good large portrait lens may be utilised, or, failing this, one of the water bottles used by watchmakers as condensers may be used. When the front lens of a portrait combination, or a single lens is used, it should be temporarily mounted on a card, which should project at least three inches on each side; this prevents any light not taken up by the lens from reaching the screen. To support the lens, an ordinary oak picture frame can be obtained and screwed down to a stout piece of two-inch deal, which should be weighted. Now make a small cage of perforated zinc, and to do this procure a piece about one and a quarter inches wide, and of sufficient length to nearly go round the lens; bend the edges up slightly on each side, and curve lengthways into a circle. In each end weave a piece of thin brass wire in and out of the holes, place the lens in the cage, and tie the wire together; now with stout copper wire fasten this cage to the four corners of the picture frame and pull taut.

If the lens thus mounted is placed in the path of the rays after passing through the prism, it will be found that a white image of the slit will again be formed on the screen, and the insertion of a white card between lens and prism will show a small spectrum, and on removing the card the lens will reform the spectrum into white light. Of course, a second prism may be used instead of the lens to recombine the spectrum, but my idea is rather to point out how experiments may be shown with very little outlay. Of course, if a second prism be used, its base must be placed next to the apex of the first.

The best definition of colour is that it is a suppression of light, and to prove this we will assume that we have recombined the spectrum on the screen. Now pass, close to the recombining lens, a piece of card along the spectrum, and it will be found that the image on the screen is no longer white but coloured, this being due to the suppression of one or more of the coloured rays.

To prove that colour is due solely to the suppression of some of the coloured rays, we can use two bits of glass, or some sheets of glass coated with collodion stained with aniline dyes.

I would point out here that the very best position of the lantern for such work as we are considering is in front of the audience, and not with the lantern away at the back of the hall. A very long spectrum is not essential, but one about two feet long shown on a good opaque screen, and the lantern and screen so arranged that the lecturer can readily have access to both is an enormous convenience. If the lantern is at the opposite end of the hall, a good lantern operator accustomed to your experiments is absolutely necessary, whereas, when both are within your reach, you can easily walk from lantern to screen, perform your own experiments, and thus ensure everything going without a hitch.

Procure from a dealer a piece of double flashed ruby glass, such as is used for dark-room windows, and show this first on the screen by merely removing the prism; now replace the prism and show that, although the glass is red, it is not so because it turns all the light that passes through it into red, but because this glass will cut off the whole of the violet, blue, green, and yellow down to about C in the deep orange. Paler shades of red, or even double flashed orange, may be used, and the paler the colour, the more spectrum colours will be seen, although the resultant visual colour is red. Some of the deepest chromium green glass may be used in the same way, and with two thicknesses of this and one of the double flashed ruby it is possible to suppress all the colours, and therefore obtain no light, but black.

Two narrow strips of the green and red glass should be cut off with a diamond or glass-cutter, and then bound together one above the other, and this, placed in front of the slit, will enable one to explain why, when superimposed, we get no light, because the green glass cuts off the whole of the red, and the red cuts off everything but the red, so that, when combined, there is no chance of any light getting through.

We can also show a very pretty experiment which I have seen Lord Rayleigh perform more than once, and that is, to show that red and green make a deep yellow. Procure some litmus tincture, and dilute with water, and then add a twenty-grain solution of gelatine and coat glass with it; it is advisable to coat a stock of these glasses. This, placed before the slit of the lantern, will project a spectrum from which the yellow and orange is entirely wanting if the litmus is strong enough. A strong solution of aurine treated in the same way cuts out all the blue and violet, and both together only allow the red and green to pass, and, by superimposing them, we get on the screen, not using the prism, of course, a deep yellow. Mr. Lewis Wright suggests the use of a solution of litmus and a solution of potassium of bichromate, and he states that finer results are thus obtained.

Innumerable and striking effects can be obtained by using,

suggested above, glasses coated with collodion stained with aniline dyes; but, in preparing these, care must be taken that the solution is not so saturated as to crystallise out on the glass in drying.

With many coloured substances we obtain not one or more particular colours visible in the spectrum, but peculiar and characteristic absorption bands, the resulting visual colour of the solution, or whatever it may be, being the sum of what is left. One of the most striking of these experiments is that of iodine vapour. To show this, a long test tube of about half an inch internal diameter should be obtained, and at the bottom be placed a few crystals of iodine, the mouth closed with a cork in which is a very small hole. On placing this in front of the slit, so that nothing but the empty test tube is there, the spectrum will be normal, but, with a small spirit lamp, heat the bottom of the tube where the iodine lies; as the heat increases the iodine rises in vapour, and gradually the absorption bands make their appearance, and on cooling the tube they gradually die out. Chlorophyll is another substance which shows well-marked bands; and, to procure this, either spinach or parsley, about two ounces of each, should be cut up fine and macerated for a week, with about four ounces of spirit and sixteen ounces of water, and then filtered off; a little zinc dust should be added to preserve it. The absorption bands shift their places considerably, or appear to, according to the thickness of solution, and, to show this, a solution may be diluted whilst before the slit by squirting water into it. By merely adding an acid or alkali too the spectrum may be changed, and this is notably the case with litmus and chlorophyll. Saffron too is another substance which gives totally different spectra, according to whether it is macerated in amylic alcohol, pure alcohol, or proof spirit. Most of the uranium salts too possess very characteristic absorption spectra, as does also blood, and the absorption bands of this may be made to change by adding acids.

A very excellent way of showing the effect of increasing the thickness of a solution on its colour and spectrum is to use prismatic or wedge-shaped cells; these can be made very easily of wood if the glass sides are fastened in with the asphalt preparation suggested last month. By filling such cells with liquids the increase of thickness may be shown by passing the wedge from the narrow end up to the thick end in front of the slit.

Before leaving this part of the subject it may be of interest to give directions for producing particular bands of the spectrum, the so-called monochromatic, which, as will be seen, is by no means monochromatic. For this purpose we require cells or troughs of definite thickness, of four-fifths of an inch internal measure, and we want three of these and two troughs with three-fifths internal measurement.

For red light from wave-length 718 to 639, or from about A$\frac{1}{2}$ B to C$\frac{1}{4}$ D, we must use a cell of four-fifths of an inch filled with a solution of crystal violet 5 BO, made by dissolving one and a half grains in four and a quarter ounces of water, in combination with a trough of the same thickness filled with a ten per cent. solution of neutral potassium chromate.

For yellow light from wave-length 614 to 574, or from C$\frac{1}{4}$ D to D$\frac{1}{4}$ E, we want three cells, one of four-fifths of an inch filled with a solution of 164 grains of nickel sulphate in one ounce of distilled water, a second cell of three-fifths of an inch thickness filled with ten per cent. solution of potassium chromate, and a third with a very weak solution of permanganate of potash, one quarter of a grain in two ounces of water.

For green light from wave-length 540 to 505, or from about E to just beyond *b*, we must use 328 grains of cupric chloride dissolved in an ounce of water in a thickness of four-fifths of an inch, and a like thickness of ten per cent. solution of potassium chromate.

For bright blue from wave length 526 to 458, or from E to F$\frac{1}{4}$ G, we must use a 0·02 per cent. solution of double green SF in a thickness of four-fifths of an inch, and a second cell of the same thickness of a fifteen per cent. solution of copper sulphate.

For dark blue from wave-length 478 to 410, or from F$\frac{1}{4}$ G to *h*, we require a solution of crystal violet just one-tenth the strength of that used for the red in a thickness of four-fifths of an inch, and a fifteen per cent. solution of copper sulphate in the same thickness.

I must apologise for introducing these somewhat troublesome details, which, by the bye, were first suggested by Landolt, but they may be useful also to the photo-micrographer, as with these he can possibly obtain better resolution of fine detail markings in diatoms, &c., and, by using the red, the green, and the deep blue, we have practically the three fundamental colour sensations, and with a triple lantern we may make the so-called white light.

We have been dealing entirely so far with transparent colours, but, before leaving the spectrum, we can easily show the action of coloured, opaque substances on the spectrum, and for this purpose it is advisable to obtain from a paper-maker some sheets of body coloured papers. These can be had in all varieties of colours, and with a matt surface; the shiny surfaced papers should be rejected. Strips of such papers, pasted singly on to an ordinary mount, may be passed along the spectrum, and it can be pointed out that the papers absorb or suppress certain colours, the sum of the remainder giving rise to certain sensations which we call red, yellow, green, &c. Of course, the spectrum may be allowed to fall for its whole length on the papers if they are pasted in long strips one above the other, and the action is well seen then.

If we use the monochromatic lights suggested above, it is very easy to show by means of these papers that, for instance, a brilliant orange looks black when illuminated by blue.

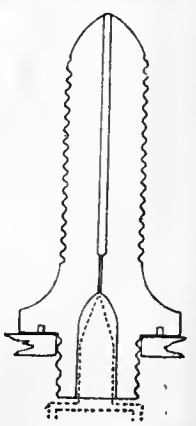
A rather striking experiment, proving most conclusively that red will not reflect green, or yellow blue, may be performed by taking a white card and writing a word or making a sketch in some such colour as cochineal solution, not very deep. This will be distinctly visible by white light, but with a deep ruby glass it no longer appears; but, change the red glass for a chromium green, and the letters or sketch instantly start up as black as possible. This may also be shown with gamboge and violet glass, or permanganate of potash, or the solution recommended above of crystal violet. For those who do not care to take the trouble to do this, the box lids of Lumière's plates may be used in this way. With a little care and experimenting in this direction, it is possible to entirely reverse a word or sketch, making it appear first red on a black ground, and then black on a green ground, or to obtain innumerable effects. Some very striking results may be obtained in this way by using the special red, yellow, and blue inks which have been placed on the market for three-colour printing, and for this hint I am indebted to a friend whose name is fairly well known in connexion with this work.

PHAROS.

PHOTOGRAPHIC WORKERS AT WORK.

II.—How Mr. R. R. Beard Makes a Regulator.

A gas-regulator is, to most people, more or less of a mystery. It is a neat-looking little brass instrument, which is screwed on to the cylinder, and, no matter what the pressure of the gas in the cylinder itself may be, it issues from the regulator in a steady stream, and at a pressure of but a few inches of water, while examination of the instrument itself only conveys the information that bellows, in some way or another, are employed. Unless these bellows are removed—and not many would care so far to tamper with the regulator—nothing further can be ascertained except from a drawing.



Much more than this we learnt on calling on the maker at 10, Trafalgar-road, Bermondsey, one day last month, and the information then gained we will proceed to convey to our readers to the best of our ability.

The first part of the regulator to be considered is the nipple. This is the stem of the instrument, which screws into the cylinder, and, as it is the only portion, except the extreme tip of the valve piece which has to bear the high pressure of the compressed gas, it is a very substantial gun-metal casting. As soon as it has been turned, screwed, and drilled to the shape shown in our sketch, it has to be tested to see that the metal is not to any extent porous. This seems almost unnecessary at first sight, but it must be remembered that, in casting, all metals are liable to the presence of minute pores, often visible to the naked eye, due in large measure to the fact that cooling takes place from the outside inwards, and that the outside of a casting is solid while the interior is

still in a molten condition. To test it, then, the nipple is screwed into a cylinder, the opening at the top is plugged up, and the gas turned on. Soap and water being brushed over the nipple, any leakage manifests itself at once by a bubble being formed; if this is not the case, and the casting is seen to be sound, it is ready to have the valve fitted to it.

The selection of suitable metal for the little valve piece was an important matter, Mr. Beard informed us. Steel was out of the question, because of the readiness with which it oxidises, while the material must be different from that of the nipple into which it is bedded, or adhesion would take place. Finally, a material something whiter than gun metal in appearance was selected; one so hard that special tools are necessary to work it, and care has to be taken in doing so, on account of the brittleness which invariably accompanies great hardness. This quality has an additional advantage in the fact that the seating of the valve being of so much softer a nature, the pressure of the valve on it makes its shape wear exactly like that of the end of the valve itself. This valve piece is to be seen at C in the accompanying sketch, along with two eccentrics which work in it, and which are attached to a system of levers known as lazy tongs.

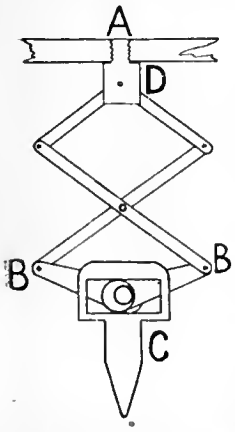
Before referring to the levers which work the valve, it will be noticed that part of a collar is shown on the upper part of the nipple. This is the base of the regulator, and is fitted on to the nipple as shown by means of two dowels, the fulcrum piece, to be referred to afterwards, being screwed down on to it and holding it in its place. The base extends outwards from the nipple considerably, carrying a projecting ring on its upper surface, grooved to receive the lower end of the rubber bellows, and having its outer edge screwed to take the brass cap which covers and protects the mechanism and bellows. It is into this base, moreover, that the delivery pipe is screwed.

The relative positions of the parts shown in the two sketches can be seen by reference to the first, the dotted lines showing the lower portion of the valve where it enters the nipple, the extreme tip of the cone entering the narrow boring in the nipple forms the actual valve which stops the outflow of gas.

Handing us the two eccentrics and the valve piece, Mr. Beard suggests with a smile that we should put them together. Like many other puzzles, it is very simple when you know how, but it takes some little time before the exact way in which it is done can be seen. Unfortunately it is impossible to explain the method on paper within reasonable limits.

The lazy tongs, which are attached at their bottom ends to the two eccentric arms, carry at their top a little piece of metal, D, which screws into a dise forming the upper end of the bellows. When, therefore, the bellows rise, as they do when gas passes into them from the cylinder and cannot get out of them again, they carry up with them the top of the lazy tongs, and in so doing the eccentric arms are raised and the valve pushed down and closed.

A glance at the sketch will make this clear. It will be seen that, if A is raised, everything being free to move except the pin (seen in section as a black dot, on which the eccentrics turn, the arms, BB, must be raised also. The effect of raising BB is in its turn to thrust downwards C by means of the pressure exerted on it by the eccentrics. The introduction of the lever results in the upward motion of A being transformed into a downward motion of C, the extent to which C moves being much less than is the case with A, but the force being correspondingly greater.



The greatest leverage is exerted by the lazy tongs when in the position shown, and not when at their greatest or their least extension; therefore the position of the eccentrics is adjusted in such a manner as to make their greatest work done when the levers are in the best position for actuating them. The eccentrics are two in number in each regulator. Mr. Beard informed us that he had found it possible to make a regulator with only one, but that this was not advisable. As it is, they have to be made with the greatest accuracy to ensure each one doing an equal amount of work; since, if this were not the case, the valve, instead of being driven fairly and squarely downwards, would be inclined on one side, and tend to wear itself oval, while the top of the bellows, being thrown on one side also, would rub against the brass cap containing them.

On the top piece, A, a circular metal disc is screwed, a portion of which is shown in the sketch, the joint between the disc and the shoulder and screw of A being first luted with white lead. This cap has a groove on its outer edge, to which the bellows are fastened.

A gun-metal casting has also to be turned and screwed to carry the eccentric pin. This piece is known as the fulcrum. It calls for no special comment in itself, but it screws on to the projection shown on the upper part of the nipple, which is inside the base of the regulator, and the extent to which it is screwed up forms the most important part of the adjustment of a regulator. As the pin on this fulcrum piece is what decides the relative position of the valve seating and the top of the levers, it is obvious that, were that pin too near the seating of the valve, no amount of movement on the part of the eccentrics could open the valve far enough to let the gas escape sufficiently, while, were the distance too great, the valve could not close. The adjustment, therefore, has to be made, and this is done by interposing stout paper washers between the fulcrum piece and the base of the regulator on which it rests until the correct position is reached.

When this has been done the bellows have attention. These, in the different forms of regulator, are of three kinds. The first have parallel sides, and are those used in the standard pattern. The second are similar, except in being smaller and stouter for very high pressures up to thirty pounds per square inch. The third kind are like the first in substance, but taper to a smaller diameter at the top, and are used in regulators which are made to deliver the gas at pressures of from twelve to fifteen pounds per square inch, such pressure, in fact, as is required by the new injector jets. This taper form, by reducing the area of the top of the bellows, in itself increases the pressure of delivery without requiring the strength of the spring to be altered. Each kind of bellows is made of the best Para rubber, and is pulled over the projection on the base provided for the purpose, and tied on to it with stout carpet thread, no cement of any kind being used. By merely tying on the bellows, should the valve through injury at any time leak while the outlet was closed, the stretching of the rubber itself allows the gas to escape without bursting the bellows, which it would otherwise do.

At this stage the circular metal piece, having a groove on its outer edge, to receive the top of the bellows, is screwed on to A, which has previously received a luting of white lead, as already mentioned, the levers being held firmly the while. The bellows are then brought over the groove and tied at the top in the same way as at the bottom.

Nothing remains now but to screw in the outlet pipe and to put the cap on the regulator, between the top of which and the bellows is placed the spring. The caps are made from brass tube, screwed at the bottom, the tops of the caps being stamped and, after fitting in, soldered.

Each regulator has, of course, to be tested before leaving the works, and to do this it is screwed on to a full cylinder of gas and connected up to a jet, the tap of which is turned off. A branch pipe connects the tube joining regulator and jet with a very sensitive pressure gauge. The gauge indicates that the regulator, if properly adjusted, maintains a pressure in the closed tube of three pounds to the square inch or thereabouts, which drops to two and a half pounds when the jet cock is opened, thus indicating that a pressure of half a pound is required to close the valve against a full bottle of gas.

Regulators with rubber bellows can be constructed on Mr. Beard's pattern to deliver gas at any pressure up to about thirty pounds to the square inch. They deliver it very regularly from the cylinders now in use, in which high pressures are maintained, more or less, almost up to the point at which the cylinder is empty; but, for purposes of other than lanternists, regulators are wanted which reduce from much lower pressures than those used by the gas-compressing companies, and when this is the case Mr. Beard informs us that he found, in his early experiments, that the delivery from a single regulator is not so steady. For such purposes a design was got out by him on similar lines, but having the regulating parts either in duplicate or triplicate, one regulator governing the pressure in the next, and so on; but, as we said before, the irregularities of the single regulator when on the high-pressure cylinders are unnoticeable.

The effect of the lazy-tong attachment is that of a very compact and powerful lever, so powerful, indeed, that, roughly speaking, the pressure forcing the valve down on its seating is eighty times as great as that exerted in moving the other end of the lazy tongs; and, when it is borne in mind that the valve itself is a little cone not more than $\frac{3}{32}$ inches in diameter, it will be seen how high a pressure of gas can be counteracted by the instrument.

The popularity of the Beard regulator was evident from the state of the works in which it is being made. Large numbers were to be seen in all stages of manufacture, but hardly a single one in stock. "We shall

start making for stock," says Mr. Beard, "in a month or two, as soon as we can, in fact, and then, next September or October, out they all go, as soon as the lantern season commences."

COMBINATION PRINTING OF LANTERN SLIDES.

II.

In a previous article I referred to the necessary preparations whereby the printing of combined lantern slides may be effected, and instanced a very common example met in with, viz., an introductory slide for lecture sets.

In cases where it has been decided to employ ordinary negatives for the various illustrations collected in the body of the slide, and around the edges of which a suitable titling has been provided in the manner previously described, these negatives will require to be furnished with some suitable masks so as to yield a uniform shape to the various views combined within the circle. Of course, in this much will depend upon the nature of the subject. As a rule, where portraits are being treated, oval shapes in the centre, surrounded by a number of small round pictures at equal distances just inside the edge of the title, are very effective; but, of course, there is no end to the variety of forms and styles that may be utilised. Whichever shape, however, is selected, it will be necessary beforehand to see that ample space is provided on the ground glass of the camera, which, of course, means also the same space on the sensitive plate, so as to contain, without undue crowding, the little pictures it is intended to print.

To accomplish this in the case of, say, round shapes, a practical method to adopt is to first describe on the focussing glass the little circles that are to contain the pictures, and care should be observed that these occupy exactly their proper places, such as at equal distances from each other, so as to prevent any eyesores when the slide is projected on the screen.

If the negatives be provided with well-shaped, round masks, these are easily reduced neatly into these little circles, which have been described on the ground glass. Of course, to enable this to be accomplished with ease and certainty, the camera that is being employed must be provided with the necessary front movement for projecting the images up or down, or from side to side, as required, and here again we have a further instance of the practicability of the good old square form of camera over the more modern conical-shaped article, which, alas, is now so much in evidence with those whose photographic experience is limited. Over and over again I meet with amateur workers who regret they ever invested in these conical bellows cameras.

The little circles referred to may be described on the ground glass by means of placing any coin, according to the size desired, and ruling round the edges of the same a sharp line with a hard lead pencil. There is no difficulty in accomplishing this. The preparation of the focussing screen in some respects is just like preparing a design of the slide, and once the shapes, whatever they may be, are on the ground glass in their proper positions, and these shapes correspond with the masks of the negatives, the most difficult part of the operation has been performed, for all the rest is merely plain sailing, and comprises the proper adjustment of the little images inside the circles, with a fair amount of photographic experience as to correct exposure and development of the plate, an amount of knowledge which, of course, no one should be without who attempts such advanced work as I am describing.

In undertaking work of this kind, it does not by any means follow that the entire subject contained in any negative has to be utilised, for it frequently happens that only a portion of a view is desired, and very probably this may be contained in some large-sized negative, such as 12×10 or 15×12, in which case, having decided upon the exact portion it is intended to embrace in the slide, special round or other shaped masks have to be provided of the exact size to suit the amount of view selected. This part of the work the writer knows from experience has often deterred some workers from undertaking the production of such combined slides as we are considering, for the providing of such sized masks is with some a matter of great difficulty, but everything is easy to one when they know the way how to do it, and, to those who imagine this difficulty insuperable, I would merely refer them to an article I wrote in this year's British Journal Photographic Almanac dealing with this subject. When any small circles are needed, an ordinary diaphragm or stop will be found just the thing when such is temporarily fixed over the part of the negative it is desired to copy, hence it is apparent that the entire or any portion of a negative may be utilised for this purpose.

In the example referred to, provided due care is observed in correct registration, but little difficulty will be experienced in producing uniformly perfect results, and such an example of double printing is not by any means so difficult of accomplishment as many suppose.

It frequently happens, however, that it is desired to produce a combination picture, in which portions of two or more negatives are combined in one picture, which shall only convey the idea but that of one negative or original view. Numerous examples of this kind might be mentioned, such as the introduction of a ship in a marine view, or a boat, containing, say, a family group, floating on the sea, or the introduction of some animal on the foreground of a landscape, or any other suitable object, to lend additional interest to a view. When dealing with cases of this kind, masking has to be dispensed with, and recourse had to a blocking-out preparation of both negatives.

In selecting suitable subjects, consideration must also be given to the matter of size, for nothing looks worse than an incongruity in this respect.

Having decided upon the subject it is intended to introduce in the picture, the first step is to block out entirely all the remaining portions of the negative. In doing this it by no means follows that such should be otherwise than for temporary purposes only, and, should the size of this selected object or part be such as not to agree with the surroundings or scale of the other negative, a positive should be made, and this again converted either into a reduced or an enlarged negative, whichever is required, until the desired size is reached.

To enable this object being introduced into the main picture, space must be reserved for it on the sensitive plate after it is printed. To provide for this, the main negative must have an exact counterpart of the object blocked out also.

This may be accomplished by superimposing one negative over the other, and tracing the outline very carefully on the main negative To enable this being done to the best advantage, a special support is required so as to permit of the negatives lying perfectly flat in a horizontal position. An ordinary retouching desk is not so well adapted for this as a box without ends, and from which one of the sides has been extracted. When such is provided, a white reflector placed on the same at a convenient spot near a window will permit of the blocking out being done with the greatest precision.

Of the different mediums suitable for such blocking out there is nothing equal to a good oil colour, burnt sienna, or black, or any opaque pigment. The great advantage of using such oil colours lies in the fineness of the outlines that may be made with such, combined with the ease with which any blocking out is removed, for all that is necessary to bring the negative back to its original condition is to apply a soft rag with a little turpentine, and the paint is removed without having in any way injured the negative.

Oil colours, of course, will not dry rapidly, but it is not necessary that any blocking out should be dry before the printing operation takes place, for such negatives, being intended for use, by means of the copying box nothing is required in contact with their surfaces.

The blocking out on both negatives being completed, the main negative is placed in the copying box, and the image is carefully focussed within the marked-off space on the ground glass of the camera. In doing this the utmost amount of illumination possible should be employed, so as to render as easily as possible the accomplishment of the next step, which is to describe upon the focussing screen an exact outline of the block out in the main negative, which, of course, will be unaffected on the sensitive plate when the same is exposed upon the main negative.

To describe the exact outline of this block out on the ground glass, the aid of a strong pair of spectacles is desirable, so as to permit of very carefully drawing the outline, as a guide into which the other unblocked object has to be registered. In practice, I like to work as comfortably as possible, and when undertaking a job of this kind I prefer to sit comfortably down at the back of the camera, which should always be so adjusted about the right height to permit of the eye and hands working at close quarters, so as to enable the outline being exactly drawn.

A good sable brush and oil paint is as good as anything to employ for the purpose of registering exactly the position of the block in the main negative. This done properly, the exposure is made, the slide closed up and withdrawn from the camera, care being taken not to shake or alter the sensitive plate or carrier in the slide. The object negative is then taken and placed in the copying box, and the camera adjusted to the required distance that will just permit of the objects registering exactly to the outline drawn on the ground glass. This done, the same plate is then exposed on this negative also, and, provided the exposure has been correct and the various manipulations carried through carefully, an exceedingly interesting photographic feat will have been performed, and one that will at all times command interest on inspection from brother workers.

This work only wants a little practice to enable successful results being achieved; it comes quite easy after a little practice, and but little consideration will be needed by any one to see that a wide field of interesting subjects may be selected as specially suitable for combination printing of this kind.

To enable the various parts being correctly joined in one and the same picture, the utmost care must be observed in registering on the ground glass. I have tried numerous methods of marking the focussing screen for this purpose, and for very fine work there is no better plan to adopt than that of placing very fine threads or hairs on the inside of the focussing screen. With such the very finest lines can be superimposed, and I know of no better plan for holding these guides in position than small pieces of wax attached to their ends. When such are adjusted on the *inside*, there is no danger. When examining the picture with the aid of a focussing glass of their being removed, these threads may be stretched the entire length of the glass, and they form the best test I know of for ascertaining when the sensitive plate and the marks on the ground glass coincide; they can be altered in position by merely changing the knots of wax, and, of course, they permit of the focussing screen being kept comparatively free of marks, and thereby enable the picture to be seen more easily when being adjusted. I have seen some focussing screens so full of pencil marks, that it would be quite impossible to make very fine adjustments over them. The threads or hairs when removed leave no marks behind them.

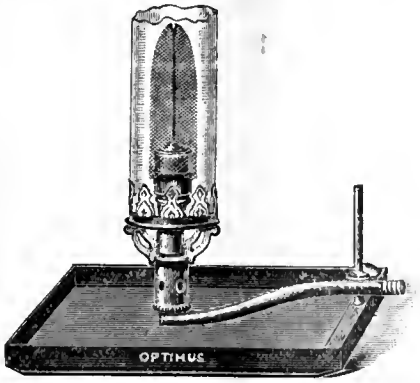
When reducing large negatives, such as 15 × 12, to sizes of one inch or less, the services of a short focus lens must be employed. In fact, it is well to have lenses of varying foci to undertake the work properly.

T. N. Armstrong.

THE OPTIMUS INCANDESCENT GAS BURNER.

Perken, Son, & Rayment, Hatton-garden.

The attention given to the use of the incandescent gaslight for projection and enlarging has induced Messrs. Perken, Son, & Rayment to devise the neat little system, which is depicted in the illustration, for



adapting the light to the lantern. It includes burner, glass chimney, brass arm, regulating tap and tray or the arm only, and the arm and tray can be had separately. The system is easily adapted, and is inexpensive, besides being cleanly in working.

FLASHLIGHT HINTS.

[Anthony's Bulletin.]

Flashlight portraits are not always successful, and, in the majority of cases, this is due to the fact that the flash is made just above and behind the camera. The result is invariably a flat, lifeless picture. Now, it is an established fact in outdoor photography, never, if avoidable, to photograph an object with the sun directly in front of, or behind, the lens. The same principle holds good in indoor work. To obtain the best results, the light must come from the side, and with the flashlight it is possible to produce results that can only with difficulty be distinguished from properly lighted daylight exposures. The flash may, and should, be fired on the side of the sitter, and the use of a properly placed reflector on the other side will obviate harshness or dense shadows. The direct light must, of course, be screened from the lens, and this is easily done. Another difficulty is the staring effect produced by the desire of the sitter to obey the injunction of the operator to "keep your eyes open." A fair amount of illumination in the room, such as the lighting of the gas or lamps, will do away with much of this trouble, but thorough confidence of the sitter in the result and a knowledge of just what is going to happen will help greatly.

A really nervous person will never make a good subject for flashlight work; but, with a model familiar with the operator and with the method to be employed, really good work may be done. Flashlight photography offers many inducements to the amateur photographer, and much in the way of perfecting it may yet be accomplished. As used at present, a large amount of light is wasted, for but a small quantity of the light produced by the burning powder is really reflected from the subject, through the lens, to the plate. The powder is fired while in bulk, and the flame is of considerable thickness. Now, flame being opaque, only that portion nearest the sitter is of practical utility, and until some method is devised by which the powder may be used in the form of a thin sheet, suspended and fired, so that practically every grain of powder tells, the waste will continue.

The late H. Fourtier, of Paris, made an exhaustive study of the magnesium flashlight, and found that, with "from one to four grammes, the intensity of the light increases in proportion to the weight of powder employed; from four to eight grammes it decreases slowly, and from eight to sixteen grammes rapidly. To use more is simply loss. The splitting up of the one charge into small charges yields much better results. A charge of two grammes burned at one time furnishes much less light than two charges of one gramme each fired simultaneously. A considerable gain in light for a given weight is always obtained when the powder is burned in several small charges. Moreover, in this way the flame thus produced occupies a large space, and, the light being thus spread, the shadows are softer, the subject better modelled, and very remarkable effects may be obtained."

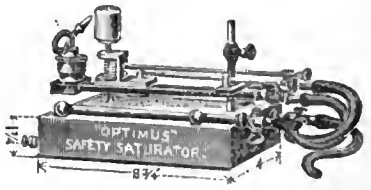
The acetylene light will, in the near future, be available for photographic purposes, and will, we believe, be of such actinic power as to render it comparatively an easy matter to obtain a properly timed exposure in a few seconds. Much, however, in the way of experimenting must be done with the new illuminant. Word of a serious explosion in New Haven has just reached us, but the details are not yet known. Acetylene will undoubtedly play an important part in photography, and the progress made with the new gas should be watched by every progressive photographer. Of course, the light most preferable is that given by the electric arc, and there is every evidence that before long every professional photographer will consider an electric lamp a vital part of his outfit, either as an auxiliary to, or as an absolute substitute for, daylight.

THE OPTIMUS SAFETY SATURATOR.

Perken, Son, & Rayment, Hatton-garden.

Since its first introduction, the Optimus Saturator of Messrs. Perken, Son, & Rayment, to the practical value of which we have before paid testimony, has been rendered still more effective by several minor improvements, and continues to be very popular with lanternists. We append the instructions for using the new and enlarged saturator. They are admirably clear, and give a very full idea of the way in which it is worked:—

To charge: Unscrew large stopper plug (filler) on the top of saturator and the small overflow plug at end of saturator. Pour methylated ether into the filler until it runs out from the overflow. The saturator should now be stood upon its end until all fluid ceases to drop from the overflow, when both plugs should be very tightly screwed up into their respective apertures. To connect: Attach one end of a short length of rubber tube to the outlet tap of saturator, and the other end to the hydrogen tap of jet. Attach one end of another rubber tube to the regulator connected with oxygen cylinder, the other end to be attached to the direct nozzle of the inlet tap of saturator. The branch from the inlet tap of saturator must now be connected with the oxygen tap of jet by a third piece of rubber tube. Immediately *before* lighting up, turn on outlet tap so as to let the saturated oxygen fill the connecting tube and the tube of jet, so driving out all atmospheric air from those tubes. To light up: First see jet taps are turned off; then turn on inlet and outlet taps of saturator. Now open valve and admit gas from oxygen cylinder, apply a light to nipple of jet; at the same time turn on etho-oxygen tap of jet until the flame is as large as that given by an ordinary house burner; then very gradually turn on pure oxygen tap of jet until you obtain incandescence of lime, without any hissing sound whatever. As you turn on the oxygen tap of jet it will be found necessary to slightly increase the quantity of the mixed etho-oxygen by the tap of jet. To turn out light: first close etho-oxygen



tap of jet, then the pure oxygen tap of jet, after which turn off saturator taps, and, finally, close valve of oxygen cylinder. The above is the proper order, and the routine recommended, but no danger need be apprehended if it be inadvertently departed from.

Crucial experiments have demonstrated the absolute safety of the Optimus Saturator, which for compactness, practicability, and the good quality of light it yields, is unexcelled.

MANCHESTER PHOTOGRAPHIC SOCIETY.

FEBRUARY 26.—Mr. J. W. Wade, of the Manchester Amateur Photographic Society, gave a description of the

VARIOUS TONES SUITABLE FOR DIFFERENT SUBJECTS IN LANTERN SLIDES,

which was illustrated by nearly 100 slides shown on the screen.

Architecture was first treated of. Old buildings and church interiors should be of a warm-brown colour, newer buildings and the interiors of cathedrals, where white marble or stone predominates, should be of a cold tone. Sculpture was next dealt with, several fine studies being shown of groups at Eaton Hall. Mr. Wade, in order to obtain the warm tones, uses the hydroquinone developer, with the addition of ammonium bromide. He had used the developer in conjunction with carbonate of ammonia, but found it blocked the shadows. Nature is beautiful in any season, as was illustrated by the bare boughs of spring with brownish black colour, *A Summer's Day*, of a reddish-brown, autumn brown, and several hoar-frost scenes of a black and blue-black deposit. The black tones are obtained by the use of hydroquinone with bromide of potassium in place of bromide of ammonium, and shortening the exposure. Mr. Wade was one of the first to observe how beautiful were the effects to be obtained by the chemical toning of lantern slides, and showed a number of cloud and seascape pictures illustrating his method. The slides which call for special mention are *Sunset at Llanberis* and *Bradda Head*. The plates used are the Alpha, and by a long exposure a red colour is obtained with their developer; after fixing and good washing, the plates are toned either locally or all over.

The toning solution is as follows:—

Ammonium sulphocyanide	60 grains.
Carbonate of soda	3 ,,
Gold chloride	2 ,,
Water	6 ounces.

This solution takes the plate through all the stages from red to brown, purple, and blue.

Mr. Wade was listened to with great attention, and hearty thanks were accorded to him.

Mr. H. M. Whitefield gave a demonstration of his method of printing clouds in lantern slides, and, in his introductory remarks, said that, with rapid plates and *f*-45 stop, the exposure for clouds was about one second. It is always better to study the clouds, their shape and balance, in order to suit the landscape into which they are to be introduced, as a picture is generally made or marred by the clouds. An angle of 45° from the sun is the best standpoint for taking them, but it generally depends upon from which side your landscape is lighted. Mr. Whitefield use a printing frame of his own manufacture, in which the landscape slide is put between the cloud negative and lantern plate; the back of the slide is made non-actinic by rubbing on the glass side a mixture of burnt sienna, glycerine, and gum water, and the whole is exposed to the light, the landscape slide making a mask on which to fit the cloud. It is not advisable to put the cloud on the same plate as the view, as in the case of a light church spire against the sky it is difficult to put the cloud on it without some mask. A slide was then exposed and developed, the developer being hydro-oum-eikon, and, after fixing, was put through the lantern. The method was much admired, and should commend itself to all who seek to improve their slides by the suitable introduction of clouds.

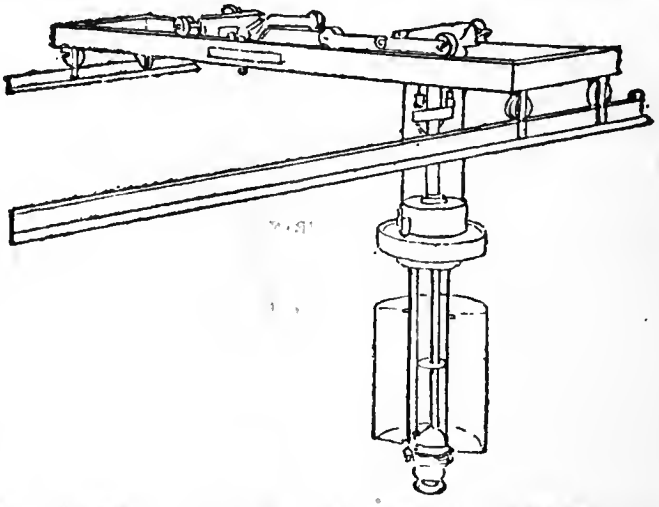
ROGERS' TRAVERSING GEAR FOR ARC LAMPS.

WE have recently had our attention called to the above-mentioned apparatus, which will probably prove a very valuable adjunct to the studio of firms who carry on the work of process-engraving, photo-etching, and photography.

It must be apparent to every one who is accustomed to the appearance of studios fitted up with the old appliances that the cranes, ropes, and loose wires, which almost fill the upper part of the studio, are extremely unsightly, and indeed dangerous, to say nothing of the light being blocked out by the network of cables and ropes, &c., which are by this traversing gear entirely superseded.

The advantages of the apparatus consist in the fact that the arc lamp can be moved in any direction whatever with regard to the copy, that is to say, it can be swivelled round on its own axis; it can be raised and lowered, it can be moved across the studio, or along the studio, with the greatest facility.

The whole of the current is conveyed along the traversing rails, upon which the cradle which carries the arc lamp moves, and is conveyed through the carrying wheels of the cradle, thence through the conductors embedded in the woodwork of the cradle, thence through the supporting



wires of the arc lamp, through the lamp itself, and back again in the contrary direction to the dynamo.

The illustration given herewith, will sufficiently explain the working of the apparatus. Mr. Henry J. Rogers, M.I.M.E., of the Watford Engineering Works, Watford, near London, is the sole manufacturer and patentee of this apparatus, and he has fitted up the majority of the studios in which the above processes are carried on, and he is, at the present time, supplying his patent gear to studios in Bolton, Newcastle-on-Tyne, Watford, Bushey, Bath, &c., &c.

Mr. Rogers, also applies his traversing gear to portrait studios, the arc lamp being in connexion with large parobolic reflectors suspended from his traversing gear in the same manner as above described.

ROGERS' BEVELLING MACHINE FOR PROCESS WORK.

THE bevelling machine, illustrated below, also will be found of great service to photo-etchers, as the edges of the plates can be bevelled in an incredibly short space of time with a perfectly true line at the edge of the

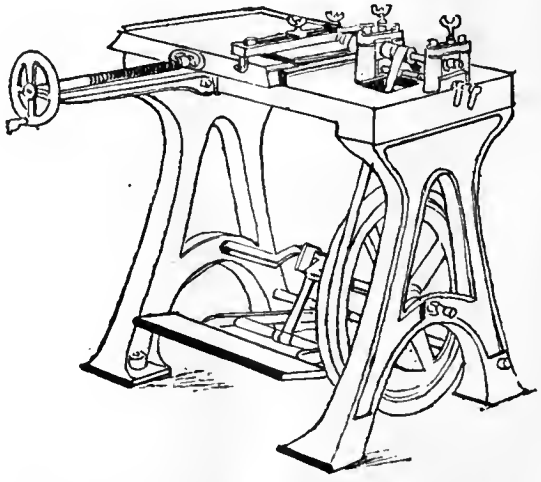


plate. The cost of this machine is very slight as compared with other machines of the same description.

We notice also that the manufacturer of the above apparatus has fitted up a large number of studios with gas and oil engines, and all necessary power for supplying the current to the arc lamps used, and a skilled electrician is at the service of any intending purchasers, free of cost, to advise them as to the best means of applying the electric light to their respective studios.

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*April* 3, 1896.

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

What is the practical outcome of the Home Office inquiry into the "causes of the explosion, and the precautions required to ensure safety of cylinders of compressed gas?" Such is the natural question asked by those interested, and, as all lanternists have not the time to go through the sixty-three pages of folio-size printed matter comprising the report, it may be useful to analyse the conclusions, and refer to the experiments conducted with a view of proving the truth or otherwise of certain theories or views propounded by men whose ideas were worthy of consideration.

* * * * *

First and foremost, it was conclusively shown that, provided the cylinder was made of good material, of a certain thickness, and duly annealed and tested, in accordance with the excellent arrangements now adopted by the gas-compression companies, it was perfectly safe for use with either oxygen or hydrogen (and coal gas) at a pressure of 120 atmospheres, or 1800 pounds to the square inch. Second, that the Committee were perfectly satisfied with the arrangements for compressing gas, and, while those self-imposed regulations remained in force, users of gas and the public need have no concern on this score.

* * * * *

It is a great compliment to the gas-cylinder makers and gas-compression companies for the Committee to express themselves in the following terms:—"It should, however, be stated that up to the present time the trade in compressed gas cylinders has been carried on both by manufacturers of cylinders and compressing firms with great care and skill. The number of accidents, considering the extent of the trade, has been very small, and the number of fatalities has been small also." Regarding the regulations affecting the trade, the Committee found that they were not altogether consistent, for there were different regulations in force by the railway companies, the Board of Trade, and the London County Council. It is to be hoped, now the matter has been so thoroughly investigated and reported on, that regulations for the conveyance and use of compressed gas will be put on a practical and sound footing.

* * * * *

Regarding the causes of explosions, only two fatal accidents have occurred through faulty cylinders or accidental mixture of gas, the other two referred to in the report in connexion with compressed gas being due, in the one case to pure carelessness in doing experimental work with mixed gases and purposely igniting them, and the other at one of the gas-compression companies' works, and ascribed to "causes such that no general regulations would have prevented." Considering these accidents are spread over a period of ten years, and that there are an enormous number of cylinders in use, the small number, although lamentable, is really less proportionately than those due to explosions of steam in boilers, &c.

* * * * *

Some idea can be formed of the enormous number of cylinders in use, when one company, in London, alone turned out, in 1894, 100,000 cylinders, that is, filled or refilled this number with compressed gas. The report says "that, looking at the magnitude of the trade, the risk to the public and to users of the gases, and the partial and imperfect regulations attempted by the action of the railway companies, the Committee think that some control of the trade, by official inspection, is required. The inspector should have the right to examine the specifications to which cylinders were manufactured, and inquire into the precautions taken to secure proper thickness and complete annealing, to examine the records of tests, and occasionally order tests of cylinders for his own information. He should, acting in accordance with instructions, order the reannealing or retesting of cylinders."

* * * * *

This seems reasonable, and, no doubt, would be welcomed by those compression companies, that have, for some time past, made such arrangements for the desired excellence in make of cylinders, and taken complete precautions as to filling, for then competition that might lead to cheapening and to their possible detriment and safety would be judiciously restrained, and made to conform to regulations that experience has shown to be necessary and advisable, for the certificate would be withheld from factories where the arrangements were unsatisfactory, or withdrawn on the report of the inspector that instructions were not carried out.

* * * * *

Another important duty of the inspector, should he be appointed as suggested by the Committee, would be that "he should have the right to test the pressure gauges, weighing apparatus, and other appliances, and to require alterations to be made if they were unsatisfactory. He should occasionally examine cylinders to see that they were not over-filled." This will please some of the lanternists who have written to the technical journals about getting more gas than they paid for; but, as no known case of explosion has been traced to over-pressure of gas in the cylinders (except the one in New York), they need no longer have any anxiety, especially as automatic and reliable safety valves will have to be fitted (if not already done so) to *all* compressors.

* * * * *

It is well known that for ballooning purposes in the English, French, and German armies the cylinders, although of a much lighter make than those lanternists are in the habit of handling, are filled to

much higher pressures—generally 200 atmospheres; but the report says, "the conditions of their use place them outside the range of this inquiry." In fact, Mr. Thomas Atkins and his Continental prototype must look after themselves, and take their risk of being sent to "kingdom come," whether it is by a shell or bullet of the enemy in time of war, or an over-strained gas cylinder in time of peace.

* * * * *

THE press still talk about the cylinder explosion in Holborn as one of compressed gas, and a usually well-informed evening paper, in its scientific notes, which are always interesting and, as a rule, carefully written, starts by way of introducing the subject of the Committee's report as follows: "The recent lamentable death of a chemist by the explosion of a cylinder of compressed gas will draw attention to the report of the Committee appointed last May to inquire," &c.

* * * * *

THIS sort of thing is likely to do a lot of harm to the lantern industry by keeping up the dread of gas cylinders. The way in which most extracts are given is anything but "comforting," for the lay papers boil the report down to such a small compass that they simply tell you either that "explosions are due to negligence in the manufacture, annealing, and testing of the cylinders, and the lack of care in filling," or else that the force of the explosion of a gas cylinder filled with compressed gas in a *mixed* state is equal to the force of an explosion of so many pounds of gunpowder, dynamite, or cordite.

* * * * *

IF they would mention, as *per contra*, that the Committee, despite all their knowledge, patience, care, time, and experiments, were not able to *prove* that the cylinders of commerce are ever filled with mixed gases of an explosive nature, or that they would explode of their own accord, or could be made to explode when purposely so filled, and with oil in the fittings, pieces of steel in the cylinders, or any of the other supposed automatic detonators—in fact, that explosions could only be produced by electrical ignition—all the results, as far as the tests went, were of negative value—*none* of the theories could be *proved*.

* * * * *

THE boom has set in for the animated pictures, and once it was installed in one of the principal "variety houses," the others, in rivalry, would sure to try and secure a similar attraction. Now, the "Cinematograph" is to be seen at the house on the north side of Leicester-square, and the "Animatograph" (late Theatrograph) at the house on the east side; in other words, one is at the Empire and the other at the Alhambra Theatre of Varieties.

* * * * *

I SHOULD have liked very much to have written something this time about Mr. Birt Acres' apparatus and its projections, but, having twice been to Regent-circus to try and see the "Kineopticon," and found the place closed and no announcement as to time of exhibition, I can only suppose that it is not quite ready for the public; or, perhaps, we shall hear of it at the other large variety house, viz., the Palace, for, as I heard some one remark, it might be politic on the inventor's or agent's part to "hold his hand" for a while.

* * * * *

THOSE who would rather see the Cinematograph at its original London home can still do so at each hour after two at Marlborough Hall, and I understand many avail themselves of the opportunity in the afternoon, but not so many in the evening; perhaps "science" is best studied in the evening, accompanied by music and gaiety, as was once the case with a society which met in the building of a variety house, and discussed or had lectures on nearly every subject but that which gave the title to the society: and it was the text for many a joke, not only at the expense of the society, but also to the worthy and respectable paterfamilias, who was accused of having an "evening out" on the pretext of science or exploration. It has now changed its meeting place, but is still cosmopolitan in the subject-matter of its lectures.

G. R. BAKER.

EXPERIMENTAL WORK WITH A LANTERN.

IN previous notes we have considered the formation of colour from the spectrum by the aid of prisms, and coloured solutions, and glasses. A very pretty experiment to show the formation of a spectrum, by diffraction, is to use a grating. Circular gratings, ruled with about 2000 to 3500 lines to the inch, may be obtained at fairly reasonable rates from many opticians, and one of these, placed between the condenser and our home-made optical front, will show a more or less satisfactory image of circular spectra. The light from the condensers should be cut down to a point, and a fairly stout dark green or chocolate mount, cut down to the regulation lantern size, and a pinhole made in the centre, must be placed between the condenser and grating.

The production of colour by interference is by no means easy with the lantern, in fact it is so often a failure that it is better left alone.

There is one method of producing colour which is, of course, well known to all, I mean that which is pursued in projecting three-colour slides. For this a triple lantern is essential, and, whilst it may not be possible for everybody to show actual three-colour slides, the principle may be easily explained. A good deal of mystery has been hung round this subject, and quite unnecessarily. The only difficulty is to procure the three colours to make white light.

Of course, theoretically, the filters should be so chosen as to excite our nerve fibrils in accordance with the curves of Clerk Maxwell or the more correct ones of Koenig; as a matter of fact, common glass may be used with a brilliancy of results which is startling. We require a red, a green, and a blue-violet glass. For the green, pot-metal chromium-green glass should be used; for the blue violet, a pot-metal cobalt-blue glass; these are easy enough to be obtained, because the above are the trade names for them. The red glass with which I have been most successful has, unfortunately, no trade name. It is, however, used for some dark-room lamps, and, when examined by daylight, has a distinct vermilion or orange-red shade, not a ruby.

For the success of this demonstration, it is advisable to obtain as good register as possible of the three discs. The coloured glasses should not be placed next the condenser, but in front of the objective. If next the condenser, all the bubbles and imperfections will be focussed and show upon the screen, whereas, if the glasses are placed in front of the objective, we merely get the blaze of colour, and nothing else.

Besides the glasses, we want some patterns. These can easily be made by sticking lantern-slide binding strips on to cover glasses in some set pattern, only the patterns must be different on each glass, or rather not all alike. A simple pattern can be made as follows: On one glass stick a binding strip running from the left top corner to the bottom right corner. On the second glass place a strip the reverse way—that is, from the top right corner to the bottom left corner. On the third glass put two strips crossing in the middle at right angles.

We will now proceed to demonstrate the formation of the colours. Place the red glass on the top lantern, the green glass on the middle one, and the blue-violet glass on the bottom lantern, and, without any slide, turn on the top lantern and explain that this excites our red sensation nerve. Turn this out and throw on the green; explain this. Turn off the green and throw on the blue-violet. Turn this out and again turn on the red, and explain that you have shown what are usually called the primary colours, or those which excite the three primary sensations, and then state that you intend to show the formation of the intermediate colours, yellow and blue. Now, having the red disc, gradually turn on the green, when the disc will change gradually into orange and then yellow, and, by turning down the red, into greenish-yellow, yellowish-green, and finally pure green when the red is quite shut off. Now, by gradually mixing the blue-violet with the green, the disc becomes first bluish-green, then greenish-blue, and finally pure blue; and, by turning off the green, it changes into violet-blue, bluish-violet, and finally our original violet when the green is quite out. By mixing the red with the violet, what might be called purple is formed, and finally a bright crimson, to which the addition of green makes white. This is

always a taking experiment, and, if properly rehearsed and carried out, generally fetches the house down.

Now proceed to show the formation of colours. Leaving all the jets burning, close the flashing shutters of two of the lanterns, and take out the coloured glass of the third, and throw on the screen one of your diagram slides to prove that it is merely a piece of plain glass with a black paper on it. Then withdraw this and insert the coloured glass, mix the three lights so as to again obtain white, and insert one of your slides in the red-light lantern; immediately you will obtain a white disc crossed by a band of bright blue, and explain the formation of this by saying that all you have done is to stop out the red light at that place, leaving the green and violet to combine to form the blue.

In the middle lantern insert the second of your diagram slides, when immediately another band of colour will cross the other, but now this band will be a combination of red and violet, or crimson. The centre, where both the bands cross, will, of course, be pure violet, because here we have stopped out the light from the green and red.

In the third lantern insert your cross when immediately the centre of the screen becomes black, and the right-angled cross bright yellow, because the diagram slide has here stopped out the violet.

In performing this experiment, it must clearly be understood that equal illumination is absolutely essential, and, if the glasses are not correctly chosen, it may even be necessary to reduce the illumination of one lantern to make up for it.

The remaining method of showing the formation of colour is by means of the polariscope and mica or selenite films, but the apparatus for these is so costly, that it is, as a rule, beyond the reach of most would-be experimenters, though, if the apparatus can be hired, by all means get it. PHAROS.

SOME ODD DODGES IN LANTERN-SLIDE MAKING.

But very few lecture sets will be met with that do not contain some subjects that have to be copied from either an old wood-engraving or the more recently produced process block picture, and when either of such illustrations fall to be photographed for the purpose of making lantern slides, some special method of undertaking the work must be resorted to, so as to avoid an unpleasant coarseness of many portions of those parts represented by bold lines or strokes, as in the case of any ordinary wood-engraving, or by the magnified dots in the case of half-tone pictures taken by means of a ruled screen when such are projected in an enlarged form by means of the lantern.

As I write, I see before me a very pronounced type of such in the instance of an old wood-engraving executed many years ago, but which is of especial value as being the only available illustration of the kind possible of attainment for the purpose required in the lecture. In examples of this kind it is by no means uncommon to find cloud effects represented by bold strokes or lines which as a rule offer no appearance of incongruity when viewed in conjunction with the rest of the picture in its original form: but these bold strokes or lines appear quite different when thrown upon the screen in an enlarged form.

The practice of obliterating these strokes or lines by means of a wash colour has sometimes been resorted to, but it will be quite obvious to many that but very few examples will ever be placed in the hands of a photographer upon which such a liberty would be permitted as the doctoring of the face of a highly valuable picture, not unfrequently met with in books or other bound forms, by means of a colour wash applied with a brush, even although such may be partially, if indeed not entirely, removed eventually by means of sponging such parts as have received an application of such colour wash.

Doubtless there are many other instances of pictures of the penny-dreadful class where such a method of treatment may be followed, and when such is applied skilfully and a judicious amount of positive retouching or working up of the surface has been resorted to, a marvellous improvement in the appearance of the original will have been produced, and this is reflected in a like manner when the lantern slide from same comes to be received upon the screen.

Such liberties, however, can be but rarely taken with many of the illustrations of the better class that are frequently presented for the purpose of being copied, so that in very special cases some workers who never object to expend either time or money on their work, but whose one object is to secure the very best results, no matter what amount of time or labour such entails, think nothing of first copying examples of the kind mentioned without any preliminary touching up on the original, the negative obtained from such being printed in the ordinary manner on a suitable paper specially selected to permit of colour washing being performed, a plain salted silver paper or platinotype being very suitable to employ.

Having now a duplicate of the original they are in possession of a print that may be treated to any amount of improvements by means of the lead pencil or colour wash, or both combined, and, when such a mode of treatment is conducted by any one possessed of a little experience at the work, it is really marvellous what an amount of improvement can be effected in this manner.

In many instances, however, it will be found that a very much similar effect can be produced in a much simpler way, and one whereby the necessity of making a duplicate print is avoided.

Many years ago there was a good dodge known to some old collodion workers, who at that time had a complete monopoly of the trade in lantern slides; but then these were the good old days of remunerative prices for such work, and this, as a natural consequence, led to more pains being taken to turn out slides of the very best quality by means of the wet-collodion process. In those days many special slides were paid for handsomely, often to the tune of five shillings each, and, of course, there was an inducement to expend some skill and labour on their production.

But with the present prices, when so many are gasping for orders at the paltry price of sixpence a slide, is it any wonder that many of the old collodion-slide makers keep their experience up their sleeves?

What can any one be expected to produce for the present prices in the way of such slides as I am considering? There is certainly no inducement to expend anything but the merest ordinary amount of labour for such a paltry remuneration, unless it is desired to work at a loss.

No doubt, to a very great extent, lantern-slide making may be said to have passed into the hands of amateur workers, who, owing to the great excellence of the modern lantern dry plate, find the production of lantern slides an operation of much simplicity.

Not so in the good old wet-bath days, when every slide was looked upon with pride as a production entailing an amount of care and experience entirely unknown to ninety-nine out of every hundred who now make a slide.

Is it any wonder, then, that many of the little dodges known to special slide-makers are fast being lost sight of entirely?

I have said that in many cases subjects will be met with that can be treated in a simpler way than by requiring to make duplicate prints first, and then afterwards colour washing, so as to convert lines into tints.

One of the good old dodges applicable to this special class of work consisted in copying such subjects through a fine quality of ground glass.

To many workers of the present day, who think they know all about lantern-side making and copying, such a statement may occasion doubt and surprise, and by some even be considered as nonsense. To those, however, who know nothing of this old slide-making dodge, I would suggest that they simply view the effects produced by placing a sheet of ground glass over a line engraving.

It won't take long to open the eyes and convince a clever worker that underneath this little dodge lies a world of power they never dreamt of; for, by a careful manipulation of the ground glass by means of oil or glycerine, quite startling results in the way of vigour in some parts, and softness in others where the glass has not been so treated, is obtained.

Of course, there are different qualities of ground glass, the finer the grain the better the results will be when used in this work, and the ground side must be placed against the surface of the engraving; as a general rule, however, the quality found in focussing screens in good cameras will be quite suitable to employ for this purpose.

Any intelligent worker will readily conceive the best manner of marking or oiling those parts it is desired to yield the utmost amount of vigour, for, by merely placing the glass over the picture, the outline of such parts may be traced on the smooth side of the glass by means of common writing ink having the addition of a little gum or sugar, and then applying underneath these parts a little glycerine and water or oil.

To those workers who are in ignorance of these simple little dodges quite a new field will be opened up in lantern-slide making.

T. N. ARMSTRONG.

COMPOSITION AND COLOUR; OR, PICTORIAL POSSIBILITIES IN LANTERN SLIDES.

[Journal of the Society of Amateur Photographers of New York.]

When that ill-natured fellow, the art critic, wishes to say something particularly mean about a carefully and conscientiously elaborated

painting, why does he sum up his contempt in the word "photographic?" Is this use of the term as an expression of reproach justified? Is photography, viewed from the art standpoint, something wholly bad? We hear of "the art of Painting" and of "the art of Photography." Has one of these professions an exclusive right to be called "art," and should the other more modestly style itself a "trade" or "manufacture?"

We term the products of all the graphic processes pictures, whether produced directly by the trained hand or through some mechanical means. In a more special sense, the painter claims the term *pictures* for his works alone, and will not admit mechanical transcripts of nature to have any right to the same title. It is with this special, this artist, sense of the word picture, that we have to deal. If we determine what a picture is, in the artist sense, then it follows that the means by which it is produced is entitled to be called *art*.

I think that I may safely beg the question that "hand painting" is not necessarily art, and its products not necessarily pictures. But there is hand painting and hand painting, and, if technical skill alone is made the test, where shall the line be drawn between pictures and daubs? Setting aside the question of colour, it must be evident that in mere correctness of draughtsmanship the best hand work can, at most, only equal the best photograph. Technical skill is admirable, it may be wonderful, and without some of it the making of a picture is impossible, but technical processes alone will not make a picture. The reason that one canvass interests us only long enough to admire the evidence of study and training, while another chains our attention and makes us forget all about paint and methods while we dream over it, this is what we are seeking, this is the reason for limiting the term "picture" to works having certain qualities.

A picture should reveal something more than the mere superficial shell of things; it should contain a personal element as well, showing the emotion or mental attitude of the artist with regard to his subject.

Place two painters before a scene, say an old building. One will paint a poem which will make the beholder feel the history, the joys and sorrows of those who lived and died there, and breathe the very atmosphere of the place. The other will paint bricks and mortar, and cracks in the bricks and stains on the mortar. Set up a camera and you may get more cracks in the bricks and more stains on the mortar, if that is what you want. And this is what the art critic means when he calls the painting of one of these men "photographic." It lacks the personal element, and displays only the technical, which the photograph can do just as well. The critic implies, however, that the photograph cannot embody any of this personal element, and that its production is not entitled to be called art in the same sense that a fine painting is. In this assumption I cannot quite agree, though I must allow that he has much apparent reason for placing a low artistic estimate upon photography. Photography cannot embody the personal element, or translate the artist's feelings towards nature to the same degree that painting may, but I believe that it can still embody enough of this quality to produce true pictures, and thus to be truly a fine art. Art, of whatever kind, is the expression, the embodiment, of human thought. What are called the "fine arts" express the higher thoughts or emotions. Emotion may be fully rendered only by music. The capabilities of painting come next, where the colour element has full play, and all the graphic arts may incorporate more or less of this human soul quality which makes the difference between true art and dry collections of graphic data.

Photography, as practised by Robinson of Tunbridge Wells, England, and Sarony of New York (to name but two in original lines out of many noted names on both sides the ocean) often succeeds in attaining a real art quality; but, as practised by the professional who makes cabinet portraits at ninety-eight cents a dozen, with a life-size crayon and frame and picture wire and screw eyes thrown in, or by the amateur who goes about pressing the button of his Kodak a hundred times a day, it *sometimes* fails in reaching the art standard.

"You-press-the-button-and-we-do-the-rest" is often followed far too literally. The "rest" that is left to the professional is frequently expected to cover nearly the whole ground, and to make up for all sorts of deficiencies, ignorances, and carelessness. The most important part of making a photographic picture is the part done before, and at the time of, pressing the button; selecting the subject, getting the best view, and the most effective light; including the right amount of view, and giving the proper exposure.

Painting, at present, is certainly much indebted to photography, however reluctant she may be to admit it. Through photography and reproductive processes dependent upon it, copies of good pictures have been multiplied, and the public eye and taste are being educated to a degree which without such aid would be impossible. And there is no doubt that, on the side of good draughtsmanship, art has profited by comparison of her lines with the accurate tracings of the sun. Photography, on the other hand, is wholly indebted to the older art for there being any such thing as making pictures, and for all the ideas of structure or composition that go into them. She should not, because of her unsurpassable accuracy of delineation, disdain to learn of her big sister all she can, so that eventually her name cannot be used as a reproach to hard-and-dry productions of paintcraft.

In science, photography has accomplished wonders, both of discovery and record, which place her among the foremost of modern agencies for the advancement of knowledge. She has pushed discoveries in astronomy far beyond the power of the human eye to perceive, even when reinforced by the most distance-piercing telescope, and she has recorded another universe of facts moving in spaces too small for the unaided eye to find. We know not how near she has come to reaching the outermost bounds of space, nor to getting down to the ultimate atoms of matter; but we do know that she has contributed much to every department of science. If she has advanced but slowly over the threshold of the Temple of Art, before whose portals she first saw and used the light, and to whose service she first offered her powers, is not Art herself somewhat to blame? She turned a very cold shoulder upon Daguerre's child, fearing it would grow into a formidable rival. But photography has now grown up and has never harmed the Muse of the palette and paint rag. In the matter of portraiture, where rivalry was most feared, the Muse has certainly gained appreciation of the fact that the owl eyes and pussy cat mouths, and insignificant hands and feet which were so much admired by our ancestors are never natural or beautiful. For this service alone, photography is entitled to all possible help in the art of seeing and representing things broadly and grandly, and arranging her subjects in accordance with the principles of æsthetics.

In the past, photographic art has been handicapped by defects in the process and materials. Until recently it was impossible to render true colour values, and almost impossible to avoid a certain exaggeration or intensification of detail, trivial minutiæ which very seriously militated against æsthetic breadth.

For the benefit of those who are not photographers, I will explain that "colour values" are the degrees of brightness or darkness in the various hues of nature. If we call black zero and white 100, then a light sky blue might be about 80 in the scale, and a brilliant orange the same, while a deep blue might fall at 50 or 25. With ordinary photographic plates these values come out reversed. The light blue will be the same as white or 100, the deep blue about 80, and the orange, which should be the same as the light blue, will appear as a dark grey shade of only 25 degrees of lightness, or perhaps almost black. From this fact and from the intensification of detail, already mentioned, and which depends partly upon chemical action, come the well-known phenomena of freckles and deep wrinkles in fair young faces of sixteen to ninety-six summers, and which are corrected by the much-abused art of retouching.

With the new orthochromatic or true-colour-value plates it is now possible to come fairly near a literal translation of nature's colours, and with the study of art principles by photographers we may expect sun painting to take its place as a recognised medium of artistic expression.

A mere collection of graphic materials is not a picture. Things without coherence or mutual relation form only chaos. A picture requires a definite plan, an harmonious arrangement of its parts. Nature may furnish the arrangement or the artist may evolve it. It is almost impossible to find a spot from which some picturesque view may not be seen; yet it is equally impossible to find a spot from which every view or segment of the range of vision shall be picturesque. Here lies the source of much failure in photography, and in painting as well. It is assumed that nature's combinations are always in pictorial form, no matter how viewed or how segregated.

I can give here but a few hints and suggestions upon a subject of endless extent; but the underlying principles are simple, and the artist, once upon the track, finds the application of constantly increasing interest. It is in the hope of stimulating some to study the bringing of art principles into their work that I touch upon a few points which are probably familiar to many of you.

Of the two ways of publicly exhibiting photographic art, the hanging of paper or other prints from negatives, and the projection of lantern slides, the latter is by far the most effective and impressive, by reason of magnitude and brilliance, and the most popular. It is especially the artistic side of lantern photography as distinguished from its scientific aspects and uses which we will consider.

The picture shown on the screen, from an old painting in the Louvre, is one of the most artificial arrangements ever put upon canvas. It was painted by Boucher, the Court painter of Louis XV., and like everything else in that period of gilding and affectation, is an elegant trifle, a design

suitable for a Court lady's useless fan. The swain and shepherdesses are masqueraders; the scenery is theatre setting. The artist never looked out of doors for a single detail. Yet this artist was, in his way, a genius; in fact, he was called the Raphael of his age; and he understood composition, so that, in spite of the artificiality and crowded frivolity of his pictures, they always continue to charm the eye. There is a grace, a suavity, an air of distinction which marks them off from many other works of much greater sincerity but poor construction.

Composition is, if you please, an artificial affair, yet it is all based upon natural laws, deducible from natural arrangements, and even reducible to mathematical formulæ, and we know that dry mathematical statements are the nearest approach possible to the eternal verities. So we will start with the proposition that pictorial composition is the coherent expression of pictorial truth, standing in the same relation to graphic art that grammar does to language. We may, indeed, contrive to express our meaning by uncouth sentences or even by grimaces and noises, and we may also utter polished phrases conveying no particular meaning, but these facts do not weigh against the general necessity for good forms of expression.

The eye receives, as well stated pictorial truths, impressions conveyed according to definite rules of *contrast* governed by *balance* and resulting in *unity*. A single apple is interesting in contrast with something else for a background. It would not be interesting if all around it was apple, indefinite apple. But the single apple hardly forms a composition. It has unity, it is true, but only that of the undivided. There are no parts to interest with their mutual relations, so a mere glance is all that it can claim. Two apples, just alike, are much more entertaining. One is compared with the other, they are equal, they are spaced equally against the background, they balance, they are in unity of exact similarity, they are irreproachable. Why, then, does the eye soon become as weary of them as we are of "the Heavenly Twins?" They lack the chief element of interest, mutual contrast, that unlikeness which goes near the danger line of discord, yet is brought back and harmonised by some common element of likeness. Alike, yet not alike similar, yet unequal, such is the law of contrast that makes the unity of lovers so much more interesting than the likeness of twins. We note the same with the single post the twin posts united by a lintel, and the enhanced interest given by setting them in perspective, or by making one shorter and letting the lintel become a sloping roof, thereby bringing in additional elements of contrast, kept in harmony by the elements common to both.

Radiation is a principle of widest extent in both natural and ornamental plans. Throughout the mineral, vegetable, and lower animal worlds it directs the organization of crystal, flower, and sea star. It represents the energy of the sun, the source of light and of physical existence, and on radiating lines move the centripetal forces which bind the universe of worlds together. Pictorial construction may follow various plans, horizonal or upright bands, diagonal or curved forms, for its chief masses, yet the radiating principle, or, as I prefer to call it here, the principle of convergence, is rarely absent, and frequently forms the whole skeleton of the picture. All perspective views and vistas, like streets and ravines, are based upon converging lines. Such may have the lines actually expressed, forming the most powerful means in the anatomy of the picture for conducting the eye to a focal point. More pleasing is the curved convergence of a country road or winding beach. The lines of convergence are often latent, not expressed, but just as powerfully felt. It is of great interest and value to trace this principle in the figure compositions of the great masters, and to discover the order with which the apparently careless crowds are placed, both in ground plan and perspective, so that the eye will be led to the figure of central importance.

There are thousands of pictures made on the idea of two opposing masses with an opening between Though the arrangement is easily effective, yet it is always in danger of looking stiff and set, like the conventional wings and back scenes at the theatre.

Observe the grace with which Corot composes! In the picture now on the screen (*A Landscape in Picardy*) he gives us contrast in the trees by perspective, contrast again between the forms and textures of trees, cottage, grass, and sky. See (I had almost said hear) the echo of the near cottage in the distant one at the left! Varied repetition is among the chief means of securing harmony. Weigh the beautiful proportion between the two open spaces, between the three principal trees, and the little round dark tree balancing, yet contrasting with the peaked roof. The flow of line across the picture is like the dip of a swallow's wing, and the arrangement of the few elements in this harmony of line and mass seems to me quite analogous to a chord of music.

Good composition will always show a predominance of one kind of line, one kind of mass, the value of which may be greatly enhanced by a contrasting form in harmonious combination. The triumphal arch of Titus has stood for nearly 2000 years as the best model for similar constructions, as well as mantels and doorways, the world over. Simply a well-proportioned rectilinear mass, pierced by an opening, arched to support the weight above, and (incidentally, perhaps, but beautifully enough to form a reason for being) ornamenting the mass by its contrasting line.

The eye is caught by salient points, and it is of great importance that the lines connecting these (which the eye feels, although they are not expressed) should fall into agreeable forms. You will find this principle observed in all well-composed pictures.

Dark spots against light are the rule out of doors, the reverse or "Rembrandt" idea being most available for interior effects.

There is a horizontal arrangement which has been very popular of late years, flowers, &c., being strung out and named with such fetching titles as *A Yard of Pansies*. This is a good decorative idea when not abused.

If the objects to form a picture are all massed on one side or down at the bottom, balance is lost, and unity with it. Balance may be attained, however, by a small telling object opposed to a large mass, on the principle of the small weight at the end of the long steelyard arm balancing the heavy one on the short arm. The eye mediates between the two, and accepts the centre of gravity as a focus. A common error in photography is leaving too much blank sky above a landscape.

Sometimes we find a square composition in a round frame. This never works. Curve goes in curve, and curve will go in rectangle, but rectangles are uncomfortable when forced inside of curves. For this reason, tangency, springing out from the main line by gradual change from straight to curve, is a law of natural growth, giving both strength and grace. But the abrupt change from curve to straight line is unnatural, ungraceful, and weak.

Including too much with wide-angle lenses is another pictorial error. Photography is capable of making, or of marring, in this and in a dozen other ways.

The association of integrity with uprightness is no mere figure of speech. The piers of the Brooklyn Bridge carry the enormous weight of steel cables and loaded roadways as easily as a fence post sustains a cobweb. Their form is in the highest degree dignified and impressive, declaring in the strongest terms that the law of gravitation will hold them in place after the mountains themselves are degraded. Horizontal and vertical lines give stability and repose; on these the eye rests. Oblique lines are elements of unrest, and should be used to conduct the eye to a point of repose. For this reason, lines leading out of the picture are bad, and, if possible, should be avoided. The horizontal line, being a line of repose, should only cross the picture, unbroken, at the horizon or distant limit of the scene.

We must be careful of our accessory figures, and not commit the fault seen in the slide now shown. Here the interest is evenly divided between the boat, and figures, and the beautiful landscape. The figures are too important for mere accessories, and the landscape setting is altogether too much for a mere background. As we cannot get rid of the boat and figures from our negative, the only thing to be done to preserve unity is to sacrifice the greater part of the landscape, leaving only enough to be subordinate to the human element. This might have been obviated by a little forethought in making the camera shot. How many inartistic things we see perpetrated in this way, such as the tramp "artist's" views of houses with the inmates all stuck out in front staring at the camera. When we are photographing the principal business street of a town, it is not necessary to call out all the prominent citizens to form a foreground.

We should be sure of our subject, and then get it up into the position of honour, where it will be estimated for something of value. Turner is said to have sometimes diminished subordinate objects in order to give greater importance to his main feature. Photography can hardly do this, even if it was desirable, but by judicious contriving it can usually get things in artistic shape. In the studio the artist can pose his subjects and compose his picture. Out of doors, he can arrange things only to a very limited extent, in the near foreground. Here he must search carefully for the effective point of view, and wait for the artistic moment of light and shadow.

One should not imagine that the setting upon a pedestal alone confers dignity. The subject must be worthy of the honour; otherwise an anti-climax is produced.

Good art discovers and develops the characteristics of its subject along orderly and harmonious lines, carrying the interest unmistakably to its strongest feature. Good art feels its own capabilities and recognises its limitations. When Leland T. Powers impersonates Uriah Heep, the

characterisation impresses us as in every way admirable. He knows his subject, and he knows his field of work. He is a success. When some barn-stormer essays Hamlet, we feel, as he "tears passion to tatters," that an artistic crime is being perpetrated.

Few writers can produce grand epic poems. Few painters can handle heroic subjects. The majority must develop the possibilities of the idyl, the pastoral, and the *genre*. A. G. MARSHALL.

(*To be continued.*)

A LANTERN WORKER'S WOES.

A LANTERNIST'S lot in life is like the course of true love—it very seldom runs smooth. It has often been remarked that experience teaches, but, if it is true, as has also often been remarked, that only fools will learn by their own experience, it follows that wise men depend for their wisdom upon the experiences of others. Without wishing in any way to set myself up as a guide and philosopher to even the most incipient wisdom of budding lanternists, I think that to chronicle a few of the rugosities which have from time to time materialised upon my path may, perchance, help to smooth over the course of other true disciples of the "Optical, but ever Magic."

I must apologetically premise the remark, however, that the cause of the mishap has not always transpired, and so, from a teaching point of view, the value of the experience is somewhat marred by the fact that the causes which led up to the *contretemps* are buried in oblivion. For instance, there was a peculiar little explosion which occurred at a lecture under the auspices of the Young Men's Christian Association. I do not know how it is—please do not take it as an implied disparagement to a most excellent institution—but I have never yet conducted a lantern show at a Christian Association, either male *or* female, that *something* hasn't gone wrong. On this particular occasion the lantern, a biunial, had been tried, and found not wanting, the oxygen had been turned off at the cylinder (I was using mixed jets), and the hydrogen turned down to a little bead of flame, to keep the lantern warm until the appointed time should have arrived. The audience—consisting, of course, exclusively of young men of all ages—had taken its seat, or their seats (which should it be, Mr. Editor?), and I was sitting quietly by the instrument, trying to look as if I did not belong to it, as is my wont, for I am a very unostentatious person. The chairman had risen to open the proceedings with prayer, for it is customary in these places to ask a blessing upon the chairman, the lecturer, the audience, and all others gathered beneath this roof, which last, I believe, means the lanternist—it always makes me squirm. The audience had leant forward in an attitude of reverence, and buried its faces in its hats, which had been removed from its heads for that purpose, and all was as silent as the tomb, save for the "cracked, monotonous mutter," as Dickens calls it, when there was a sudden terrific bang from the lantern. The chairman sat down, the young men sat up, and I blushed, though it was not my fault. The noise was caused by a small explosion which had occurred inside the indiarubber pipe leading from the oxygen cylinder to the jet. Now, the two gases must have become mixed in that tube somehow; but how? that is the question. I have vague suspicions regarding a possible leak in the dissolver, but even with that clue the matter remains a considerable mystery. As to the force of the explosion, there can be no doubt. A piece of the rubber tube, about the size of a half-crown, was blown to the other end of the hall, and its natural curvature was entirely reversed; that is to say, the little piece, when picked up, was permanently curved, so that what had been the outside of the tube was now the inside of the curve. As for the remainder of the tube itself, that was quite unaffected, except just at the place where the explosion occurred, and here there was a clean cut hole, as if the piece of indiarubber had been punched out with an oval-shaped steel punch. Of course, it did not take long to remove the faulty place and couple up the rest of the tube by means of a piece of metal pipe, and the performance went off all right, but I always tremble through the preliminary prayer now.

Much more easily explicable was a mishap that befell me, at a Young Woman's Christian Association, some years ago. This time it was in the middle of the performance, which, up to the critical moment, had been "going swimmingly." The first intimation that anything was wrong came in the shape of a sudden "dousing of the glim." The hydrogen had apparently entirely come to an end. The young women smiled, and the lecturer paused, and then asked sweetly what was the matter. I shut off both taps at the jet, and told him as quietly as I could that there was no more hydrogen. This brought him down to the lantern pretty quickly, and the young women tittered. Then he just turned on the hydrogen, and lighted it, and followed with the oxygen, and all was apparently perfectly right. The young women laughed, but the lecturer didn't say anything to me; he just *looked*, and I felt moderately cheap. However, he had scarcely got back to the platform when the light went out again just as before, to the great delight of the young women. This time all our efforts were unavailing, and we were obliged to call for "Lights! lights!" The discreet reader may think that the sudden stoppage of gas was caused by one of the young women surreptitiously pinching the tube, but let me at once clear their characters of that charge. It occurred in this wise: The coal-gas cylinder had been charged for some time—about two months, I think—and the result was a plentiful deposit of a thick, sticky fluid, very much like Stockholm tar, but of a much more evil odour. The cylinder was lying on its side while being used, and some of this fluid had found its way into the aperture, and stopped it up. So we removed the regulator, supported the cylinder in a vertical position, nose downwards, and gradually opened the valve, the young women watching the operations with keen interest. At first nothing occurred, but presently, when the valve was moderately wide open, a quantity of this tarlike fluid was suddenly ejected, and then the gas followed with a roar. The young women shrieked, the valve was turned off, the regulator replaced, and all went on again as merrily as a marriage bell. But ever since that day, whenever the coal gas has been long bottled, I blow out the tarry deposit before commencing the show, and I always work the hydrogen cylinder in an upright position. *Verbum sap.*

Limes are a fertile source of trouble, at least so I find them. Their strong affinity for moisture constantly leads to difficulties; but, as that is a well-known characteristic of all limes, it can be more easily provided for. Soft limes are, as a rule, pretty well made, but that cannot be said of the hard limes, which are necessary when using a powerful mixed jet. For instance, the central hole is very seldom in the centre, and in consequence, whenever the lime is turned, its distance from the jet nozzle has constantly to be adjusted. Then this hole is nearly always choked up with lime dust so tightly that it takes some minutes to clear it out, and this occasionally comes very awkward, as, for instance, when I got hold of a box of "hard" limes, which were not nearly hard enough. Under the action of the jet, these became pitted at such an alarmingly quick rate that I used up nine of them in the course of an hour's show with a double lantern. I was fain to ask an obliging member of the audience to clean out a supply of fresh limes for me while I was attending to the lantern, where a new lime was required almost as soon as he could get it ready. As he broke three of the limes in attempting to clear them, I felt very much relieved when the lecture came to an end, just as I was getting uncomfortably near to the last piece of surface of the last lime.

On another occasion, a small piece of incandescent lime became detached and fell right out of the lantern into the box in which the gas cylinders were, and immediately set fire to a quantity of loose paper which was used to pack the regulators in. Such an incident as this might have led to serious results, for a considerable amount of flame and smoke rose from underneath the regulators before I had time to crush out the fire. If, for instance, the indiarubber tube from the oxygen bottle had been burnt in half, it would have been a very difficult matter to crush out the flames when fed by a plentiful stream of pure oxygen, while the attention of all in the room must have been called to the scene of the disturbance by the sudden failure of the light in the lantern. Even as it was, there was so much smoke and flame that a panic might easily have resulted; but happily the large audience was either a very phlegmatic one, or it was deeply interested in the lecture, and no notice was taken of the episode.

A very curious mishap befell me once at a large London institute where I was operating a biunial lantern with mixed jets. It was at about the twelfth slide that I thought the light in the upper lantern seemed hardly as bright as it had been, and I turned on a little more of each gas. After a few minutes, however, the light began to get distinctly less, and it continued to diminish until it was of less than a quarter the intensity it had at starting. Meanwhile the light in the lower lantern was as good as ever, so I decided to use this singly, and shut off the upper lantern altogether. Judge of my dismay when, after the lapse of about ten minutes, precisely the same thing began to occur in the lower lantern. To cut the matter short, it ultimately transpired that the nozzle of each jet had become stopped up by an internal deposit of some substance unknown. Of course, as soon as this discovery was made, it was easy to remove the obstruction by means of a pin, and to continue the performance again, but it was some little time before I did discover it. And I do not feel at all certain as to the cause of the trouble, though it would seem that the aforementioned tarry constituent in the compressed coal gas had something to do with it, for the hydrogen cylinder

had been charged for some considerable time before it was used at this performance. It is quite conceivable that, under certain conditions, the intense heat which the gas meets with at the nipple of the jet might induce it to deposit one or more of its various constituents, which hitherto had been held in suspension. There seems to be no doubt that compression has a modifying effect upon common coal gas, and that, if the pressure be maintained for some weeks, a point is reached where some of the hydrocarbons, which give it its illuminating power, will become separated from the hydrogen, and be deposited in the form of a thick brown semi-fluid substance upon the sides of the containing cylinder. Now, it is quite possible that, in the above-cited case, the coal gas had *almost* reached the age when deposition of tarry constituents should occur, and that the heat of the jet had hastened the process which was just ready to commence, and caused the tar-like substance to be deposited inside the intensely hot nozzle, where the liquid would naturally be quickly converted into a cinder-like solid. But this is all theory and guesswork on my part. The practical point is that, forewarned being forearmed, the lanternist should defend himself against such a disaster by means of an ordinary pin.

Many and various are the mishaps that have befallen me owing to the vagaries of the British working cabman, the moral of all of which is, Never trust a cabby to turn up at the appointed time. He may mean well perhaps—very likely he does—but his good intentions are easily upset by small things. I have known a cabman to stop away because it was a bit colder than he liked, and I have waited perhaps half an hour for him, and then been obliged to fetch another cab, altogether making me about an hour late at the hall, which means hurrying considerably to get things ready in time for the performance. The railway companies, too, are not altogether blameless in this connexion, or, perhaps it would be more fair to say that the South-Eastern Railway Company is not blameless, for on one occasion they very nearly got me into a terrible scrape. I had a lantern show at a small town in Kent, about twenty miles down the line, and the hall was three miles from the station. The train was timed to leave Cannon-street at 3.35, and I was at the station with the apparatus about twenty minutes before that time. At 3.45 they were loading the luggage van with fish packed in boxes, and nothing could persuade them to put my apparatus in first. At 3.47 the last box of fish and the lantern box had been placed in the van, when the station-master, who all this time had been growing impatient—for twelve minutes late in starting is a good deal, even for the S. E. R.—gave the signal, and the train began to move out of the station. I had just time to snatch up the two boxes containing the sheet and the slides, and other paraphernalia, and rush after the disappearing train, and jump into the van, before a porter bolted the door on the outside, so I was alone with my misery (and the fish), and the gas bottles were left behind. I was released, on arriving at my destination, just in time to telegraph for the bottles to be sent on by the next train, and I had to arrange with the fly proprietor to take me to the hall and come back for the gas cylinders. In the sequel, they did arrive all right, and in pretty good time, but it was an anxious time for me until I got my two "babies" safe in my arms.

These same "babies" nearly got me into a somewhat similar scrape at another big railway station. It was just after the famous explosion at Fenchurch-street Station, and, for the sake of argument. I had packed them up together in a travelling case, in the fond hope that they would pass the official eye as a change of raiment. As a matter of fact, it did pass the official eye, but, when the official came to lift the case, he speedily came to the conclusion that "this 'ere couldn't be personal luggage." We argued it out, but he suddenly tested the matter by *weighing* the trunk, when, to my horror, it turned the scale at over a hundred pounds. However, I soon saw that what the man wanted was a little of that key which unlocks most doors. He got his backsheish, and I got my babies, but it was a bad half-minute when they were put into the scale and found wanting, for I thought they would be taken from me, and that I should be left desolate. "Verily the weigh of transgressors is hard." C. Milton Haydon.

THE DANGER IN THE USE OF FLASHLIGHT POWDERS.

Caution may be mistaken by some persons for timidity, says Mr. W. M. Stine, in *Anthony's Bulletin*, while confidence may seem to bespeak familiarity and practical knowledge; but there are many cases in which such erroneous ideas lead to disastrous results. This is emphatically true, both of the preparation and use of the various flashlight powders. Perhaps too scant attention has been directed to such dangers, and frequently one sees formulæ, which the chemist would regard as highly dangerous, given without a word of caution. Not a few of the flashlight compounds may be classed as high explosives, while it may safely be said that the operation of every flashing device, except the electric spark, may be considered as an explosive. Caution, then, in the use of such substances is highly commendable.

The danger is by no means confined to the ranks of the amateur photographer, for experience has shown that the scientist and practical photographer are not exempt. The experimenting habit is strongly developed in the amateur. When he desires to use a flashlight he will frequently consult a book of recipes and formulæ, or the files of some technical journal, for directions to enable him to manufacture his own compound. While the spirit of experiment is a laudable one, in this case it is to be condemned, unless the experimenter be thoroughly versed in chemistry. It is a safe rule to allow the chemists to do all the experimentation, and purchase the flashlight powder already prepared. One may safely add that precautions cannot be too strongly laid down in the circular of directions accompanying such preparations; and it might not be amiss to suggest that the periodicals and journals always accompany a flashlight formula with the requisite precautions.

The base of such preparations is usually either potassium chlorate or nitrate, to furnish the oxygen to combine with some highly oxidisable substance, such as some metallic sulphides or phosphorus. These substances should never be triturated together in a mortar. Each should be separately ground in a clean mortar, and the mixing be effected with a spatula, and done gently, to avoid heating by friction or blows.

In Chicago alone, in the past few months, the flashlight has been responsible for several bad accidents. In one case a professional photographer was mixing a large quantity of powder, as he was in the habit of making up his own preparation. It accidentally exploded, and partially wrecked the studio, and set fire to the building, besides burning the operator very seriously.

A case within the experience of the writer may be cited. Several years ago, a professional chemist was experimenting with a view to develop a slow-burning flash powder. A compound of powdered magnesium, potassium chlorate, and sugar was used. This gave excellent results, but yielded too much smoke. On one occasion black sulphide of antimony was added, to increase the intensity of the light. While firing a charge the experimenter burned his right hand very badly. The addition of the sulphide caused such a rapid explosion that the flash spread laterally, owing to the cushioning of the air. Such powders can only be fired with safety by the use of a torch or fuse.

Mr. Frederick Wilhoit has kindly furnished the writer the particulars of an accident which recently occurred to him. He states that he had been using a flashlight powder which, when fresh, exploded rapidly and was almost entirely odourless. The powder was made according to the formula:

Chlorate of potash	1 ounce.
Powdered magnesium	4 drachms.
Amorphous phosphorus	10 grains.
Black antimony sulphide	20 ,,
Golden antimony sulphide	10 ,,

This powder deteriorates rapidly, owing to the phosphoric acid contained in the phosphorus. The acid may be removed by washing. On this occasion he had washed some phosphorus and dried it on filter paper, while he was preparing the other chemicals, sufficient to make 1½ pounds of the powder. The requisite weight of the dried phosphorus was placed in a brass sieve, and, while sifting this into the chlorate of potassium, it suddenly ignited, setting fire to the entire mixture. A violent explosion followed, throwing the sieve out of his hands, and the burning mixture over his face and clothing and on the floor. Fortunately he was able to quickly extinguish the flames on his clothing and the floor, but his hands and face were severely burned by the explosion. These accidents are typical of experiences that are only too common. Some photographers, for such reasons, abstain from the use of all explosive compounds, and prefer to depend for a flashlight on magnesium powder burned in a flame. W. M. Stine.

MOËSSARD'S APPARATUS FOR VIEWING STEREOSCOPIC PICTURES.

This invention enables persons assembled in a lecture-room or theatre to see from their places, with all the appearance of relief, ordinary stereoscopic pictures projected by a lantern or lanterns, on a white screen, or otherwise exhibited by known means, so that every one can see them at the same time instead of each one having to look at them separately, as when looking through an ordinary stereoscope.

For this purpose each person is provided with a special glass, either binocular or single, by looking through which the two pictures can be caused to blend as they do in a stereoscope, so giving the required effect.

An advantage of this means of viewing stereoscopic pictures is that they can be placed one above the other, instead of side by side, and can consequently be made of considerably greater length.

The special binocular or twin glasses for viewing the stereoscopic pictures are provided with two similar prisms, or with mirrors, for causing the pictures seen by the two eyes to blend together. The prisms, whose faces may be inclined at about 10° to each other, are held in tubes suitably connected by double rings. They are provided with means, such

as teeth, or slotted arms, for rotating them simultaneously in opposite directions through 90°, so as to suit for pictures placed side by side, and to cause the pictures to blend properly. If the pictures are placed one above the other, then one of the prisms requires to be turned upside down, or end for end, to facilitate which it may be mounted in a ring capable of turning in its place with a certain amount of friction through 180°.

If mirrors are employed instead of prisms, they are arranged in pairs in front of each eye, one of each pair being arranged to move or partially rotate.

The mirrors are so arranged that the image of the picture is seen after being doubly reflected. When the pictures are arranged side by side, the mirrors are upright, and one pair is inclined towards the other pair. When the pictures are superposed, the mirrors are inclined to the horizontal. In the latter case, a single long mirror may be employed in combination with two short movable ones to give the double reflection.

The special single glass is provided with only one pair of mirrors, and is intended to be applied to one eye only, so that, while this eye sees a virtual image of one of the two stereoscopic pictures, the naked eye sees the other picture directly, the two images blending and giving the stereoscopic effect.

To prevent the same eye seeing both the pictures, the glasses are provided with screens or stops for blocking out the picture which it is not desired to see, thereby confining the view of each eye to its respective picture, to avoid confusion.

When using mirrors, these may be made small enough only to reflect one picture, thus obviating the screens or stops.

The prisms give clear, bright images if their angle is sufficiently acute, but cannot be used very close to the screen or picture, whereas the mirrors are not open to this objection.

IMPROVEMENTS IN FLASH LAMPS.

Mr. A. A. Archer thus summarises the improvements he has patented in flash lamps for photographic purposes:—

It has been usual to charge the powder tube or basin of the lamp with the required amount of powder by hand after each flash, that is to say, after each exposure in the camera. This mode of charging is very inconvenient, particularly where a number of flash lamps are required, as, for instance, when it is required to light up a banqueting hall or large room.

Now, one object of my invention is to effect the charging of the powder tubes of any required number of lamps automatically and simultaneously by simply pressing a pneumatic ball or other air-propelling device. For this purpose I employ, in connexion with the powder tube of every lamp, a powder reservoir provided with a charging device which can be wound up or set, and which, when released by the action of a pneumatic ball, bellows, or the like, acts so as to deliver the required amount of powder into the tube through an opening in the side of same. The same pneumatic ball, bellows, or the like, can be connected with the charging devices of any number of tubes, so that the operator can charge the tubes of any number of lamps simultaneously from any convenient and prearranged part of the room. The charging device can be constructed in various ways. According to one construction, a cup or spoon is carried on the end of an arm, which can revolve on a horizontal axis in the powder reservoir. The device having been wound up, the pneumatic ball, when acted upon, releases it, it rotates once on its axis, and is then stopped by a catch. During the rotation the cup first scoops up powder from the reservoir and then delivers it into the tube, the opening of which may be fitted with a valve or slide that is opened and shut automatically; or a series of scoops or cups can be carried on an endless chain, like a dredger, and move to the extent of one scoop at every action; or the reservoir may be in the form of a hopper, the outlet of which is closed by a revolving wheel, having compartments that become successively filled from the hopper, and then discharge themselves into the powder tube; this revolving wheel will be wound up as above described, and revolve to the extent of one or more compartments whenever temporarily released by the action of the pneumatic ball.

Another object of the invention is to make the spirit lamp to be readily ignited from a small burner just before being required for use, so that it is not kept burning unnecessarily and proportionately consuming spirit. For this purpose I fit a small wick by the side of the main or large wick of the lamp, and I cover the main wick with a cap or other suitable cover, which prevents it from becoming ignited from the small wick. The small wick is ignited some time before the lamp is required for use. When the cap of the large wick is moved away, this wick becomes ignited from the small flame. The cap is preferably acted upon pneumatically by means of a bellows or other air-propelling device, which may be arranged so as to operate on the caps of any required number of lamps simultaneously, or the cap may be acted upon by a string or cord. The large wicks can be extinguished by returning the caps to position over same by means of the appliances that move them away from the wicks or by separate appliances. If gas be employed instead of spirit, there will be a small gas jet previously ignited and a bypass leading therefrom to the main burner, so that, when gas is turned on to the main burner, it becomes ignited from the small jet.

I preferably make the main burner, whether for burning spirit or gas, of oval or circular form, with two or other number of breaks in the circumference, for the purpose of admitting air for supporting combustion not only from the centre as usual, but also from the sides.

THE CROYDON CAMERA CLUB'S LANTERN NIGHT.

The Club's twenty-fifth public lantern show, held on Wednesday, the 25th ult., at Braithwaite Hall, was honoured by his Worship the Mayor of Croydon, who, with his usual untiring readiness to help forward all good movements, not only presided, but, in the interval, made a telling speech laudatory of the Club and its objects, in the course of which his Worship dealt upon various past advances in the improvements and applications of photography, and prophesied from the latter developments, such as shadowgraphy and cinematography, that an important and wonderful future was in store. Some timely advice of a humorous nature, addressed to the fairer portion of the audience, which caused much laughter, and a suggestion that the Club would find much fine subject-matter in the interior portions of the new municipal buildings, were, amongst other points, touched upon in the Mayor's address, which was punctuated by hearty applause by a densely crowded audience. The whole of the pictures (except six shadowgraphs, by Mr. Campbell Swinton) shown were the entire work of actual members of the Club, and as such afforded striking testimony to the talent and training of the members.

The series opened with an interesting set, illustrating the quaintness of the "two ancient cities" of Rye and Winchelsea, by the President of the Club (Mr. Hector Maclean), who accompanied the views with a pleasant ripple of anecdotal description. Several amongst the slides were warmly applauded, notably the little house which is the rural retreat of Miss Ellen Terry. Mr. A. W. Hirst followed with a splendid series of transparencies of the scenery and people of British India, from negatives taken by another member (Mr. Lucy) during a sojourn of several years. Mr. Hirst, who described the points of interest attached to the seventy or more pictures, is to be congratulated.

Next, Mr. Isaac, who managed the lantern, explained some thirty records of a holiday spent in Jersey. Many of these induced warm marks of approval, the snap-shots of the Corbière Rocks, with splashing waves and dripping streams of water, being particularly striking.

The popular Hon. Secretary did not belie his high reputation, but showed a number of Surrey and South Devon studies, which deserved, as they gained, high commendation. *Evening on the River Teign* was especially praiseworthy. Mr. J. T. Sandell's series of *The Palaces of our City Guilds* literally teemed with points of interest, and of surprising beauty of embellishment.

The President, who explained the two foregoing sets and all which followed, rightfully stated that a whole evening would not exhaust all that might well be said explanatory of the suggestive subject-matter of Mr. Sandell's slides, which formed another testimony to the advantage of a three-coated plate for the photography of interiors.

Mr. G. W. Jenkins contributed a score of well-executed illustrations of the picturesque portions of Maidstone and Seal, whilst Mr. Alfred Underhill showed a series characterised by great brilliancy and considerable charm. Some shadowgraphs by Mr. Campbell Swinton followed, and also two remarkable slides of a pair of scissors and some keys, which a member of the Club (Mr. Rogers) had obtained shadowgraphs of these had been enclosed in a package from which all light was excluded by means of six layers of various opaque substances. The strange fact is that no X rays were employed, but the package simply laid in a window for a few hours.

On March 23, Mr. W. Lamond Howie, F.C.S., lectured before the Lantern Society, his subject being what he called *The Scottish Alps*. This and the preceding demonstration of the New Photography, by Mr. Snowden Ward, have been the successes of the season; the interest excited was keen and sustained, the audiences crowding the meeting-room, at 20, Hanover-square, to its fullest capacity. The glen, river, lock, and mountain scenery of the western Highlands was illustrated by about 150 slides of the highest photographic merit. In appreciation of striking points of view, artistic grouping, and technique, Mr. Howie's photographs left nothing to be desired. The spring snows on Ben Nevis and other hills appeared on the screen with a quite startling fidelity to nature—peaks soared, precipices frowned, lakes mirrored their surrounding beauties, and over all were some wonderful effects of cloud and broken sunshine. The figure subjects were full of human nature—Highland lassies, peat-gatherers, fisher folk and cottagers, old smugglers, illicit still-keepers, and deer-stalkers introduced to the audience in Mr. Howie's own graphic and humorous style, increased the popular interest of the evening. The Highland castles and graves of the clans at Culloden added a touch of pathetic romance. The electric light, just presented to the Society by its Chairman, Mr. Vezey, was used in the lantern with the best results. Hearty thanks for the same were duly rendered to Mr. Vezey and to Mr. Howie for his in every way delightful exhibit and lecture.

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*May* 1, 1896.

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

Animated lantern pictures are still the rage, for not only are there four different machines or projection apparatus being publicly exhibited at the present time in London, but these are being duplicated at the east and west ends, besides arrangements being in progress for provincial exhibitions. I had the opportunity, recently, of seeing Mr. Birt Acres' "Kineoptikon" at the hall in Piccadilly-circus (just at the junction of Shaftesbury-avenue), and the subjects shown were of a very effective nature, and point to a great future when the initial difficulties, inseparable from new inventions, are overcome.

* * * * *

It seems to me, in this class of apparatus, the ultimate success will depend on the co-operation of the film-makers and the perfection of material forming the base, whether it be celluloid or something yet to be manufactured. The great light necessary for the projection of the present size of kinetoscope designs, to make them visible life size on the screen, or of sufficient size to be seen by a large audience, is such that it makes apparent the slightest blemish in either film or support, and consequently pinholes, scratches, and marks, obtrude themselves, and are particularly noticeable in the quick changes that have to take place to keep up the appearance of motion, or living photographs.

* * * * *

Mr. Birt Acres, with a modesty very rare in these days of advertising, does not anywhere on his prospectus put his name, nor did he announce himself personally as the inventor, on the day I saw his exhibition, but contents himself with the following note at the end of the programme: "Our apparatus is an English invention, and was the very first shown in England, an exhibition having been given, with great success, at the Royal Photographic Society, early in January last. An entirely new series of pictures is now being prepared, and we shall frequently vary our programme."

* * * * *

I quote this more as a text, for, from the results of each projection I have seen, I feel that it is a great pity, after once the plan of projecting the kinetoscope designs was found practical, that a much larger photograph was not arranged for, and the ultimate success of the invention will depend on the taking and projection of photographs of at least double the size of the present small photographs, for it is too much to expect to get perfection in detail in such a limited space.

Considering the material available, the results were remarkably good, particularly in such subjects as the *Breaking Waves of a Rough Sea at Dover; The Derby Day*, with its concourse of people on the course, the actual race, and the crowd after the race; *The Boxing Kangaroo*, and the *Arrest of a Pickpocket*. One could see from the various results shown that a great deal of the success of the pictures depended on the position available for taking the photographs, for, in those where the subjects could be to a certain extent "placed" or kept at a definite or fairly regular distance from the camera, the natural appearance was well maintained; while in others, such as the *Royal Review*, the exaggerated perspective had a most comical effect, the strides of the Emperor being in rapid succession Brobdingnagian and Liliputian; while, with the *Derby Day*, with the camera pointing nearly straight down the course, the horses, as they neared the end, and were thus close to the camera, were somewhat out of focus.

* * * * *

It is, of course, easy to criticise, and I only allude to these little matters in the hope that some of the workers on machines for this class of work will see their way, not only to arrange for larger films being used, but induce some film-maker to produce them with the utmost care. That something has already been achieved, is amply testified by the reception accorded to the projections of the Kineoptikon and the Cinematograph daily, and, as I understand, in the modern patterns of the former instrument, it not only projects the subject, but can be used for photographing it, and is so constructed that the same plan, with probably a little modification, could be used for subjects of a larger size. Further development may be expected when a further supply of machines is made.

* * * * *

The aphengescope, or opaque lantern, figured largely the other evening at the Royal Institution in illustrating M. Lippmann's lecture on *Colour Photographs;* also at the Society of Arts last week, in illustrating a lecture on *Gems and Precious Stones*. Wherever reflected light has to be employed or opaque objects shown, some apparatus of this kind must be used. M. Lippmann's glass photographs, showing natural colours, are placed in the rays of light and inclined at such an angle that the incident rays are reflected. It may be that these photographs are very difficult to produce, but certainly the results are very beautiful, and the method of production, as explained, seems simplicity itself. Whether it is practical in ordinary workers' hands or not, time will show; but, if, as stated, all extra that is wanted is a mercurial backing to the photographic film arranged specially in an extra thick dark slide, and the plate coated with an extra substance of gelatine, then it does not seem that the obstacles should be insurmountable, commercially, or in an ordinary way, especially as, in sunlight, it is stated that three minutes' exposure was sufficient for photographing flowers and fruit.

* * * * *

Mr. Ives's coloured photographs, as seen in the perfected photochromoscope, are very beautiful, and, when taken as stereograms,

most natural; but I am more concerned about the projection of colour photographs, and the apparatus for showing results on a screen to a large audience. His modified apparatus is very ingenious, one light only being used to illuminate the three films taken through different coloured screens (red, green, blue), and afterwards focussed and projected by objectives or front lenses, having prisms attached to their fronts or hoods capable of being rotated independently. The way the one set of rays is divided up into three sets, and made to evenly illuminate an area of the necessary size for the object, is particularly clever.

* * * * *

Imagine a pair of plates of transparent glass placed in the path of the rays at an angle of forty-five degrees to each other, and forming in section a V-shape, with the point turned to the right-hand subject. The light is both reflected by this glass, and also permitted to pass on to the central subject. The reflected rays travel at right angles on to a mirror placed parallel to the first side of the V, and at an angle of forty-five degrees to the incident ray, and are reflected at that angle, and so travel on parallel with the original ray, but in such a position that they illuminate the right-hand subject. The third or left-hand subject receives its illumination by reflected rays from the inside surface of the second transparent glass forming the V, a mirror being put in its path in line with the left-hand subject, and at an angle of forty-five degrees to the reflection. Thus all three subjects are illuminated, and it only remains to project the same on the screen.

* * * * *

If objectives only were employed, these three subjects would appear side by side on the screen, but by putting a displacement prism in front of each, of such a degree that each subject can be made to overlap, then it is only a question of revolving the same to get coincidence, providing the subjects themselves are in perfect register. In order that there shall not be too much difficulty in getting superposition in public, the base of the central prism is fixed in such a position that the subject is only displaced upwards, then all that is necessary is to turn the prism in front of right-hand subject (counting from source of light), so as to displace it upwards and inwards to the left, while that in front of the left-hand subject is turned to displace upwards and inwards to the right. The various colour screens are placed behind the slide. It is very interesting to see the effect of placing one projection over the other, for it is not until the third is superposed that the beautiful and natural colours appear.

* * * * *

The fact that a camera has been designed and constructed to take these subjects for the photo-chromoscope at one operation, either as single pictures or stereograms, should, when the apparatus is placed on the market, lead to a large field of work among amateurs and others, for it is promised that very little more trouble is involved in the operation than that required for the production of original lantern slides. The lens for the camera consists of a single achromatic lens of large diameter in a sliding tube, and a series of two transparent and four silvered reflectors (somewhat as previously described) to divide the light into three separate rays so as to produce three subjects identical in size and perspective. The size of the plate used is $7 \times 5\frac{1}{2}$ inches.

* * * * *

Verily the age of "New Photography" has set in in earnest.

G. R. Baker.

MICRO-PHOTOGRAPHIC REDUCTIONS.

[London and Provincial Photographic Association.]

It occurred to me when I gave my name for a paper to be read before the Association that there was a subject at which I had worked some years ago, and which, so far as I can remember, had not been introduced to the notice of any Photographic Society, at any rate during recent years.

The title of this paper is self-explanatory, and treats of the minute photographic pictures mounted on the usual microscopic slips three inches long by one inch wide, and also to be found in fancy articles, such as thimbles, miniature opera glasses, knives, &c. These latter are very minute, that is, not exceeding, and often considerably less than, a square of $\frac{1}{16}$ inch side, and are complete as to their optical outfit, being mounted in contact by Canada balsam between the thin glass which bears them and a much thicker piece, the external surface of which is worked to such a convex curve as will focus the picture when the eye is placed close to it.

During the last few months there have been read before this Association excellent papers upon enlarging and copying, and it seems to me that the series may be fitly completed at the small end of the scale by this subject, which is, theoretically speaking, a reduction in the camera optically the same as the operation of reducing an ordinary negative to lantern size, that is, there is a source of light, condenser, negative, lens, and sensitive surface.

But, the theory being granted, the practice is so different, that a brief description of the apparatus with which I hope to successfully produce one of these small images before you is desirable, and, in passing, I may say that to-night I shall not attempt to go to the extreme minuteness which I have mentioned, but will content myself with a reduction of about thirty diameters, which will give, with the size of negative employed, an image of about $\frac{3}{32}$ inch side.

Taking the apparatus as it stands on the board, there is:—

1. The source of light. This consists of a gas Argand lamp on a low stand, but the usual glass chimney is replaced with one of thin copper, the joint of which is folded, not soldered, on account of the heat. This chimney has two openings, one opposite to the condenser, glazed with a small circular window, over which can be swung a ruby glass "shade," the object of which will be seen later on. This is the exposing light. Opposite to it is another opening, glazed with ruby glass, curved to the copper and cut from a commercial chimney; this is the developing light.

2. The condenser consists of an equi-convex lens four and a quarter inches in diameter, being one glass of a lantern condenser of the meniscus and double-convex form. This is held in a wooden upright at the correct height, so as to line with the source of light; the upright also carries a shelf and turn buckle to hold a negative three and a quarter inches high, also a piece of ground glass for focussing.

3. We come to a 5×4 parallel bellows camera, intact but with its focussing screen laid back out of the way; it is packed to height on a wooden frame, which slides in graduated guides on the board. Its front carries a special fitting, which it will be necessary to describe in some detail, and I may here remark that an upright board representing the front might only have been used, but the camera was to hand, and answered the purpose of keeping off stray light during exposure, giving as well a means of exact centering adjustment by the cross front. The fitting just alluded to answers the following purposes: lens-holder, rough and fine focus adjustment, and plate-holder. The inner tube slides into the body of the fitting, and carries at its inner end the standard "Society" screw thread, into which can be screwed all modern microscope objectives. This, with a one-inch objective attached, is pushed into approximate focus, and the final adjustment is made by the micrometer screw and index seen on the top. As the screw has forty-eight threads per inch, and the index is divided into twenty-five parts, it follows that one division will give one twelve-hundredth of an inch movement to the plate on the stage. The process used being wet collodion, it is necessary to provide four silver studs to come into contact with the plate, these being analogous to the silver-wire corners in a wet-plate camera slide. Two projecting screws at the requisite height, upon which to rest the plate, and a spring to hold it against the studs, complete the stage.

No dark slide, in the ordinary sense, is necessary, as collodion is not sensitive enough to be affected by the dull artificial light of the room, a small piece of velvet or cloth thrown over it during exposure being sufficient protection.

Naturally, the first operation, after setting up the parts, will be focussing the image, and I may observe that this is a matter of some little delicacy, the focus running away rather quickly, as may be seen by the six trial exposures on one slip (each differing by one division of the micrometer), which I will put under the microscope, and it will then be seen that even this small error is quite appreciable, the subject being the *Ten Commandments* in print.

As to this question of focussing, I have tried several methods, viz., examination of the reduced image by a strong Ramsden eyepiece adjusted to the thickness of the plain glass slip, as when examining an ordinary camera image; also examination through a microscopic objective fixed behind the stage, and adjusted to its focal plane.

Neither of these methods was satisfactory to me, and I then utilised the principle of focussing the enlarged image of an object (clamped upon the stage) at the longer conjugate focus, the object necessarily occupying the same position that the collodion film will eventually take. Having removed the condenser, put a piece of

ground glass in the negative-holder, and a mounted microscopic object on the stage, you can, by means of the milled head, obtain a sharp, enlarged image, the lamp being removed to the other end behind the stage.

This proving satisfactory, you may be sure that, if the negative be made to take the place of the object, correct visual focus will result. Some objectives, however, require slight correction for the chemical focus, which can only be ascertained experimentally; the one-inch which I am using to-night, however, is fairly correct in this respect.

The wet-collodion process is chosen for these pictures on account of the extreme fineness of the deposit, more especially when developed with pyrogallic acid, which developer will be used to-night instead of iron. I thought, perhaps, that dry collodion might do, but I found the particles much coarser and not all the same size, so I did not proceed further in this direction.

Taking all things into consideration, wet-collodion is probably the best process, inasmuch as the several operations of coating, sensitising, developing, fixing, drying, and mounting can be gone through very quickly, and with greater certainty than obtains with other processes.

Respecting the apparatus before you, I may add that, with the exception of camera and condenser, all is home-made, from the first materials at hand, and I also wish to say that the idea of the focussing and stage arrangement was derived from a view of Highley's camera, illustrated at page 159 of Hogg's *Microscope*, 1883 edition.

It is almost needless to say that the fitting can equally well be used for the reverse process of photo-micrography with low powers, the only other condition being that the space between the objective and the sensitive plate at the longer conjugate must be in darkness, as in an ordinary camera, or the room itself furnished with non-actinic light.

With these few remarks I will proceed with the demonstration.

G. W. Atkins.

COMPLEMENTARY COLOUR STEREOSCOPY.

The successful demonstration recently given by Mr. T. E. Freshwater F.R.P.S., upon this method, as applied to screen pictures, before the members of the London and Provincial Photographic Association, raises considerations of some interest in regard to the origin, progress, and further development of the invention.

Without questioning for one moment the *bona fides* of Mr. Freshwater in claiming that his demonstration is the first practical exhibition of the method yet shown to an audience in this country, I may say at once that the claim cannot be admitted, and that, when he mentions the device as *his* system, he may be regarded as a "true," but scarcely as the "first," inventor.

So far as I am aware, the earliest published notices of the method refer to my demonstrations of it in 1885, when I showed it practically to some of the members of the Manchester Photographic Society.

In *Knowledge*, of July 24, 1885, the following succinct account of the invention appeared:—

"Mr. W. E. Crowther, of the Manchester Technical School, has devised a scientific arrangement for the production of stereoscopic effects in pictures drawn upon the screen by the lantern. The method is as follows: Two lanterns are used, each of which projects one of the two corresponding stereoscopic transparencies upon the screen, so that both fall together upon the same field. The light from the lanterns, however, is not white, but of any two complementary colours, as red and bluish-green. The spectators wear non-magnifying spectacles, fitted with glasses of the same tints as those used in the lantern, and the result is that each individual sees one picture only with each eye, viz., the picture thrown from the green lantern is alone seen by the eye wearing the green glass, whilst the eye shielded by red glass sees only the picture thrown from the red lantern. In this way each eye is affected only by its appropriate view, whilst the brain, receiving simultaneously the two views in complementary colours, combines them into a stereoscopic light and shade representation, which possesses some peculiar properties of lustre.

"The combined picture, as viewed by the naked eye, is, for the most part, white, from the union of the red and green lights upon the screen. The stereoscopic differences of the pictures, or overlapping portions only are chromatic. By slowly turning the lanterns so as to shift the screen pictures slightly to the wrong side of each other, so that the optic axes of the spectator may intersect in front of the screen, the picture appears to advance and become suspended in the air before the screen."

The new method was fully noticed in the Manchester press, and in scientific journals, both English and Continental, and was also recorded amongst the year's progress by one or more of the photographic annuals. Your contemporary, *Photography*, of October 23, 1890, mentions a demonstration of the arrangement by M. Schrober, of Antwerp, before the Antwerp Photographic Society, and I could point to other publications of the idea sufficient in the aggregate to constitute almost a bibliography of the subject.

It is therefore abundantly clear that, whatever may become of my claim to priority, that of Mr. Freshwater cannot stand.

Although since 1885 the invention has perennially cropped up in various societies and journals as a new thing, little variation and no progress have been observable in the arrangements and in the degree of success attained. The cardinal defect of the exhibition for popular purposes is the serious loss of light which results from the employment of coloured screens in the lantern, which renders the picture, though perfectly stereoscopic, much less pleasing than an ordinary well-lighted projection. The apparent impossibility of overcoming this objection seems to have induced the various experimenters to abandon the further prosecution of the idea, worthy, as it seems to be, of continued attention on the part of lanternists. There are, however, several possibilities of progress which may be mentioned. It would appear that the colouring of the light has always been effected, in the way most convenient to the operator, by the insertion of slips of coloured glass with the slides, thus interposing a large area of light-stopping material in the path of the rays, whereas, if a small screen were used within the objective tube, at or near the internal focus, much less light would be lost, and yet the colouration of the rays would be fully accomplished.

With regard to the provision of the necessary coloured eyeshields, a cheaply manufactured article of cardboard and coloured gelatine is sufficient, whilst spectators who have any difficulty in fitting and wearing spectacles or eyeshields may prefer the use of opera glasses fitted with coloured glass screens.

It is much to be hoped that this interesting field of invention may not be allowed to lie fallow for want of workers, especially as the ultimate goal of lantern projection is becoming clear, viz., the representation in full stereoscopic relief of moving objects in their natural colours. It is undeniable that some recent advances suggest the possibility of realising this ideal.

W. E. Crowther.

ACETYLENE GAS.

[Photographic Times.]

It is only within a very few years that electricity has become an important source of light for photographic operations. The development of this light has been marvellous; its adoption followed immediately upon the evidence of its practicability. It has been a great boon to those photographers who have been in a position to command its services. The readiness with which it was taken up shows how great is the need of some artificial source of light in many kinds of photographic work.

Electricity, however, is only to a limited extent available, and at best it is somewhat expensive. It may find a rival in efficiency and economy in the brilliant light of acetylene gas. At present, acetylene gas is by no means a cheap product; but improvements in the manufacture of the calcium carbide, from which the gas is produced, are to be expected. Even now the cost of the carbide should not be more than $100 per ton, from which about 10,000 cubic feet of acetylene gas should be obtained, making the cost of the gas $10 per thousand feet. But the illuminating power of this gas is much greater than that of ordinary gas. Discarding the extravagant claims of parties directly interested in the sale of acetylene securities (who have even made the astonishing assertion that 1000 feet of acetylene gas is equal to 30,000 feet of common illuminating gas for house lighting), we may fairly assume, that acetylene properly burned, will yield ten fold more light than good illuminating gas. Hence, an equivalent of 1000 cubic feet of illuminating gas would be furnished by 100 feet of acetylene, at a cost of $1·00. This is on the presumption that the carbide is sold for 5 cents a pound. In small quantities it costs considerably more, the lowest quotation that has come to me being 18 cents a pound, in 100 pound lots. Even at this price, however, the acetylene light will have numerous applications in a small way, when a thoroughly practical, convenient, and economical generator for the gas is on the market.

Calcium carbide is a heavy crystalline compound, dark grey in colour, with a specific gravity of about 2·2. It absorbs moisture from the air with avidity, setting free acetylene gas, which is recognised by its characteristic odour. In contact with water it is instantly decomposed, acetylene gas being set free with tumultuous bubbling, a deposit of lime

and carbonaceous matter remaining in the liquid. The course of decomposition may be simply represented with chemical symbols as follows:—

Calcium carbide.		Water	Lime	Acetylene.
CaC_2	+	H_2O =	CaO	+ C_2H_2.

From this it will be inferred that the generation of acetylene from calcium carbide is a very simple operation, which can be effected with the crudest form of apparatus. This is quite true. I have many times exhibited the acetylene light to friends by merely dropping a lump of the carbide into water, in a bottle provided with a cork and a suitable burner. But it will be found, in practice, that it is not quite such a simple matter to generate and deliver the gas under suitable conditions of flow and pressure, without the use of some form of gas-holder and regulator.

In this connexion, mention should be made of the generator, manufactured in different sizes by Messrs. Fuller, Walmsley, & Co., of this city, which has been on exhibition at several places, and warmly commended. It is simple and practical; but, since it will, doubtless, be described in these columns by others, I will not take up the space with any other words concerning it.

There is, however, another form of generator, not yet on the market, which, in my opinion, possesses certain points of superiority over this one, especially in the matter of compactness, lightness, and control over the generation of gas, but the inventors are not yet ready to make public the details of construction.

Another method of utilising acetylene gas is to furnish it to consumers in the form of liquid acetylene. It is proposed to condense the gas to a liquid, under a pressure of about fifty atmospheres, in cylinders, which have only to be attached to the gas pipes of a dwelling, very much as carbonic acid gas is furnished to drug stores. This also is a very simple matter, on paper; but there are practical difficulties which, so far as I am aware, have not yet been surmounted. There is a tremendous difference between a pressure of fifty atmospheres in a cylinder and the pressure required in the pipes to burn the gas, so that the mechanism for reducing the pressure and automatically regulating the flow of gas must be very nicely adjusted. Liquid acetylene may yet come into general use in the manner proposed, but the writer is sceptical concerning this matter, not only for the reason indicated above, but for another reason. Calcium carbide itself is not only much more manageable as a source of the gas, but it is inevitably cheaper. On the one hand, we have the cost of compressing the gas, not a serious matter, it is true, since the pressure can be produced by the generation of the gas itself; but, in addition, there is the cost of cylinders and fittings, needle valves, regulators, &c., transportation charges back and forth, and the time required to make proper connexions with the pipes and to ensure correct adjustment of flow. On the other hand, the carbide has only to be put into the generator, and can be furnished in sealed tins at a nominal cost for packing. Further than this, a cubic foot of liquid acetylene, exclusive of the heavy containing vessel, weighs about 28·15 pounds. This weight of gas, at ordinary conditions of temperature and pressure, occupies a volume of 387·5 cubic feet, but a cubic foot of calcium carbide, sp. gr. 2·2, would yield almost double that volume of gas. The advantages are, therefore, decidedly in favour of the use of the carbide directly.

I have gone thus fully into the matter of generating the gas for the reason that I fully believe the subject is certain to become of considerable interest to photographers and others, and there is so much false information circulated concerning acetylene, industriously disseminated by interested parties, that it is well to consider carefully all statements that are made.

As to the relative merits of the acetylene light compared with other sources of light, I regret to say that I am not yet able to write as specifically as I would wish. From such data as are at hand, however, it would seem that the photographic action of the light is sufficient to warrant the assumption that it will prove an effective substitute for the electric light for use in gallery work, for copying and enlarging, and wherever artificial light is required. It will certainly prove a great boon to photographers in small towns, where electricity cannot be obtained, and perhaps it will be found to possess certain advantages over electricity in the way of ready adjustment and even diffusion for portraiture, which will be quickly appreciated by operators.

The flashlight has given a great impetus to home photography, and the professional photographer is often called upon to do outside work in houses and machine shops which would be impossible but for the magnesium powder. With acetylene, however, the same work can often be done in a still more satisfactory manner. The small generator referred to in this article, of a capacity sufficient to afford ample illumination for the purpose, can be readily carried about and the light distributed in a manner to ensure the most effective results.

Among other important applications of the light may be mentioned an ingenious lamp for bicycles, which is about to be placed on the market by a company in this city. More within our immediate province, however, is the application to lantern exhibitions. Here is a truly great field for it. Much more convenient than the oxyhydrogen light, with the heavy cylinders which must be frequently filled, the brilliancy of the acetylene light is entirely satisfactory, even with the burners at present used, and these, I am convinced, are not by any means of the best form for the purpose.

For microscopical photography, as well as for ordinary observation with the microscope, the light is very superior indeed, a small and exceedingly luminous flame being available with comparatively little heat.

The light is not only intense, but it is also very white. Colours are seen by it in almost their daylight shades, although it is said that a slight lavender tinge of the light itself somewhat modifies the shade of certain colours. Owing to the relatively small quantity of gas consumed for any stated illumination, as compared with ordinary gas, the heat produced is very much less, the contamination of the air is reduced to a *minimum*, and there should be no products due to imperfect combustion. With all these valuable qualities in its favour, one can scarcely doubt that the acetylene light is destined to assume very great importance in the immediate future.

ROMYN HITCHCOCK.

INCANDESCENT MANTLES.

THE observations of Mr. Justice Wills in giving judgment in the actions brought by the Incandescent Gaslight Company against the Mare Incandescent Gaslight System and the Sunlight Gas Lamp Company, are of so much interest in connexion with the subject that we here reproduce them. The learned Judge said: The plaintiffs complained of several infringements by defendants of letters patent granted to Dr. Welsbach for the manufacture of illuminant appliances for gas and other burners. The defendants denied that what they proposed to do constituted an infringement of the patent, which they also attacked on nearly all possible grounds. It had long been known that certain substances, such as lime, magnesium, and zirconium, when heated with the flame of mixed coal gas and air, would produce brilliant incandescence, but it was quite safe to say that Dr. Welsbach discovered the practicable and simple method of so treating oxides that it was possible to use them in burners. He also discovered a class of substances known by chemists as rare earths, which, when blended with zirconium, would afford the necessary illumination. Since the date of the Welsbach patent a great industry in the production of the salts of rare metals and substances had sprung up. It was important to ascertain what was the true meaning of the specification. The patentee claimed that a combination of various essential elements used in the process which he described for the manufacture of a hood or mantle composed of fabric dipped in a solution of oxides produced light by incandescence, and it was for this invention that protection was asked. If the process which the defendants held out that they were going to use was substantially the process described in the plaintiffs' specification, they were liable in this action; but, if not, they were entitled to his judgment.

As to the objections raised by the defendants, it was said that the invention was not the proper subject for a patent, having regard to the state of common knowledge at the time, that it was not new or useful, and that the specification itself was too vague, and that the proportion of oxides was misleading that would not produce a good result. In his opinion the first objection was singularly ill-founded. The invention of Dr. Welsbach, with the improvements following upon it, had undoubtedly produced a great new industry in England in the extraction, for the purpose of the manufacture of these caps and mantles, of oxides, salts and rare metals, and the globe had been ransacked for new sources of supply. In the words of Professor Dewar the invention had accomplished what had been attempted before with want of success, and had, for the first time, brought within the range of practical manufacture the production of a brilliant light by incandescence within an ordinary gas flame. The evidence on this point seemed to be absolutely conclusive. He had carefully examined the various specifications which were alleged by the defendants to be anticipations of that of Dr. Welsbach, but they did not bear out the contention that his particular patent was not novel or had been anticipated. Again, there appeared to him to be no ground whatever for the attack on the patent on the score of want of knowledge, for the field upon which Dr. Welsbach entered was hitherto untrodden or marked by absolute failure. The objection that the invention was useless was a singularly hopeless contention. A further objection was raised that the specification was too vague, but he was of opinion that any one could make a Welsbach mantle by following the specification if he saw that the materials used were pure. This ground of objection to the validity of the patent also completely failed.

Passing to the very important question of the infringement threatened by the defendants, he said there was no doubt as to what the defendants intended to do. They proposed to make a plume consisting of a number of threads tied on to a platinum wire and arranged so as to form a sort of

fringe, all the threads of which were brought very closely together, but allowed to separate as they needed. The plume was dipped into a solution of sulphate of magnesium 20 per cent., sulphate of erbium 40 per cent., and sulphate of zirconium 40 per cent. There was the omission of lanthanum, which was used by the plaintiffs, but that omission would not obviate a serious infringement of the plaintiffs' process. The defendants said that their plume was not a fabric at all. He failed to understand why it was not. It was true it was something different to that of the plaintiffs in some respects, but Dr. Welsbach said that his fabric might be varied so as to suit different burners. The question was, whether what was proposed to be done by the defendants took from the patentee the substance of his invention. So far as the result was concerned, what was the character of Dr. Welsbach's patent? The result was something entirely new, and deserved the description of the pioneer invention. Dr. Welsbach discovered for the first time a method by which a skeleton, frail but durable, of the resistant earth oxides mentioned by him could be obtained, and which was the means of obtaining light by incandescence which would surpass in economy the best method known of obtaining illumination from gas. He had no hesitation in saying that the defendants proposed to take the substance of the Welsbach process. The substance of that patent, as described in the specification, was, in his opinion, appropriated by what defendants proposed to do. He therefore gave judgment against the defendants upon all the issues, with costs, and granted the injunction prayed for by the plaintiffs. He also certified that the plaintiffs' patent was valid.

In the case against the Sunlight Incandescent Gas Lamp Company his Lordship said the defendants had been formed to work a patent granted to one, Dellwick, for improvements in incandescent lighting. Dellwick's patent did not impress him favourably. Indeed, parts of it he was justified in calling nonsense, and he doubted whether this rubbish had been inserted for any other purpose than that of trying to make it look unlike the Welsbach process. The learned Judge then proceeded to describe the process of manufacturing the mantles adopted by the plaintiffs and the defendants, and said that he felt that defendants had taken a valuable process from Dr. Welsbach without giving any remuneration to him. The defendants had not taken the substance of the Welsbach invention, and therefore he gave judgment for them in the matter of infringement. He, however, found for the plaintiffs on the issue as to the validity of their patent, and reserved the question of costs.

PROFESSOR DEWAR ON ACETYLENE.

Professor Dewar devoted most of his last lecture at the Royal Institution to this gas, which, as he previously explained, is now obtained in large quantities by the simple expedient of dropping carbide of calcium into water. Of course you have first to get your carbide from the electric furnace. At present, by using the power of Niagara Falls, the carbide can be had for 5*l.* per ton. One pound of it gives off five cubic feet of gas, but, as this gas is eight times more brilliant in illuminating power than that from common coal, the ultimate cost of the light works out very favourably. But it is a very explosive gas. "going off" at a much lower ignition point than coal gas when mixed with a little air, and, what is more remarkable, it will often explode on its own account (without air), if submitted to shock or concussion. All these faults are due to what the physicist would call its strange "endothermic" properties. Still, with care, it can be used safely enough. But it has a cheerful habit of forming explosive compounds with any brass, copper, or silver that comes in its way, which is again awkward. It is better, therefore, to turn aside from these dangerous eccentricities to other characteristics notable in this gas, which are of more interest to science. One of these is, that if you freeze it at eighty-three degrees of frost (Centigrade scale), it turns straight from gas into a sort of paraffin wax, without troubling to pass through the intermediary liquid stage, but the solid can be subsequently liquified by heating under pressure. In all this we must not forget that all the credit belongs to the electric furnace, which has enabled us for the first time to complete the synthesis of the organic chemical compounds. From these carbides we can get benzine (and therefore all the aniline dyes), and even crude petroleum; acetylene combines directly with nitrogen in the presence of an electric discharge, and gives prussic acid. From this we can easily get cyanides, which, treated red-hot with steam, yield ammonia. In fact, the chemist sees no end to the sphere of usefulness of the electric furnace, which may even solve the problem of making nitrogenous manures.

COMPOSITION AND COLOUR; OR, PICTORIAL POSSIBILITIES IN LANTERN SLIDES.*

The photographer need not feel beneath Raphael, if he knows and applies his art as well. After all, it is the doing rather than the deed that makes us great.

Everything, both animate and inanimate, has its characteristic expression. Did you ever catch a building looking at you? I have often been watched in the most inquisitive manner by some old farm-house, until I could fancy it possessed personality, and was making comments on all passers by. And again, at night, I have been glared at by a house in a highly unpleasant and cat-like manner.

Repose, majestic calm, is the great characteristic of the architecture of ancient Egypt and Greece. The predominance of horizontal lines is marked in all their temple constructions. The race with the oblique eyes carries something of a smile into the upcurved roofs of their temples and pagodas. And we find that the gently sloping hill sides make the term "smiling valley" entirely appropriate. Gothic architecture, with its steep-pitched roof lines, becomes grave and solemn, and the grandeur of the mountain peaks, rising above the solemn pines, is thoroughly removed from levity. The sense of sublimity is aroused as the steeps approach the perpendicular, and we begin to feel our insignificance when hemmed in between rocky walls thousands of feet in height. The awe-inspiring effect of many of Doré's weird compositions is due to the pushing of this principle to an ideal exaggeration.

When we behold the "beetling crags" and "frowning battlements" overhanging our heads, we realise an impression of savageness, and know that nature has her terrible moods; that her bosom bears the potency of destruction, as well as blessing, for her children; and that her unchained elemental forces may, in a few brief moments, consume the fairest works of man.

A lecture without some allusion to Japan is not to be taken patiently to-day. Her ancient religion may be dying, but her beautiful temples still stand and attract pilgrims from the shores of the west. Her ancient arts are said to be decaying before the commercial spirit of those same shores. In the smoke of modern warfare, her charming old superstitions have probably vanished. We, who love her tea and her bric-à-brac, cannot help a sigh for the ghosts that are no more. Photographers are sometimes troubled with "ghosts." There may be a nebulous light spot in a picture caused by an imperfect lens, or a reflection, which is technically known as a "ghost." But more troublesome is the belief some of the fraternity fondly cherish, that the camera cannot lie. Another ghost, which sometimes haunts the artist is the idea that subjects worthy his brush or his camera can only be found in far distant lands. When thus possessed, everything at home becomes "flat, stale, and unprofitable," and one is profoundly unhappy and envious of those who can voyage to some Asiatic seaport, and at the hazard of famine, and fever, and massacre, journey painfully across some burning desert, and capture a band of Bedouins, dirt and all.

But we should not therefore imagine that we are without fields just as good for our best efforts. We dwellers in the wilds of Brooklyn find the voyage across the East River shorter, safer, and less expensive than the trip to the Orient; and there is no region on the planet more crowded with interest of every conceivable sort than the coasts and lands of "Gotham." Being the most cosmopolitan huddle in the world, if one wishes a foreign flavour, rich with all the tints, and redolent of all the spices and other odours of the old world, let him step into such a spot as the lamented Mulberry Bend.

Not long ago, an art critic, in his smart strictures upon the pictures in one of the Fall Exhibitions, denounced the subjects painted by a man, the least of whose works is a thing worthy of reverential study, as "insolently commonplace." Dismissing the commonplace insolence of such remarks as rather an impious criticism on the Creator, who permits the same glorious sunlight, the same harmonies of colour, to play alike on palace and potato field, we may well consider whether the revelation of the beauty of familiar things is not one of the highest of artistic missions. This is one of the functions peculiarly within the province of photography.

We go heedlessly to and from our business, absorbed in schemes or reading the delectable crimes and scandals in the daily papers, never seeing the picturesqueness of the old mill dam, never realising the wonderful growth going on among the green things, never feeling the delicate contrasts and blendings of soft and rough texture and warm and cool tints, as we whirl past on the rail. Then, as we hustle along the street, we notice nought of joyous young life, still untouched by care, but hurry on, intent only on preserving our anatomy from the street cars and getting as quickly as possible to our daily grind. But, if art is our vocation, we ought always to be on the alert for the bits and scraps by the wayside.

However, every one to his taste, and, if one's bent is towards the far-away and romantic, let him, by all means, follow the wedding journey of Lalla Rookh until it brings him to the palace of the Prince.

We often hear the expression "unnatural colour." There is no such thing as an unnatural colour. All conceivable tints exist in the solar beam, ready to be selected and reflected from the myriad surfaces around

* Continued from page 30.

us, each of which is really a mirror for certain rays and a transmitter or extinguisher of other rays. It cannot be said that any object is always of one particular hue. Colour varies from hour to hour, under the influence of the cool light of dawn, the glare of noon, the grey of cloud, the flush of eve, the pallid splendour of moonlight.

The atmosphere, that wonderful ocean at whose bottom we crawl about, the most indispensable of all the requisites of life, the most abundant, the only one which is free, and the one which, apparently, is the least valued or considered, this life-giving medium of communication between the heavens and the earth, is also the great composer of nature's colour harmonies. The atmosphere takes the crude and discordant tints, picked out from the sunlight by earth, rocks, water, vegetation, and tones them here, softens them by reflection there, hangs transparent veils through vistas and over distances, and in every way acts the part of the most consummate painter. Without this magical influence, so familiar that we rarely stop to consider its wonderful beauty, nature would present but the baldest and harshest aspect. With a blinding burst, the first rays of morning would shoot across the horizon, succeeding inky blackness, without one instant of mediating twilight. The landscape would be discovered in a few hard tints of red and yellow with wastes of leaden grey earth and Stygian waters lighted only by a metallic reflection of the fiery orb from the waveless surface. The sky would be always black, every distance would show the same sharp-edged contrasts. Retiring to a shade, to escape blistering on one side while freezing on the other, would be going into night again. A world without half-tones! The two ends of the scale only—no clouds, no mist, no delicate blue or purple grey distance, no verdure, no fresh water, no breeze—what a place of horror the planet would become without this atmosphere!

It is just a lack of appreciation of what the atmosphere is and does that makes so many pictures unnatural and unpleasant in effect. All colours are natural. The same object may, under various circumstances, reflect every possible hue. It is in the painter's combination that the unnatural so often results. Could one paint with vibrating ether and living flame, he might think of successfully imitating nature. As it is, the painter can only translate nature many degrees lower in key, with pigments which are but ashes, the oxides or cinders of earth's elements. Small wonder that he sometimes makes *mésalliances* of colour, putting together what God has kept asunder.

There is a recent movement in painting which calls itself Impressionism. It claims to render truths of atmosphere and vibratory effects of light as nothing else has ever done. I think it does. And it has occurred to me as a good way (while the fashion lasts) in which to utilise slides spoiled from lack of focus or other accident. The impressionist painter of this school analyses the colour rays, and counts drawing, depth, harmony, beauty, and everything else well lost if only vibration (by which he seems to mean doing violence to the optic nerve) is secured. He tells you that his pictures are painted to produce this magical effect at a certain distance, at which "they come together." But, setting aside faddism, there is a true impressionism which aims at the grand truth instead of the little, and which is of the highest importance for artists of all ranks to understand. Turner was, in many ways, the first true impressionist, as distinguished from the mere plodder over details in landscape; he was the first painter to thoroughly render all atmospheric phenomena.

In the morning of life we set out fresh and innocent, bravely riding upon ignorance. We accept the smaller truths that the rose is red, the grass green, &c. The larger truths of atmosphere and space and the mutual relations of things are beyond us, as we play with our brightly tinted toys. We have not yet learned to appreciate the promise of the first bright days of spring. An hour of time is beyond comprehension. Life goes as a sparkling stream flowing among the gaily tinted banks of a royal park. A few days pass, and we have forgotten that the grass was not always green, and the calves were not always grazing and gambolling. A gaudy picture book pleases us far more than the works of genius. A passing shower, a trifling grief annihilates us. We have as yet no sense of proportion, no deductions from past experience to help us over into the future. We live only in a moment, we see only a point at a time.

So it is at the outset of the study of art. It requires time, and exercise, and the guidance of the wisdom of the past to open our eyes and enable us to see the general, the broad truth, instead of the special, the isolated fact, the merely local colour, the one detail at a time.

Considered as an attempt to instruct, my fragmentary essay this evening will be of little value. I have touched but a few of the points included in my subject, leaving unmentioned many of equal importance. My aim has been to suggest to my photographic friends, if any of them have not before realised it, the great value of art principles in their work, and I particularly recommend the study of antique sculpture for developing appreciation of form, and the great masters of painting, the Dutch, the English, and modern French, for landscape, and the whole range of figure painters from the early fifteenth century to the present, and especially Rembrandt and Velasquez, the two greatest masters of opposite styles, for ideas in portraiture.

Life is short and art is long Whatever the artist does, he should do with sincerity. Whether professional or amateur, he should respect his art too much to consider it a mere pastime, and, whether he can follow its service far or not, let him be faithful to that service, and he will help the material world in its progress towards the ideal.

I wish to see the greatest possible art value put into stereopticon work. In our schools the idea is carried into practice that every exercise, in every branch, should be a lesson in language. I will make the plea that every lecture illustrated by lantern pictures should also be a lesson in art.

The first manifestation of the spirit of God in the material world was the creation of light. We are told that the rainbow, the revelation of the seven colour elements of light, was set in the heavens as a sign of divine care for man's development. The growth of the ages, the generosity of the Almighty, is behind the arts employing the sunbeam and its seven children.

Let us, then, realise the lofty mission of our work, and remember not to lose sight of the spirit in the eternal form, "the letter which killeth," but to seek and express the broad, the grand truths of nature in all art.

A. G. Marshall.

TELE-PHOTOGRAPHY ILLUSTRATED WITH COLOURED LANTERN SLIDES.

[Society of Amateur Photographers of New York.]

There was a special lantern exhibition on Friday evening, February 7, the subject being "Tele-photography, illustrated with coloured lantern slides," by Dr. D. L. Elmendorf. The tele-photo lens has not been a great success in the hands of ordinary amateurs, but Dr. Elmendorf is not an ordinary amateur, as all who have seen his coloured pictures and heard him describe them will testify. He did not say much about the technical side of long-distance photography on the evening in question, preferring, with his usual tact, to avoid tiring his hearers with purely scientific matters, and letting his pictures do most of the talking, which they did most effectively. He did say, however, that his negatives were taken in a small camera, having a long extension, with devices, besides the ordinary tripod, for keeping it perfectly rigid. The lenses were the ordinary rapid rectilinear of about seven inches focus, a long-distance lens of fourteen inches focus, and in addition a Dallmeyer tele-photo lens, of moderate amplification, the equivalent focal length of which was not stated. Most of the slides of purely picturesque value were taken with the two smaller lenses, as a matter of course; for, where details of very distant objects are taken with a telescope arranged as a photographic objective, the rays of light entering the lens being almost absolutely parallel, the resulting projection becomes a geometrical delineation, utterly wanting in the suggestion of the third dimension necessary to show solidity—it shows height and breadth, but not thickness. Dr. Elmendorf's slides, however, were so admirably chosen and so exquisitely coloured, that much of the flatness, so characteristic usually of telescopic views, was avoided. Indeed, many of his long-distance photographs were of architectural details, lying pretty much in one plane, and therefore faithful renderings of the subjects. Europe furnished most of the material for the entertainment, and, as the doctor is an accomplished and observant traveller, he kept up a running chat, as the pictures came on the screen, that was entertaining and instructive and full of variety. Perhaps the most popular of the series were the illustrations of Venice, and, of these, the copies of the doorways of St. Mark's Basilica and the wonderful mosaic paintings. The latter were given on a larger scale than we have ever seen here, and the colouring seemed to be faithful and harmonious. Dr. Elmendorf stated, however, that they required some further tinting, and that the basis of his lantern-slide colouring was water-colour sketches made by himself on the spot. From this it would seem as if Dr. Elmendorf's success in producing lantern slides almost in the colours of nature results not so much from manipulative skill and discretion and taste in the use of transparent pigments as the disposition to take infinite pains in one endowed with no small amount of artistic talent. The exhibition was viewed with pleasure by a large audience, and one of our members, in his enthusiasm, was moved to purchase the only tele-photo lens offered for sale at the February auction, and he intends to go forth and do likewise.

IMPROVEMENTS IN FLASHLIGHT APPARATUS.

Herr Bosl describes his improvements as follows:—

"On each side of a bottom plate two lugs are arranged, into which are screwed two parallel bars of iron or the like. Movably attached to these

bars is a casing provided with a clockwork, which casing is pressed by means of two spiral springs away from the cartridge or the like to be fired.

"This clockwork causes a disc which is placed on the clock casing, to rotate, said disc being provided with a cylindrical periphery. The clockwork is wound up by means of a key, and the disc is kept in its place by a brake lever which is fastened on to the bottom plate, and by means of a nose engages with a notch in a circular plate placed underneath the aforesaid disc. The disengaging of the brake is accomplished by pushing forward the casing, inasmuch as the disc is then removed from the brake lever and the plate freed from its engagement with the nose of the same.

"At the upper end of the bottom plate a box is attached, the object of which is to receive the flashlight cartridge, it having at its bottom a slit to receive the nipple or fuse of the cartridge. The latter may be secured in any suitable manner in the box.

"When a cartridge placed in the box is to be exploded, it is necessary to push forward the casing by means of a latch or the like, until the disc, which is then set in rotation, reaches the fuse, thereby exploding the latter.

"This having been accomplished, the latch is released, and the casing together with the disc is, by the action of the springs, pushed back to its initial position. The disc now again engages with the brake lever as above described, and the clockwork immediately stops.

"Instead of employing the rotating disc a bar with rubbing plate may be used which, with the aid of a rotating frictional or toothed attachment in connexion with a toothed bar or the like, is brought in contact with the fuse; or in place of that bar a percussion pin, coated with a frictional substance, may be employed so as to strike against the cartridge, thereby exploding the same."

Mr. C. A. McEvoy's improvements:—

The apparatus is formed of a base plate having at one of its ends a spring clip or holder to carry a short candle, having two, three, or more wicks in a line, and at a distance apart from one another, so as, when ignited, to produce a broad sheet of flame through which magnesium powder is projected—the candles may conveniently be made up of three or more short lengths of candle, of small diameter, stuck together side by side. The candle will burn for a sufficient length of time, and, when one has been burnt out, another can readily be put in its place.

"The magnesium powder to be projected through the flame is placed into a tubular holder, which is directed towards the flame, and which can be slidden endwise to and fro within a cylinder fixed to the base plate. At the back of the tubular holder I place a coiled spring, which tends to throw the holder forward towards the flame. I also provide the holder with a stem projecting backwards from it, by which it can be drawn back, and also provide a spring catch for retaining the stem when drawn back. When the tubular holder is held back in this way, the requisite quantity of magnesium powder can be poured into it, and, if the candle has been lighted, the 'flash' can at any time be produced by releasing the spring catch, either by depressing it by the finger or by pulling a cord, or otherwise; the coiled spring then throws the tubular holder quickly forwards, and the powder by its momentum is projected through the flame. The apparatus can either be held in the hand, or rest on a table, to be fixed to a pole or otherwise, and can be held in either horizontally or vertically without interfering with its action."

In place of employing a powder-holder, which is thrown forward to project the powder into the flame, a fixed holder might be used formed with a passage projecting forwards for a distance from its rear end and leading to a nozzle having a flexible pipe extending from it to an elastic ball by quickly compressing which, a blast of air may be directed into the rear end of the powder-holder, and the powder be thereby blown forwards into the flame.

JOLY'S TRANSLUCENT COLOURED SCREENS.

In describing his invention of translucent coloured screens for use in his process of "colour photography" Dr. Joly says that fine silk threads or other suitable filaments, dyed or otherwise, given the required colours, are laid down upon a support of translucent or transparent glass or on some other support through which light can pass, as, for instance, a frame with a central opening; the filaments are imbedded in or otherwise treated with varnish or other translucent adhesive medium, serving to impart translucency to the filaments or to increase any translucency they may originally possess, and to cause them to adhere to the surface of the support and preserve them from injury. The filaments are preferably laid parallel with each other and in contact. In this way a multi-coloured screen, consisting of a pattern of fine translucent or transparent parallel lines can be obtained. Thus, red, green, and blue filaments may repeatedly succeed each other upon the support. The colours employed need not, however, be red, green, and blue; they may be any colours suitable for taking or for viewing the image by the particular process of colour photography in which they are used, or they may be such as will serve both for taking and viewing the image, or two colours, or four or more colours, for special colour effects, may be used.

The glass plate or other support may be coated before, after, or during the deposition of the filaments thereon, with the aforesaid varnish or other suitable adhesive medium; this medium should preferably be of as nearly as possible the same refractive index as the filaments. It may consist of a crystal varnish made of any suitable resin, or of a varnish of Canada balsam in a suitable solvent, or of dextrine, collodion, gum arabic, gelatine, or the like. When any medium which is not waterproof, such as dextrine, for example, is used to receive the filaments or attach them to the plate, I may subsequently apply a coating of waterproof varnish to the surface of the non-waterproof layer, in order further to protect the filaments.

The colour, if carried as a dye upon a silk filament, should preferably be imparted to the filament before the latter is placed on the support.

The filament may consist of ten, twenty, or more constituent silk fibres, or fibres of artificial silk, or of a less number, or of one fibre, according to the width of the line of colour required in the screen.

The several coloured filaments may be brought together from reels before being applied simultaneously to the surface of the support, but so as not to mingle together or overlap one another. Thus one reel may supply red, another green, and a third violet filaments, or several reels carrying each a single-coloured fibre, or more than one fibre, may be used to make up each line of colour on the support. Thus there might be five or ten reels of green fibre to build up the green filament.

The filaments may be prepared so that the individual fibres thereof are held together by an adhesive material till they are laid upon the support; this adheeive material is then dissolved out or melted to fluidity, or it is so chosen as to be soluble in a medium previously laid upon the plate.

Thus, if the fibres are coated or retained together by dextrine, this will dissolve in a solution of dextrine previously laid upon the plate; or the filaments may be of one fibre each, and these may be of silk or artificial silk of the required dimensions; or a filament of one colour only may be laid down at one time to be succeeded by the other colours applied immediately or subsequently. I may use other material than silk for the filaments; for instance, glass, cotton, or celluloid in the form of fine filaments, artificial silk, especially drawn silk gut, or other suitable threads or fibres, natural or artificial.

The several filaments or threads may pass through a bath of varnish, dextrine, or alcohol, or other suitable medium before reaching the plate; this medium serves either to retain in coherence, or wash or desiccate the fibres of which the filaments are constituted, or the filaments may be desiccated by being passed over a heated roller before reaching the support.

A burnished roller, smooth straight-edge, or soft pad may be drawn along the freshly deposited filaments immediately after their deposition, pressing them against the support, serving to smooth them down, straighten crooked fibres, and expel air from them when they are applied wet or on a varnished support. A smooth blade or guide may also be provided to run along the outer edge of the freshly deposited filament to smooth the edge of the same and press in any projecting fibres.

After the support is completely supplied with filaments and varnish it may be pressed, when the varnish is nearly dry, against a flat, hard, polished surface, in order to confer a smooth surface upon the facing of filaments and varnish.

To secure the required regular deposition of filaments on the support, I may adopt any of the following contrivances:—

The filaments can be received upon a polygonal cylinder or drum, upon the faces of which may be attached a convenient number of the translucent plates or other supports; or the drum is cylindrical and wrapped round with celluloid or other flexible support, upon which it is desired to deposit the filaments. This cylinder or drum is rotated uniformly before the nipple delivering the threads, and, simultaneously with its rotation, it is displaced in the direction of its axis at a uniform rate. Or the drum rotates on fixed bearings, while the support carrying the nipple, or both the nipple and reels, is displaced longitudinally. In the first case, a screw carried upon a prolongation of the axis of the drum, and engaging in a fixed nut, will cause the drum to be displaced longitudinally in its bearings simultaneously with its rotation. In the second case, the support carrying the nipple, or both the nipple and reels, may be provided with a nut which engages with a "leading screw" geared suitably with the rotatable drum. Or, instead of the cylinder or drum, a frame carrying two supports only, placed back to back, may be employed for a like purpose. In the foregoing apparatus the supports may be stationary, and the reels and nipple may be carried round the drum or cylinder, simultaneously advancing parallel to the axis of the drum. In screens produced by such devices, the lines of colour are short lengths of spirals.

It is convenient, when a sufficient number of filaments have been laid on the frames, to apply adhesive material to them at the edges of the frames to attach them to the latter, and when, this is hard, the frames can be severed from one another.

A machine of the nature of an ordinary ruling machine, in which the pen or graving tool is replaced by the nipple delivering the silk, may be used to deliver the filament instead of the rotary devices previously described. A large screen may thus be coated with filaments. At the completion of each line the filament may be laid reversely to form the next line, a line being thus laid at each stroke of the machine.

Or the filaments may be first brought into a warp of parallel threads, in the correct alternation or order of colours, somewhat in the manner in which the warp is made ready for the weft in the practice of weaving.

Against this warp the support is applied, carrying varnish or some other adhesive medium in a tacky or wet state upon its surface, so as to engage with and retain a series of parallel filaments. Or the varnish can be applied after a dry support has been applied to the web. Or the individual, separate coloured filaments may be caused to take the correct positions for the formation of a warp by placing properly disposed notches on the opposite sides of a warp-straining device, and then applying the support to the filaments thus stretched, these latter being caused to adhere to the support by an application of varnish.

I may use filaments of only one colour on each warp-straining device. In this case the said device may be provided with regular indentations on the edges, serving to guide the filaments to the correct position. For three filaments the notches on the warp-straining device would be at a distance apart equal to double the width of one filament, so that sufficient space remained between every two adjoining filaments to subsequently receive two other filaments. In the winding of such devices, which may be effected on rotatable carriers of the kind hereinbefore described, I may dispense with accurate leading screws for the carriers or other rotating appliances, relying upon the regular spacing of the aforesaid notches. The three several webs so obtained may then be successively applied to the support, or may be applied thereto simultaneously if the devices are of such dimensions that one may be fitted into the other, so that the three series of filaments will come properly into the one plane.

I may also weave the filaments into a fabric to be applied to the support, the coloured threads forming the warp, and the weft consisting only of a sufficient number of colourless threads to cause the threads of the warp to retain their proper relative positions until they are secured on the support.

In the foregoing methods of depositing the silk or other filament, more than one nipple, each delivering the complete set of colours, or each delivering but the one colour, may be used.

In any of the machines hereinbefore referred to I may introduce an automatic arrangement whereby the machine will stop running in the event of a thread breaking, or whereby notice of such breakage will be given by the ringing of a bell.

In place of using ready-manufactured or natural filaments I may prepare these immediately before their application to the plate. Thus filaments of rapidly drying material, such as artificial silk, may be expelled or drawn from minute perforations communicating with a supply of the viscous substance suitably dyed.

Dr. Joly's claims are: 1. A screen for use in colour photography consisting of translucent coloured filaments. 2. In a screen for use in colour photography, the combination of translucent coloured filaments with means for retaining them in the desired position relatively to each other. 3. In a screen for use in colour photography, the combination with a "support" of a series of translucent coloured filaments carried thereby, and means for retaining those filaments in place relatively to the support. 4. In a screen for use in colour photography, the combination with a "support" of translucent coloured filaments, and a coating of adhesive material to protect them from blows or from the action of moisture and keep them in place. 5. In a screen for use in colour photography, the combination with a "support" of coloured filaments carried thereby, and rendered translucent by being impregnated with varnish or the like. 6. In a screen for use in colour photography, the combination with a "support" consisting of a sheet or plate of translucent material of translucent coloured filaments carried thereby. 7. In a screen for use in colour photography, the combination with a "support" of a single translucent coloured filament in a series of turns thereon. 8. In a screen for use in colour photography, a warp of coloured translucent filaments having a weft of colourless filaments. 9. A method of manufacturing translucent coloured screens which comprises the operation of winding the translucent coloured filament or translucent coloured warp helically upon a carrier, whereon the "supports" for the filament are placed. 10. A method of manufacturing translucent coloured screens, which comprises the operation of delivering a coloured filament or more than one coloured filament from a delivering device into the desired position on a "support" by reciprocating the said device relatively to the support, or *vice versâ*. 11. A method of manufacturing translucent coloured screens, which comprises the operations of forming a warp of coloured filaments and laying against it an adhesive "support" to engage such filaments, or laying against it a "support" to which an adhesive material is subsequently applied.

COMBINATION PRINTING.

[Manchester Amateur Photographic Society.]

In attempting to interest in you on combination printing, I do not wish you to run away with the idea that I am advocating the use of two or more negatives to produce a picture on all and every occasion; it is only now and again that these expedients have to be resorted to, and each year, as our mechanical appliances become more perfect, they become less necessary.

The successful use of several negatives depends largely upon the skill, care, and artistic taste of the operator, the latter quality especially being brought most prominently into play; but, even with the necessary skill, the artist is generally hampered by the want of adaptability in photography. A painter often introduces extraneous objects in his picture, and omits others, which would be almost impossible to the knights of the camera, though there are many things we can do to improve our pictures by double printing, such as the addition of trees, rocks, or other objects in the foreground. Some enthusiastic photographic mechanics may object and challenge the right to play fast and loose with photography in this way; but, when your sole aim is to produce a picture, and not a portrait, it matters little as to the means taken to produce that end. I have brought down a few hurriedly printed photographs, which will, perhaps, illustrate what I mean. The one of the river from Otterspool Bridge has received four separate printings — first the landscape, then the clouds, &c.

The use of separate cloud negatives has been so fully described by me that I do not care to occupy much of the time now by repeating what I said before, though I may briefly demonstrate the mode of procedure. Every one present will, I think grant me that a white sky is unnatural, and that, unless clouds are obtained in the original negative, it is better to print them from a second negative, and by so doing many an otherwise uninteresting subject is made pictorially interesting.

I have here a print with a white sky, and one with clouds added by double printing. It is done in this way: First print the landscape, then take away the negative and substitute a suitable cloud negative (and there is much food for thought in that word suitable), and, covering up the portion already printed, carefully print in the clouds, watching the progress every few minutes, so that the clouds do not overlap the light portions of the landscape, or fall short, so as to leave a light space between the two; the former is the lesser of the two evils. I find it advisable to print the clouds in the sun, keeping the cover in motion. May I repeat, to emphasise a former utterance, Do not print the clouds too dark?

The next printing is the reflection of the clouds on the water. To have the surface of water-white is just as great a mistake as in the sky, and, to get over this difficulty, we must turn the cloud negative upside down, taking particular notice that the angle of reflection is correct, and that they are printed to the right depth, that is, a shade deeper than the counterpart above.

The next addition is that of a foreground. This is easily done when we have only water to contend with, and, fortunately, it is then we need a foreground most. To obtain a balance in a picture, a tree or some such object may be necessary, and, in printing the landscape, any dark object which would come across the tree must be covered over, care being taken that the covering does not overstep the boundary of the trunk.

Portions of many apparently useless negatives can be used in this way. I make it a rule not to destroy a negative unless really worthless, for at least a portion of it may come in useful at some future time. A slide I showed at our last Exhibition, and which gained some applause, was one that had been put away as being unfit to be exhibited. It was hard—"soot and whitewash," but, by the addition of clouds, ripples on the white water, and a strong foreground, it made quite a presentable appearance, and was used as an important collecting link in the series.

Another and very effective method of combination printing is to produce several pictures on one sheet somewhat after the manner of a mosaic, and it might be used for birthday or Christmas cards. Several pieces of white paper of different shapes and with black borders are arranged on a board, and then photographed. To do this it is better to place the board on the floor, and point the camera downwards. You have now a negative with several white spaces. From this print on thin paper, such as albumenised, two or three prints, and cut out masks from them (unfixed). Also make another for the finished picture, and on this print from any other negative on the white spaces, using the masks to cover up all the other portions. When all the spaces are printed upon, tone and fix as usual.

Pictures of statuary have very often unsuitable backgrounds, and to get over this difficulty all that is required is a steady hand and a sharp knife. A rough print is taken on thin paper as before, and on a piece of glass carefully follow the outline of the figure with a knife. Expose this to the light and you have a black mask. Having obtained a print from your statue negative, place it against a piece of plain glass with the mask intervening, and print until all detail in the background is obliterated. This *modus operandi* is very useful when the statue is enclosed in a glass case, like the statue of "Echo" at Peel Park. If the outside mask is used when printing the figure, so as to have a white background, a floral or landscape could be substituted in place of the black background.

J. W. Wade.

Gospel Oak Photographic Society.—April 21, the subject on the programme was the exhibition of some prize slides.—These were passed through the lantern by the Secretary before a large number of members and their friends, who admired and criticised the beautiful and various subjects put before them.

A feature of the above Exhibition was that the oxygen gas, instead of being brought to the hall compressed in cylinders, was manufactured as required by the side of the lantern in a generator invented by Mr. Stedman, who demonstrated its capabilities to the entire satisfaction of the members present, the light fully illuminating a fifteen-foot disc.

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*June* 5, 1896.

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

Animated photographs are everywhere. One might almost say, with regard to them, "They come not in single spies, but in battalions;" and, as to their names, it seems almost as if the final "graphe" could hardly do duty for any more prefixes to express motion, what with the animatograph, cinematograph, theatograph, vitagraph, motograph, panoramograph, and kinematograph, besides the kineopticon.

* * * * *

This form of illustration has undoubtedly "caught on" with the public, and such is the demand for machines that are capable of projecting the designs with anything like fair results, that there is the greatest difficulty in getting an order executed, and, as regards the design films, there is barely one to be had in London, except at a premium, and the film-makers in England, not having anticipated the sudden demand, are not in a position to supply, except at fairly long notice, the blank films for producing new subjects.

* * * * *

Most of the machines introduced since the public appearance of Lumière's Cinematograph are dependent on the Edison Kinetoscope for the films, and these in some cases give remarkably good results, but in the majority of instances are denser than they should be for projection. Those who have produced photographs themselves from films specially made, and then made transparencies from them, get brighter and clearer results; and as the whole matter becomes commercial, and professionals and amateurs are able to photograph what they most fancy, some excellent examples will, no doubt, be forthcoming.

* * * * *

I went to see an apparatus that I understood was the outcome of Edison's inventive genius, and which was announced to be the steadiest extant, and, hoping to witness a decided improvement on what had been produced before, I must confess I was disappointed to find the results not equal to those obtained at the Empire and the Alhambra. In these matters a great part of the success is due to stage management and due regard for impressions. The apparatus was, I believe, of American make, but not solely Edison's.

* * * * *

To be in a room of comparatively small size and fairly illuminated with a particularly strong light just in front of the screen, and then, as in this case, with scarcely any interval between the switching off of the light and the projection of the picture, it follows naturally that the result is comparatively dull, for the eyes of the audience are flooded with light, and by contrast the picture seems dim. If the lights were turned down at least a minute beforehand, then the eyes, accustomed to darkness, would appreciate the light when the picture is on the screen. After each scene again the lights were turned up, and so a constant dilatation or contraction of the pupil of the eye was going on, and consequent weariness. This, when pointed out to the management, was acknowledged, and will, I believe, be obviated in future.

* * * * *

A similar thing takes place at some of our scientific societies and institutions, and, venturing to risk being thought to harp on one string, I must emphasise this, after attending a lecture at the Royal Institution (I think it was the one when M. Lippmann read his paper on *Colour Photography*), when it was brought forcibly home to me, so much so that I had to shield my eyes to lessen the fatigue. There is no occasion to have a place so brilliantly lighted when the demonstrations take the form of lantern or optical projections, and just sufficient light to make the lecturer visible to the audience and themselves to each other is all that is wanted. The admiration of the notables or fashionably attired can be managed before the lecture commences, or before the lights are once turned down for a projection to be made, as that is the time for the *majority* of the electric lights to be switched off, or, if gas, to be turned down.

* * * * *

The conversazione of the Royal Society was conspicuous for the photographic element and the assistance the optical lantern lent in demonstrations. The New Photography was placed in the front, rank, examples and demonstrations being shown and made by Mr. A. A. C. Swinton, Mr. Sidney Rowland, and Mr. Herbert Jackson, while a rapid mechanical photographic printing apparatus was exhibited by Mr. Friese Greene, which permitted photographic reproductions in periodical or book form to be turned out at the rate of 2000 per hour. Another exhibit was a remarkable series of instantaneous photographs of splashes by Professor Worthington and Mr. R. S. Cole, the exposures being less than three-millionths of a second the progress of the bubble formed by a drop being recorded and any stage picked out within limits of error not exceeding generally about two-thousandths of a second.

* * * * *

Added to the above in the photographic line, one has to notice Captain Abney's apparatus for producing on a screen or photographic plate monochromatic images; Mr. F. Maclean's photographs of the spectra of characteristic helium stars, and photographs of the spectra of six stars of the third magnitude; Mr. Ives's stereoscopic photo-chromoscope; Professor Meldola's demonstration of Professor Lippmann's colour photographs by the interferential method; more photographs of spectra of stars by Mr. J. Norman Lockyer; and also photographs showing position of coronal spectrum rings in total eclipse of the sun, April 16, 1893. Photography was also

employed by Mr. C. Carus Wilson to show "cup and ring" markings naturally formed in stucco similar to those seen in rock faces, and usually ascribed to the hand of prehistoric man. A further series of photographs of spectra of flames produced by the Bessemer process during the "blow" and "over-blow" were exhibited by Professor Hartley. G. R. Baker.

SOUND CURVES WITH A LANTERN.

It is so customary to speak of the optical lantern as almost owing its existence to the art of photography that its many practical applications in which photography has no share are, in a great measure, lost sight of. It is true, no doubt, that before the advent of sun-painting it was, to all intents and purposes, nothing more than a mere toy, but it does not, by any means, follow that its sphere of usefulness is confined to the projection of photographic pictures. It has no equal as a means of making visible to large numbers of persons many significant scientific experiments, which, from their nature, must be performed upon too small a scale to be of any use for lecture-table demonstration, but which are, nevertheless, most important for teaching purposes. For instance, a large number of chemical reactions can be rendered perfectly understandable and interesting with the lantern's aid which, if performed on the platform on a scale even twenty times as large, would be clear only to those in the first or second row.

The majority of chemical operations, to be successfully performed in the lantern require the instrument to be fitted with an erecting prism in order to exhibit the experiments, which cannot very well be inverted before they are placed in the lantern, in an upright position, otherwise some of them would be very difficult to understand. For instance, the bubbles rising from a metal, say, being dissolved in dilute acid, appearing on the screen like huge globules of molten metal, falling heavily to the bottom, is decidedly mystifying to an audience that has not mastered the art of standing on its head.

But all this is very obvious. Many of the experiments connected with the science of optics, as adapted to the lantern, have already been most ably explained to the readers of the Lantern Record, and I should like to point out how a few of those appertaining to acoustics may be rendered intelligible to lecture audiences through the medium of the lantern.

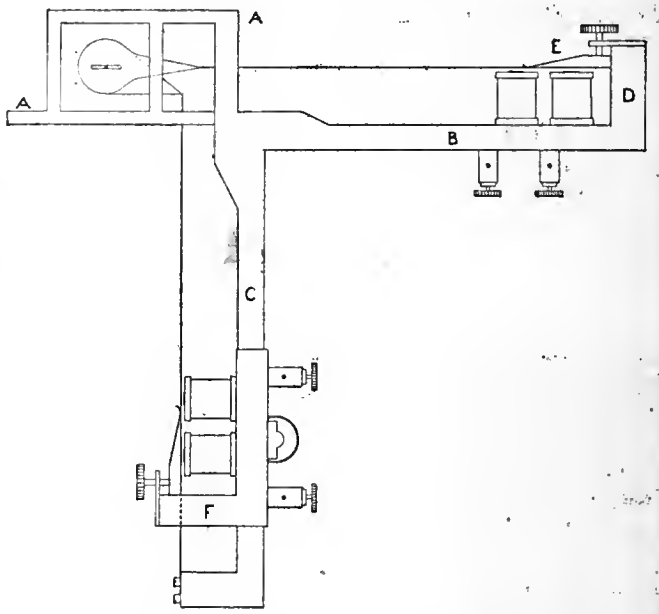
The illustration, fig. 1, represents, somewhat diagramatically, a little instrument which I have designed to show sound curves projected upon the screen. The usual way of showing this most beautiful and instructive effect is to employ two upright rods capable of vibrating at right angles to one another, each being fitted with a small mirror. A parallel beam of light is made to traverse the two mirrors, and, when the rods are caused to vibrate, the spot of light upon the screen darts about, and produces the characteristic sound curves of the particular relative vibrating periods of the two rods employed.

Such an arrangement, of course, necessitates a special form of lantern, giving a parallel beam of light, besides the vibrating rods and their mirrors, and it necessarily involves a deal of careful adjustment, and, unless the rods are kept in continual vibration mechanically, the resulting figure is considerably distorted.

The little piece of mechanism shown in the diagram is designed to fit the slide stage of any ordinary, not *science*, lantern, the usual combination of lenses being all that is required. It consists of two vibrating rods, one vertical and one horizontal. The plane of the vibrations is in each case at right angles to the optical axis of the lantern; that is to say, the horizontal rod vibrates up and down, while the swing of the perpendicular rod is horizontal. At the extremity of each rod is a disc of sheet metal, having a slit cut in it parallel to the length of the lath, and therefore at right angles to the direction of vibration.

For convenience' sake, and in order that the apparatus may the more readily be placed in an ordinary lantern, the vertically slotted metal disc is not connected directly to the vertical rod in the same straight line, but is attached to it by means of an elbow piece, as shown at A. The horizontally slotted disc is directly connected with its vibrating rod. But perhaps it will be as well to describe the manner in which the instrument is made, and its action can be then more easily explained.

A A is a wooden frame of the size and thickness of the frame part of an ordinary to-and-fro carrier, and having two arms, B and C, continuations of the bottom and one side of the frame, extending vertically and horizontally for about sixteen or seventeen inches. As the function of each is much the same, we may take the arm, B, as being typical of both. Near the end of the arm most distant from the "carrier" portion or field is a small electro magnet, whose duty it is to keep in continuous vibration a steel spring or lath, whose end is firmly fastened to the support, D. The arrangement is precisely the same as that employed to ring an ordinary electric bell. The current passes from the battery through the magnet by way of



the little contact spring, E, which normally presses against the steel lath and completes the circuit. Directly the battery is put into action, the iron core inside the bobbins of wire becomes a magnet, and the steel vibrating rod is attracted towards it; but, in doing so, it parts company with the contact spring, E, with the result that the electric circuit is immediately broken, the magnet loses its power, and the lath is free to fly back again. Then it again encounters the contact spring, E. Again it feels the pull of the magnet, and so, as long as the current is maintained, it continues to fly backwards and forwards *with its own particular period of vibration*, depending upon its length, weight, thickness, and rigidity, just as any other vibrating body.

Now let us see the effect upon the screen. It will be remembered that, while the instrument is quiescent, the field of view is occupied by two metal discs, one having a vertical and the other a horizontal slit cut in it, and of course, where these two openings intersect one another, there will be a single small square spot of light, which will occupy the centre of the sheet. The effect of causing the horizontal lath to vibrate will be to lengthen out this spot of light into a straight vertical line, whose appearance will not be much affected by difference of period in the vibrations, but whose length will correspond to their amplitude. This amplitude, or distance through which the end of the rod swings, depends upon several factors, of which the strength of the magnet is one; but, given a magnet of sufficient strength for the work it has to do, the amplitude of the vibrations can be controlled by varying the elasticity of the contact spring, E. A small thumb screw gives a means of controlling the pressure of the spring upon the steel lath. In the same manner, the effect of causing the vertical lath to vibrate is to produce upon the screen a horizontal band of light.

The arm, C, carries the vertical vibrating lath, held firmly at the end by means of a support precisely as in the other case; but, after that, a difference comes in, for the magnet, together with a block of wood carrying the contact spring, are mounted upon a carriage sliding upon the supporting arm. The block, F, to which the contact spring is attached, has a slot in it, through which the vibrating lath passes, and by which it is tightly clamped, though not so tightly that it cannot be slid through, as the distance between F and the end support of the lath is varied. This block, F, forms what in a musical instrument would be called a "fret." It acts as a clamp on the lath at any point in such a way that the vibrations begin, as it were, from that point, all portions behind it remaining at rest. Practically, therefore, it varies the length of the vibrating lath, and, as the number of vibrations per second varies inversely as the square of the

length of any vibrating rod, other things being equal, it follows that we have here a ready means of varying the period of the vibrations, or the pitch of the note, as a musician would call it. It is advisable to have a rack and pinion fitted to this sliding portion, for greater convenience in varying the length of the vibrating part, for accurate "tuning" of the two laths, either to unison or to the recognised musical intervals, is of great importance when demonstrating the theory of music.

Let me give a rough idea of the manner in which an experiment with this instrument—to show, say, the difference between harmony and discord—may be performed, for that will give a better insight into its capabilities. First, however, a word as regards the motive power, electricity. I have found the most convenient form of battery for such work as this to be that known as the dry cell, and I prefer Dr. Lessing's pattern to any other I have tried; but a single cell, of the one-fluid bichromate of potash type for each magnet would perhaps be the best, if not the most convenient. To get the best results with the dry battery, two cells should be used to actuate each magnet; but, whatever form of cell or cells is employed, each magnet should have its battery all to itself, to avoid any sympathetic action between the two vibrating systems.

Now for the experiment. Before commencing, let both laths be turned to unison, that is to say, let the length of the two rods (other things being equal) be precisely similar. Turn on the light, and show the small square spot in the centre of the disc. Now connect the upper magnet with its battery, and the spot upon the screen will immediately be lengthened out to a vertical band of light. After explaining that this is due to the vibration of a single rod, emitting a note of a certain pitch, break the circuit again, and, when the spot of light has come to rest, connect the other magnet with its battery, and show the spot stretched into a horizontal band of light, explaining that its motion is due to the to-and-fro movements of a vertical rod. Now connect both magnets with their respective batteries, and show how the two motions are combined in one, producing either a straight oblique line from corner to corner of the sheet if the two sets of vibrations are strictly in "phase" with one another, that is to say, start and finish their to-and-fro journeys exactly together, or, if one is ahead of the other by half a swing, the spot of light will describe a circle. Should the figure be oval in shape, it will show that one rod is swinging just a little ahead of the other, though each is occupying exactly the same fraction of time to complete a vibration. In any case, the figure is of the simplest possible description. It denotes a unison, and unison is the purest harmony.

A very small touch of the pinion head will suffice to throw the vertical rod slightly out of tune with its neighbour, and the figure will then gradually twist itself from the circular through all the degrees of oval to an oblique straight line. Then it will become a thin oval again, which will fatten out into a circle, to be flattened again on the opposite sides until it becomes a straight oblique line stretching between the two opposite corners to those before occupied. Every time it completes a cycle of changes, one rod will have gained upon the other to the extent of one vibration. This illustrates the phenomenon of "beats," which are always heard when two musical notes, slightly out of tune with one another, are sounded together. When the two vibrating bodies are swinging in phase with one another, the resulting sound is at its maximum intensity; but, when one is half a swing ahead of the other, each tends to undo the other's work, and the sound is at its minimum.

Now allow the spot of light to come to rest for a moment while the adjustable vibrating rod is set to half its original length, which, in musical parlance, would be called sounding the octave of the original note. Next to the unison the octave is the best possible harmony, which can be easily understood when it is remembered that in such a case one rod will be emitting two waves to every one of the other; consequently, the sound curve, as shown upon the screen, may be expected to be of a simple form, and so it is. Those conditions, which in the case of the unison produced a circle, will now yield the figure 8, which is, of course, tantamount to two small circles merged into one figure, while the oblique line becomes, in this case, a semicircle. Again, when the rods are thrown slightly out of tune, the changes will be rung between these two figures as before, the 8 gracefully twisting itself into a semicircle, first on this side, then on that.

The two rods may now be tuned to all the various musical intervals, showing why some consonances are much more pleasing to the ear than others, the figures of the more pleasing chords being simpler and less complicated in design, while the dissonances are easily distinguished by the rapid and continual contortions of their representative figures.

CECIL M. HEPWORTH.

TAKING AND PROJECTING KINETOSCOPIC PHOTOGRAPHS.

MR. BIRT ACRES' SYSTEM.

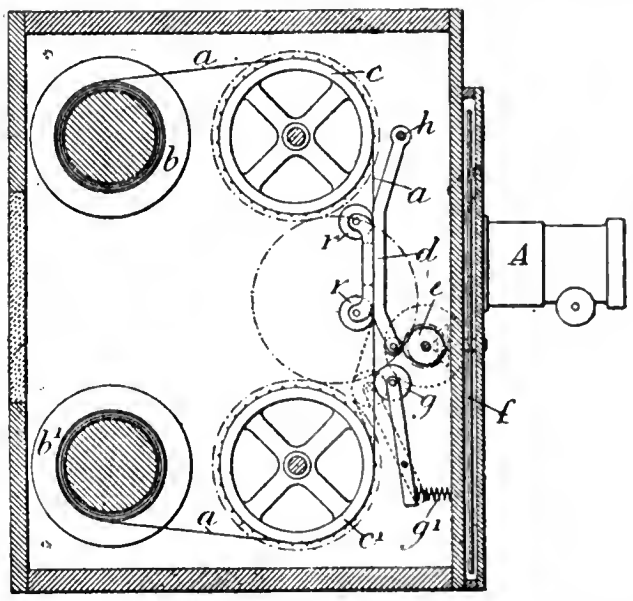
MR. BIRT ACRES' description of his improved apparatus for enabling photographic images to be taken, projected, or viewed, in rapid succession, is as follows:—"It consists more particularly in so arranging the apparatus as to permit of the film being clamped for the period necessary for exposure, projection or viewing, without causing undue strain on the film notwithstanding that the motion of the apparatus is continuous.

"For this purpose a continuous sheet of film is drawn by feeding wheels off a roller by means of two pin wheels taking into perforations made at the edges of the film. It is caused to pass behind the lens and is clamped there for the short period necessary for exposure. The clamping is effected by an open frame pressed against the film by a cam turned by gear from the axis of the shutter, which is turned by hand or otherwise.

"During the time the film is so clamped, the pin wheels still revolving would cause undue strain on the film. This I obviate by causing the film between the clamping frame and the pin wheels to be deflected out of the straight line by a roller acted on by a spring. Whilst the film is travelling this spring deflects the film, but whilst the film is clamped the spring yields and the pin wheels continuing to revolve take up the slack. Immediately the clamp is released the spring again acts on the roller, causing the film to be deflected as before. The film is then wound on to a second roller.

"Instead of acting on the deflecting roller by a spring, it may be moved by a cam lever timed to the cam which works the clamp.

"The accompanying drawing is a section of the casing of a photographic apparatus with mechanism according to my invention for



moving and clamping the film. A is the objective tube, behind which is mounted the disc shutter, *f*, which is caused to revolve by hand or otherwise, driving by any suitable gear a cam, *e*, and pin wheels, *c c*^{1}, over which passes the continuous film, *a*, drawn from one spring roller, *b*, and wound on another, *b*^{1}.

"The film passes between a pair of rollers, *r*, and the face of a lever, *d*, which is pivoted at *h*, and is alternately pressed by the cam, *e*, against the film clamping it and holding it stationary, and releasing it so as to allow it to move onwards. The pin wheels, *c c*^{1}, which are geared together, are so set in the first instance as to leave between them a certain amount of slack of the film which is taken up by the roller, *g*, urged by a spring, *g*^{1}, causing a bend of the film. As the wheels go on while the film is clamped, the wheel, *c*, delivers slack, and the roller, *g*, yields, allowing the wheel, *c*^{1}, to take up the slack of the bend."

The patentee's claim is: In photographic apparatus, in combination

with continuously revolving feeding and drawing wheels for moving the film, and a clamp for temporarily holding it, a roller arranged to deflect the film while it is not clamped, and to yield while it is clamped.

STEREOSCOPIC RÖNTGEN SHADOW PICTURES.

[Journal of the Franklin Institute.]

THE ordinary single shadow picture, as produced by Röntgen's method shows the position and dimensions of an object in a single plane only The thickness, depth, or relative positions of objects in a direction perpendicular to the plane of the sensitive plate are not shown or indicated in any way. Thus, in a shadow image of a hand, showing the bones with a faint covering of flesh, there would be no indication of a flexure of a finger or of its being directed upward or downward. Neither is there any indication of the actual position of the bones within the soft integuments, except in the direction of length or breadth. The third dimension is missing.

It may, however, become useful in surgery to know the actual space elations of objects involving all three dimensions. To do this, we may take advantage of the principles of stereoscopic vision as in the stereoscope, which the writer has found perfectly feasible. A moment's reflection will, however, show that stereoscopic shadows are something of a novelty in themselves. A shadow is ordinarily thrown upon a surface, and is seen simultaneously by both eyes. An ordinary shadow having no thickness cannot, of course, be seen stereoscopically. With Röntgen shadow pictures we can, however, secure stereoscopic effects in a very simple way. If we take one such picture of an object or set of objects with the Crookes' tube in a certain relation to the objects and sensitive plate, then place another plate back of the objects and obtain an impression upon it with the Crookes' tube somewhat displaced laterally from its first position, we obtain two stereoscopic shadow pictures, which may be used to produce prints to be viewed in the stereoscope. The shadow of a coiled spring, for example, obtained in the way mentioned, will, in the stereoscope, show the turns of the spring in relief. The bones of the hand will be seen in space surrounded by the hazy flesh, and, if one or more of the fingers be flexed, the degree of flexure will be indicated. A foreign object embedded in the soft tissues would thus have its position with respect to the bones at once declared. As furnishing a background from which depths may be seen or estimated, it is well to place between the object and the sensitive plate a netting of wire with open meshes, which casts a distinct shadow. In such case the stereoscopic shadow images, when viewed stereoscopically, show the objects above the screen and at proper relative distances therefrom. This netting, or screen, also ensures the proper mounting of the pictures in relation to each other; for, should the screen be seen in the stereoscope above the objects, it would indicate that a transposition of the pictures had been made, and that for correct indications to be obtained the error must be remedied.

A number of experiments, made with a view of testing the method above described, have been made by the writer, and have given very satisfactory results. The skeletons of small animals may be thus examined in relief, and the actual position of objects embedded in solid material discovered. It is conceivable that by the use of a fluorescent screen, and two cathodes placed some distance apart in the Crookes' tube, these cathodes receiving discharges alternately, and thus producing two separate displaced sources of Röntgen rays, two stereoscopic fluorescent images may be produced on the screen. If, now, shutters or diaphragms are placed between the screen and the eyes, opened and closed synchronously with the discharges, and alternately with respect to each other, the image will be seen on the screen stereoscopically. In this way, by a rapid examination, the true space relations of embedded objects may be noted. ELIHU THOMSON.

ALL ABOUT ACETYLENE.

[American Journal of Photography.]

PROFESSOR JAMES M. CRAFTS, of the Massachusetts Institute of Technology, read a newsy and instructive paper on the new illuminating gas, acetylene, before the Society of Arts, in the Kidder Lecture-hall, Walker-building, Boston. The hall was crowded, and great interest was manifested in his statements and experiments. The presence of Boston men financially interested in acetylene, and the fact that they took notes of some figures and facts go to show that the lecture was valuable and brought out new points.

Before beginning his experiments, Professor Crafts briefly told what is generally known about the new gas and the discovery of carbide of calcium, from which acetylene is made by the addition of water. By means of electricity, generated at Niagara Falls, the Professor stated, it is expected that the carbide will be produced at a cost of $23·70 a ton. It is selling now for $100 a ton in New York; but, as there is both limited supply and demand, this cannot be called the true price. Passing on then to the field covered by his experiments, Professor Crafts said:—

"Boston gas has close to 25-candle power and Brooklyn gas a little more—*i.e.*, five cubic feet burned in an hour gives a light equal to 25 candles. The same amount of acetylene gives 200-candle power, and the light is white, clear, and steady—more like sunlight. Under the best conditions, therefore, acetylene is eight times better than the gas we now use. But either our burners are faulty, or we put on shades that absorb about one-half the rays. In practice, we get only about 11 or 13-candle power with our gas. The true test is that of the bill for the gas burned in a house for an extended period. We will know little until this house test comes.

"The acetylene flame clings close to the burner and heats it more rapidly than common gas. Because the light is close to the tip, however, it is valuable for locomotive head lights, and other parabolic reflectors, where it is important to have the rays start close from the focus. The fishtail burner is not suited to acetylene."

The lecturer exhibited several tips of his own make, their construction permitting of the easy circulation of air and consequent gain of a larger volume of oxygen than tips in common use give.

"Pipes of smaller size and better quality than we now have may be used with acetylene," he continued. "The joints may be soldered and all leakage prevented. Leakage is dangerous, as I will show later on. There is no ammonia in acetylene to eat the grease around the stopcock and cause leaks such as now are caused by the ammonia in common gas.

"It is proposed to store the new gas in a liquid form in steel cylinders, where it will have a pressure of 600 or 700 pounds to the square inch. By means of a Pintsch reducing valve, an exceedingly ingenious device, the gas is allowed to escape at very slight pressure. Each cylinder also is provided with a mercury seal, so that, if the pressure gets too great for safety, the seal will break and allow the gas to escape. It is calculated that the seal will be broken in case of fire in the building. Should the cylinder become red hot, the gas would be reduced to its constituent parts—carbon deposited on the interior of the cylinder in the form of soot, and hydrogen. The hydrogen generated would have a pressure of 20,000 pounds per square inch—enough to burst the cylinder and cause great damage. More dangerous would be the probability of the breaking of the mercury seal and the discharge of the gas into the atmosphere. Three or four per cent. of it in air would form a mixture of terrible explosive force. Therefore the use of many of these cylinders in an office building is not to be commended."

After discussing the use of acetylene to enrich common gas, the lecturer said he would pass over its poisonous, and discuss its explosive, qualities. Acetylene is more explosive than common gas. Using a piece of tubing for a popgun, he exploded two mixtures, one of common gas and air, the other of acetylene and air. Six per cent. of the acetylene in air had twice the effect of the same amount of common gas. A room, twenty per cent. of whose contents was acetylene, would be blown to pieces along with the house. The study of the poisonous effects of the new gas, the lecturer thought, would be more practical if a five per cent. instead of a twenty per cent. mixture were taken. A man would not have opportunity to breathe the latter mixture if there was a fire in the room.

Equal parts of the acetylene and oxygen to the total weight of five grains in the popgun made a tremendous explosion. Five grains of gunpowder, the lecturer explained, would not have exploded with anything like that power. "The fact is—and here lies the secret of the great power of the gas—acetylene stores up heat at its birth. It is spontaneously explosive. The danger is slight, but it is there in a peculiar form. If we thrust a burning taper into the gas, no harm is done, but we can get the explosive effect with fulminate of silver. The copper salts of this gas are also violently explosive. I prepared a compound of this kind for this lecture, but it exploded in the drying chamber. The fulminate formed by silver and acetylene explodes with a pressure of 600,000 pounds per square inch in 1-30,000,000th of a second. It is too capricious to be handled under water in the lecture-room, although common fulminates are handled in that way. The danger in our homes would be in the formation of a copper salt near the acetylene tank.

"To sum up, I would say that the peculiar property of acetylene which gives it strength is its storing up of heat. I consider it very desirable that a great deal more work and study be put into acetylene than have been. Its use for gas engines is worth looking into. I hope the companies dealing in it will see their way clear for larger experiments. I would like to see a railroad train from head light to rear lanterns lit with acetylene and given a thorough trial. A small village should be equipped with the cylinders. Only in this way can an old industry which has been built up by years of thought and labour be supplanted."

A TRAVELLING LANTERN SLIDE SCHEME.

[Read before the Congress of Natural History and Scientific Societies of South East of England. Held at Tunbridge Wells, April 25, 1896.]

THE very limited time at my disposal will not allow me to expatiate upon the advantages possessed by lantern slides in illustrating the salient

points of lectures, nor would such a course be at all necessary. During the last twenty years the optical lantern has firmly established itself as an all but indispensable adjunct of the scientific lecturer, for in point of clearness and reliability, to say nothing of ease of preparation and facility of multiplication, the superiority of lantern slides over diagrams is obvious and incontestable. Transcendental critics are to be met with who deny the possibility of an art side to photography, but men of science have thankfully accepted its aid, and by its means are enabled to keep a faithful and permanent record of phenomena that are frequently so evanescent as to elude all other means of representation. It is my duty this afternoon to put before you a scheme whereby, with a comparatively small expenditure of time, labour, and money, our Natural History Societies may have ready access to a collection of slides which shall illustrate as fully as possible the geology of that portion of our country in which we possess a local interest, and which has, intrinsically, an interest far more wide. The foundation of such a scheme has already been laid by the energy of Dr. Abbott, and the response to the appeal which he issued about a year ago has been such, I think, as to encourage us to proceed further. The set of some fifty slides which was circulated among many of our societies during the past winter was the first fruit of this appeal, and may well form the nucleus of our proposed collection. It is not to be wondered at that the result of this first attempt should be incomplete and open to criticism. The slides were very local in character, and consequently not sufficiently comprehensive. The only formations represented were the Hastings sands, the chalk, and the lower Eocene tertiaries; while the Weald clay, lower greensand, gault, and upper greensands were not illustrated at all. The only coast sections shown were those of the chalk and Hastings sands; the only fossils, a few typical ones of the Hastings sands; and no characteristic scenery of the various formations except the above coast sections, the Tunbridge Wells rocks, and a view of the chalk escarpment of the South Downs. With regard to the notes supplied with the slides, there was a very obvious lack of co-ordination and unity of purpose. Some descriptions were far too brief and vague; others erred on the side of prolixity and technicality, and consequently the whole produced a somewhat disjointed effect. All this was inevitable; but the very imperfections serve a useful purpose by suggesting means of improvement, while steps have already been taken to supply the gaps that have been indicated. It is proposed that for next winter slides should be prepared to illustrate the upper and lower greensands and gault, while the tertiary formations might be left for another year's work. Those of us who have had the opportunity of using and studying the slides already contributed cannot but have perceived the promise of much larger possibilities, and, if each society here represented were to take up the matter heartily, these possibilities would soon be converted into realities. There are few, I suppose, if any, of our Natural History Societies that do not include in their membership one or more geologists; or, at any rate, one or more who have some acquaintance with, and take an intelligent interest in, geology. Let each delegate here take the earliest opportunity of bringing the scheme under the notice of such, and persuade them to co-operate. If they should happen to be photographers, so much the better; if not, let them invoke the aid of some fellow-member who is a devotee of the camera. The growth of amateur photography has been so rapid of late years that there should be no great difficulty in arranging this. The names of all willing to help should then be sent to the General Secretary of our Union. Let the Union request some one thoroughly acquainted with the geology of south-east England, to draw up some general instructions and hints applicable to all who have consented to co-operate, and at the same time a special scheme of work for each, as suggested by individual geological situations. These suggestions would then be distributed by the Secretary. Some arrangement of this kind would be advisable so as to prevent overlapping in the spheres of work, and to secure that unity of purpose which hitherto has been lacking. At the same time much would have to be left to individual tastes and opportunities, and any suggestions offered should be regarded merely as such. It is hardly in place, in a brief paper like this, to go very deeply into all those geological details which any scheme of this kind would cover. It would embrace a complete series of coast-sections from the Nore to the Isle of Wight, with the strata clearly differentiated in each slide; sections artificially exposed in quarries, railway cuttings, roads, drainage works, building foundations, &c., more especially when they illustrate junctions of strata; diagrammatic sections to illustrate the geological structure of districts; vaults and their contents; false bedding; unconformability; erosion; and many other phenomena connected with the stratigraphical side of geology. Palæontological side should be well represented by slides of typical or specially interesting specimens of the ancient fauna and flora of our districts, and for this purpose the resources of both public and private collections should be drawn upon. The effects of denudation and its influence on natural scenery; examples of aerial, fluviatile, and marine destruction and construction would also have a place in our scheme. The contributed slides should be entrusted to an official appointed by the committee of the Union, who would make the arrangements for their circulation amongst the affiliated societies. As the carrying out of the scheme in its entirety would involve a large number of slides, it would be necessary to catalogue them with a line or two of description of the salient points of each; the societies could then make their selection; or, as an alternative involving less labour and correspondence, the slides could be divided into sets illustrating the various formations, each set being regarded as indivisible. This, I am inclined to think, would be the better plan, and the remarks which follow will be based on it. Applications for the loan of slides should reach head-quarters before the winter session, say by the end of September, and should specify when they would be required; and, in the case of two societies wanting them by the same date, priority of application should decide. If the order of circulation could thus be arranged beforehand, the expense of returning the slides each time to head-quarters would be obviated. Each society would prepay the carriage, and forward the slides the next morning after use to the society next on the list. Societies which do not contribute slides could have the loan of them on payment of a fee, say of 2*s.* 6*d.* each time of use. The slides should remain the property of the Union, and in the event of its dissolution be returned to the contributors. Notes on the slides should be of such length as to take, on the average, not much more than one minute's reading. It would be a great advantage if a print from the negative of each slide were also furnished, and placed at the head of the corresponding remarks. For the perfection of the scheme, the notes should be submitted to an authority for revision and co-ordination; he would cut down or expand them as circumstances might require, and blend them together into a readable form. Various objections may be urged against the elaboration of any such plan as the one I have sketched. Perhaps the one that will occur first is the fact that geological slides of the highest technical finish may be had from the dealers. To a certain extent this is true, but such slides are chiefly stock ones of fossils, and naturally the dealers have no means of taking advantage of evanescent geological phenomena. On the other hand, the widespread character of our membership presents opportunities denied to the dealers, and in my view it is rather *our* place to supply them and keep them up to date. It is just in this respect that we *can* work for the advancement of science, by keeping our eyes open and being on the alert to secure records of what may shortly be obliterated. A more serious objection is the one that geology appeals to a very limited number. Unfortunately this is the case at present, although there is no branch of science that is more thoroughly English in origin, or that can be better studied than in England. Our little island is a veritable geological microcosm, and a journey of two or three hundred miles across it will present us with more facilities for investigation than a pilgrimage of as many thousand miles through a whole continent. If, then, this part of our plan of co-operation can awaken interest and stimulate research in a somewhat neglected but fascinating study, we shall have done something at least towards that end for which we are met together to-day.

H. E. Turner, B.A., B.Sc.

THE INCANTO ACETYLENE GAS GENERATOR.

F. S. Thorn & Co., 169, Camberwell New-road, London, S.E.

That acetylene as an illuminant for photographic enlarging and optical projection purposes is destined to find very great favour has been our conviction ever since the reading of Professor Vivian Lewes's paper at the Society of Arts last year. The suitability of the light for such purposes is generally admitted, while the simplicity of the necessary apparatus for its generation and combustion obviously paves the way for its general use.

Fig. 1.

Messrs. Thorn & Co. recently gave us an opportunity of testing the working capabilities of the generator they have devised for burning acetylene. Fig. 1 gives an exterior view of the apparatus, the working of which may be understood from the following directions for use:—

"Lift out the inner cylinder or gas-holder, and fill the outer cylinder or tank with water up to the black line marked inside. Then turn the stopcock full on, and attach by flexible tubing to the burner fitting. Now unscrew and remove the cross bar and valve cover at top of gas-holder. Lift out the calcium carbide container and fill same (allowing about one pound for two hours' light with the two-burner lantern fitting). Care must be taken that some small pieces of carbide fall to the bottom, and a space of four inches from the top must be left for expansion. Then replace the container, valve cover, and cross bar, and screw down tightly. Next place the gas-holder into the water tank, and let it slowly sink until the water reaches the carbide, when acetylene gas will be immediately generated. As soon as the gas-holder begins to rise, a light should be applied to the burner, but a perfect flame will not be obtained for some minutes, on account of the air being confined in the gas-holder. No further attention will be required if the gas is kept burning; but, should it be necessary to reserve the gas for a time, the light should be turned very low, and again turned up for a few minutes if the gas-holder rises more than eight inches, as, although the carbide is lifted out of the

water, gas is still slowly generated. When the light is no longer required, the carbide container should be lifted out of the generator and cleaned out. The small tap at bottom of the generator should then be turned on for a minute or two, to draw off the water from the cooling chamber, or the light will jump a little when next used. The container is made to hold sufficient carbide for two hours' light (two burners), but it can be recharged by taking it out, removing the residue, and refilling as before. It is not necessary to lift the gas-holder out, but it should be held up about six inches, when the container is replaced and the valve screwed down. The water level should be maintained as at first. The best way to empty the residue from the container is to hold it upside down and gently rap the sides with a stick, when it will fall out; then rinse out with water and drain dry before refilling, being careful that the small holes are perfectly clear. The gas should always be lighted before placing the fitting in the lantern."

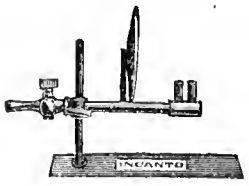


FIG. 2.

Fig. 2 illustrates the burner employed, which consists of two Bray's No. 0000 burners placed T-wise, with a small reflector attached, and fig. 3 the method of attaching the generator to a lantern.

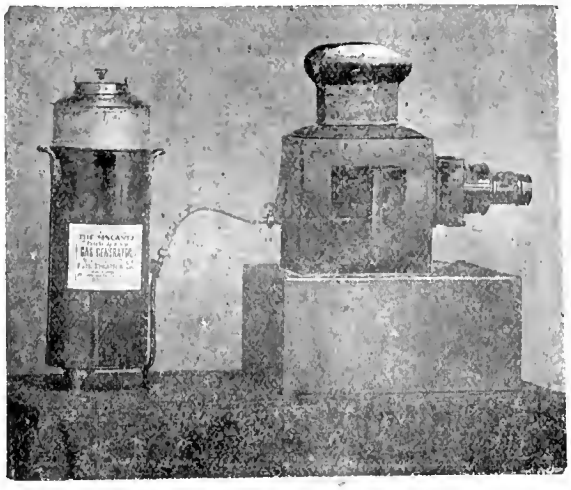

FIG. 3.

The apparatus is exceedingly simple to manipulate, and the light given off very bright, penetrating, noiseless and smokeless. Tested against a good oil lamp and an incandescent burner, its marked superiority was amply demonstrated. For small discs (say up to eight feet) and for enlarging purposes it is not very far behind a blow-through oxy-hydrogen jet. Thorn's acetylene generator deserves to be popular with photographers and others.

NOTES ON SOME PHOTO-MICROGRAPHS OF GELATINO-BROMIDE PLATES.

[Photographic Scraps.]

THE object of this paper is to endeavour to discover what the microscope may show as to the distribution of the grains of bromide of silver in the modern gelatino-bromide plate. It has no reference to the chemistry of the plates nor to their comparative rapidity. So far as I am aware, no microscopic examination of the silver bromide in gelatine films has been made, and it occurred to me that a few negatives might be taken of fast and slow plates which if thrown on the screen by means of transparencies would show some features which might be useful.

I have obtained from various sources a few spoiled negatives, and have, by means of my photo-micrographic camera, taken about a dozen negatives from these plates. I used, for this purpose, my Zeiss 4 mm. apochromatic objective combined with a No. 4 compensation eyepiece, which gave me, at a distance of 18 inches of the plate from the screen, a magnification of 350 diameters. This objective is one of recent make, and probably as fine a lens as is possible to get. I prefer the compensation eyepiece to the projection one, although I have both. The field of view with a 4 mm. lens is ·0135 of an inch when used with this eyepiece. You do not, however, see on the transparencies the whole of this, but only $\frac{7}{1000}$ parts of an inch, as the $\frac{7}{1000}$ parts of an inch are just included within the 2½ inches the diameter of the mask used in mounting them; or, to put it another way, 2½ inches on the screen of the camera just includes $\frac{7}{1000}$ of an inch of the magnified image, First of all I wish, to show two photo-micrographs of collodion plates. I have not worked any collodion for more than twenty-five years, and, as I had no collodion negatives except varnished ones, I have made two photo-micrographs from collodion positives made by myself long before the introduction of the gelatino-bromide plate about 1879–80. I am unable, at this distance of time to say what salt was used as the sensitiser for these plates, but I have no doubt it was a bromo-iodide one.

Plate No. 1 shows the grains of silver abnormally large, the cause of which I do not know, but plate No. 2 shows them in what I regard as their normal state and size. I have measured the size of these grains, they are not all of the same size, but the $\frac{1}{100}$ to the $\frac{1}{200}$ of an inch may fairly be taken as the two extremes.

It must be kept in view that, when a collodion plate is placed in the bath, one would not expect the silver to thoroughly permeate the film, but that the greater portion would be found adhering to or near the surface. These two plates appear to show that to be the case. They also show, I think, that the grains of silver keep, to a great extent, separate and distinct from each other. They do not appear to coalesce and form themselves into bundles or groups. They appear to be distributed very much as if one would take a handful of peas or barley, and scatter them on the ground, as by the motion of the hand and arm in sowing. This distinctive character may account, to a large extent, for the slow character of collodion plates.

In the gelatino-bromide plates, on the other hand, a totally different set of circumstances arises. The silver bromide in this case is in the film itself, perfectly distributed in it; and, from the viscous nature of the medium, the silver takes a different form. I have measured the size of the silver grains in many of these films where one could find them separate and apart, and these measurements show that the individual bromide of silver grains are practically the same size as those in the collodion plates.

The divisions in the eyepiece micrometer of my microscope with the 4 mm. apochromatic objective are $\frac{1}{500}$ of an inch apart. The largest of these grains do not quite fill one of these divisions, while two of the smaller grains can lie quite easily in one of the divisions. In gelatino-bromide films, however, the grains do not appear to remain separate and distinct to the same extent as in collodion. They seem to run together into bundles or groups. There is also in a gelatino-bromide plate a certain depth, as it were, filled with silver. This abundance of silver bromide which the emulsion process enables the gelatine to receive and retain would appear to be one at least of the primary causes for the extreme sensitiveness and rapidity of the modern gelatine plate. No portion of the film lacks the necessary quantum of silver. If it is deficient in the upper layer or focal plane, that deficiency will be supplied by an abundance behind. The so-called coarse grain of the rapid plate seems to be entirely due to the aggregation of the silver into bundles or lumps. The separate grains are the same as in collodion, but the gelatine medium on which they are placed seems to have the power to cause them to coalesce and run together.

I am looking into the matter entirely from what the microscope reveals. As to the quantity of silver in the film, the microscope cannot reveal anything. That is a matter for the chemist.

The slides I have made are taken from thin portions of the negatives as I found when using an eyepiece there was a difficulty in getting the light to penetrate the denser developed portions. There are generally found, however, even in the densest portion of a negative, a few grains of silver which have not been affected by the developer.

It has been stated that the size of the grains may be altered by the developer used. The accuracy of this statement I doubt very much. The collodion plates were developed with iron, while that developer has almost entirely passed out of use with gelatine, and yet the grains remain practically the same size.

The transparencies are as follows:—

No. 1. From a thin portion of a collodion positive made upwards of twenty-five years ago. The grains in this plate are abnormally large.

No. 2. From a similar plate of the same age. The silver on this plate I regard as of a normal size, varying from $\frac{1}{100}$ to $\frac{1}{400}$ of an inch.

I do not think it necessary for me to advert to any of the other photo-micrographs of the plates, as they speak for themselves. It is quite evident from them that in the Ilford plates, both Ordinary and Empress and Extra Rapid, the bromide of silver more nearly approaches the state of division of the silver in collodion than in any of the other plates I have examined. This fine subdivision of the silver must render them a long way the best plates for really fine work, and particularly for astro-photographic work where the star discs require to be afterward measured by microscopes to ascertain their actual distance from each other.

W. FORGAN.

LANTERN-SLIDE MAKING AS AN ART.

[Royal Photographic Society.]

WITH the Hon. Secretary must rest the responsibility of inviting me to address you upon the subject which appears on this evening's agenda. I feel myself that some apology is due for bringing before the members of the Royal Photographic Society a subject which, to some, may appear

almost trivial; but probably Mr. Chapman Jones, with his usual forethought, considered that at this time of the year many of you would only just have returned from your annual holiday, and therefore that something of a light and popular nature would be less likely to disagree with your mental digestion than the more ponderous and scientific matter which will, doubtless, form the bulk of your fare during the remainder of the session.

But, in all seriousness, the subject is one which, I venture to think, well deserves the attention of the Society; for, notwithstanding that the making of lantern slides and their exhibition is still sneered at and affected to be despised by a certain section of photographers, the fact remains that this branch of photography has rendered incalculable service, from an educational point of view, in the practical dissemination of technical and artistic knowledge in many spheres altogether outside the realms of photography.

When I first began to consider the subject, after receiving Mr. Jones's request, I thought I might perhaps usefully address to you some observations upon the artistic side of the question, for from that point of view lantern slides are admittedly very often open to adverse criticism; but I am sorry to say that even there the ground has been, to a large extent, cut from my feet by the publication of a valuable communication from Mr. Tulloch on that very point, from which I shall later take the liberty of making a few quotations.

Lantern slides, as I have said, are still looked upon by some photographers with undisguised contempt; these, however, are for the most part the gentlemen who know all about art, though very little of technical photography. A lantern transparency, that is both technically and pictorially good, deserves to rank high among photographic reproduction methods. What printing process exists, may I ask (and if existent, where is the printer?) which can so faithfully render and preserve the beautiful gradation of a perfect negative? And the small image, when projected, will, I think, in many cases favourably compare with the more or less sunken appearance which, in a greater or less degree, is unfortunately common to all our paper printing methods. If perfect lantern slides are rare, the reason may, I think, be found in the fact that comparatively few clever photographers take up slide-making rather than to anything inherent in the method which in itself would be fatal to artistic effect.

A lantern slide, to be perfect, must satisfy the most exacting requirements of two critics—the technician and the artist. I propose, in the first place, to deal with the subject from the latter standpoint. A lantern slide, if entitled to rank as a work of art, must possess pictorial qualities, it must be a picture. If such a position be conceded to a photographic print—a positive on paper—the same concession must be allowed to a positive on glass. If a negative possess pictorial merit, why should a lantern slide produced from it be less entitled to rank as a work of art than a print? The proposition appears to me to be unanswerable. It has been said that a projected lantern slide is simply the result of an optical illusion, vanishing when the operator lowers the gas. Even if this be conceded, it does not appear to weaken the position. A further argument, and one that probably possesses more weight, is that the great magnification to which the slide is subjected upon the screen produces a coarseness of texture, and an altogether different rendering to that shown in the print. This defect, when apparent, is partly the fault of the slide-maker, although the exhibitor may, to some extent, also be to blame. I am aware that many lanternists and lecturers will disagree with me upon this point, but the artistic qualities of many slides are injured, if not destroyed, by showing them upon too large a scale, and, in some instances, by using too powerful a light. In the majority of cases the audience, at all events those seated in the front rows, are a great deal too close to the screen, and the objectionable granularity, which under such circumstances is so noticeable, will be at once modified by increasing the distance between spectator and screen, and sometimes by slightly lowering the light. A really clever lantern-slide maker is, notwithstanding the number who now practise this most interesting branch of photographic work, comparatively speaking, a *rara avis*, and consequently good lantern slides are not too often met with. Slides are under-exposed, development forced, and every good quality sacrificed in order to secure that which is too often an unnatural brilliancy. This is the commonest and most fatal error into which slide-makers, both professional and amateur, fall.

Unfortunately, neither the general, nor, indeed, the photographic public, are very discriminating in their appreciation of the quality of lantern slides, preference being frequently shown for slides which present an undue amount of contrast. As an instance of this, the very worst slide, artistically, and I think also technically, in one of my lecture sets illustrating the scenery of a particular district, almost invariably receives most applause. This want of appreciation is very discouraging to the really conscientious slide-maker, who is thus sorely tempted, for the sake of winning applause, to sacrifice his artistic instincts. The power of the public mind to discriminate between good and bad will, however, doubtless improve in these days, when so much is being done to cultivate the artistic instincts of the people. The slide which is now upon the screen will not, I think, be likely to tempt your applause, for it is a rather glaring example of the undue brilliancy which I wish you to avoid. The next slide is one produced from the same negative, but in which the relative values, I venture to think, are more truly rendered; yet the former slide would, with the majority of audiences, be much more likely to win applause than the one now before you.

There is, I am sorry to say, very often great room for improvement in the quality of commercial lantern slides, for not only do they frequently lack any pretensions to artistic merit, but, from a technical point of view, are also open to criticism. To the almost universal adoption of masks with either square or circular openings the first fault may be traced, but to this point I propose to more specifically address myself later. The cause of defective technique is, perhaps, more difficult to trace, but it would appear to be due in the first place to the employment of unsuitable negatives; and, secondly, to want of care in the working of the process (wet collodion), which is commercially almost universally employed. I trust, in giving expression to an honest criticism of this kind, I shall not wound the susceptibilities of those who are engaged in this class of work, for commercial lantern slides of the very highest quality, both artistically and technically, can be, and are, obtainable. I should perhaps mention that my strictures are more particularly addressed to subjects of an essentially pictorial character, illustrative of scenery at home and abroad; diagrammatic slides leave little to be desired from any point of view. As an instance of what I mean, I may mention that some time ago I required two special slides to make a lecture set illustrating the scenery of North Wales complete. After inspecting the stocks of three leading London houses, all of which, by the way, bore a striking resemblance to each other, albeit that two of the firms in question professed to make their own slides, the slide I am about to show you was the best specimen I could procure. It is a well-known view. A year later I revisited Wales, and was enabled to take another negative, from which I made the next slide. Without being accused of egotism, for I am sure many of you could produce a far more pleasing rendering of the subjects, you will not wonder that, when exhibiting, I show my own slides in preference to the commercial.

In an appeal for more art in slide-making it is impossible to overlook the influence which the quality of commercial slides has upon the question, for it must be remembered that, for the purpose of illustrating lectures throughout the country, commercial slides are far more often used than slides prepared by the lecturer, who is himself a competent photographer.

If it be said that such subjects are often of a topographical character, and do not permit of artistic treatment, I would point out that an artistic photographer should be able to infuse something pictorial into the most topographical subjects. I do not, therefore, hesitate to make the suggestion that slide-manufacturers should give their old negatives, which, in many cases, have done them good service in the past, a well-earned repose, and intrust their replacement to photographers possessing not only technical but also artistic ability. The firm who takes a lead in this direction will, I am sure, reap a substantial pecuniary reward.

The question, "What process yields the finest results?" is a difficult, if not impossible, one to answer. The question has always been a vexed one, and is likely to remain so. I cannot do better on this point than repeat what I have already said in another place: "For myself I incline to the opinion that, although some processes may lend themselves more readily to the slide-maker's particular requirements than others, there is not one among them that can be called 'best.' A great deal more depends upon the man and his method of working than upon the process he employs. Some photographers declare that wet-collodion slides cannot be equalled; others, again, pin their faith to collodio-bromide, whilst very old workers shake their heads, and assure their younger brethren that a really perfect slide can only be produced by the albumen process. There is truth in each opinion, but it is to be found in the fact that its holder has made the particular process extolled a study, and mastered it in its every detail."

JOHN A. HODGES.

(*To be continued.*)

LANTERN SLIDES FROM WEAK NEGATIVES.

SOME time ago I saw in some photographic publication (says Mr. R. D. O. Smith in the *Photographic Times*), not at this moment at hand, a

article upon the above-named subject. The directions were: Make two positives from the negative, superimpose them in a most perfect register attainable, cover with a third glass, and seal.

The lines of one are, therefore, reinforced by the lines of the other, but there is between the images the thickness of a glass, and there are three thicknesses of glass in the slide.

I can discount that plan largely, both as to result and simplicity of method. If the negative is a film, the prints may be made by contact printing. If the negative is on glass, it must be made in the camera or in some apparatus which will ensure parallel rays.

Make a print as usual; then turn the negative over, and make another. Thus you have two prints from the same negative, but one is right-hand and the other is left-hand. When placed face to face, they will register perfectly, with no space between, and each glass is a cover for the other.

By far the finest slides I have made recently were made on Carbutt's process plates. Possibly they are made with the same emulsions used for regular lantern plates, but it seems to me they are superior. I have also made some very handsome slides on Carbutt cut films. I was fearful they would not stand the heat of the lantern, but I now think there is not likely to be any trouble from that source during the short time the slide usually remains in the lantern. I have not yet experimented sufficiently to determine that point, but I do not look for trouble. If slides can be made on thick films, there will be all the gain that attends the use of films for negatives, viz., lightness, compactness, avoidance of danger of breakage, and, to a very large degree, danger of damage from contact. Film slides would very largely avoid the necessity for cover glasses.

THE STEREO-PHOTO-DUPLICON.

JONATHAN FALLOWFIELD, 146, CHARING CROSS-ROAD, W.C.

THE Stereo-photo-duplicon is the name of a piece of apparatus introduced by Mr. Fallowfield, which enables a binocular photograph to be taken by means of a camera carrying only one lens.

Reference to fig. 1 will make clear the fact that the instrument is based upon the principle of double reflection—two sets of inclined mirrors

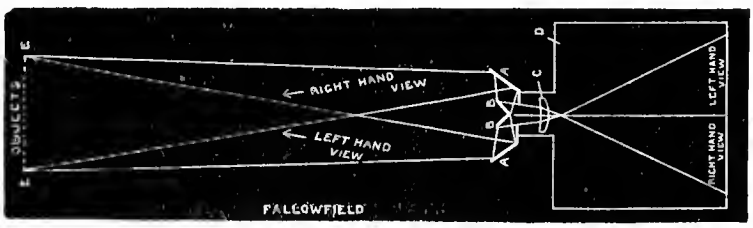

FIG. 1.

transmitting the two images of the view or object photographed through the lens, and, as it is pointed out, in such relative positions that, when prints come to be made from the negatives, cutting and transposition are obviated.

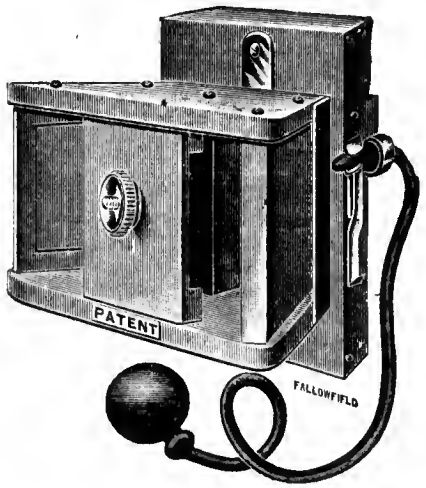

FIG. 2.

Fig. 2 gives a front view of the instrument, which is fitted with a time and instantaneous shutter, and figs. 3 and 4 show how it is affixed to either a hand or stand camera.

FIG. 3.

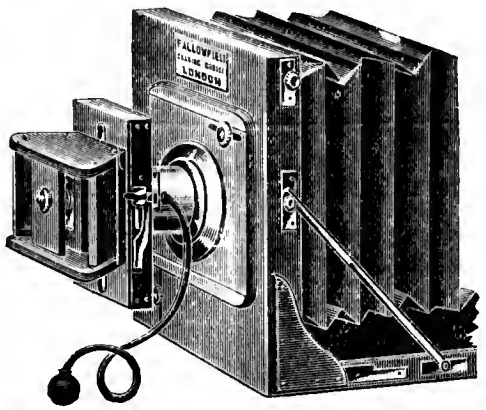

FIG. 4.

It is a very simple and effective way of making stereoscopic pictures by means of a single lens, and we are not surprised to be told by Mr. Fallowfield that a large sale is expected for the Stereo-photo-duplicon.

IMPROVEMENTS IN MAGAZINE STEREOSCOPES.

MESSRS. BRIGGS & MASTERS state, in regard to their invention, that the chief object is to improve the construction and arrangement of parts so that the slides or pictures can be changed much more quickly and conveniently than at present.

"In carrying our improvements into effect, we fit any desired number of stereoscopic or other slides or pictures in a drawer or receptacle provided with grooves or divisions, which separate the slides. This drawer, full of slides, is placed upon a movable carriage mounted in the stereoscope in such manner that by moving a lever or handle and thereby actuating sliding rods or equivalent mechanism, one of the slides of the series in the drawer is raised and brought into the correct position to be viewed through the lenses or lens. When it is desired to change the slide, the lever or handle is moved back, by which means the slide descends into the drawer, and then the sliding carriage with the drawer is moved forward sufficiently to bring the next slide into position, so that, by again moving the lever or handle, the next slide is raised into the correct position for being viewed.

"After all or any required number of the slides have been viewed, the drawer can be drawn back in any convenient manner, and a new drawer full of slides substituted."

THE *Alliance Record* thus refers to the lantern-slide work of Mr. Alfred Underhill, the well-known lantern-slide artist of Croydon: "New pictures for the mission.—A small but very fine collection of lantern pictures has just been received from the studio of Mr. Alfred Underhill, the eminent lantern artist of Croydon, England, by whom they have been specially painted to the order of the Hon. Conductor of the Picture and Lantern Mission. Several of the slides illustrate the evils of the liquor traffic in a very graphic manner. Another, which will in future form the 'trade mark' of the mission, has for a centre piece, the well-known emblem of the Victorian Alliance (designed by Mr. John Vale), surrounded by an elegant typographical border by Mr. A. Dunn, and painted in Mr. Underhill's best style. Some very fine scenic views and a few humorous pictures complete a collection which reflects great credit on the artist, whose assistance will, no doubt, be again secured when further additions to the stock of lantern pictures are to be made."

THE Southport Social Photographic Club announces the following interesting members' competitions:—1. June 10, Clond "printing in." 2. July 1, Pleasure boats, shipping, &c., in the Channel, Southport. 3. August 19, Southport street scenes (*not views of streets*). 4. September 2, Film photography. Other societies might possibly derive a useful hint from this interesting programme.

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*July* 3, 1896.

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

There are problems in photographic science as there are in mathematics. I am led to this conclusion by a pertinent question, asked of a friend of mine, regarding photographic records of a recent and very popular horse race. He said, "How could it be explained that one operator managed to get animated picture photographs of the finish of the race with appreciable brilliancy, notwithstanding the film was travelling at a considerable rate, and exposures were being made at eighty to ninety a second, when a hand camera, working at full aperture and giving an exposure of one tenth of a second, only produced an under-exposed negative?" In fact, the exposure was so long that the movement of the horses had multiplied their legs on the sensitive film, which was of a rapid kind, the light at the time being anything but good.

* * * * *

I have no interest whatever in any apparatus for taking or projecting animated photographs; but, if photographs have been shown as *this* year's race, with a certain horse said to be winning, that could not be authenticated, then it is great business smartness to advertise them as such. Probably one horse race is very similar to another where the finish is close, but it does not do to include in a picture, where the record is photographic, a number of horses different to the one it is supposed to represent, or with the field so placed that they do not correspond to a description of the event as seen by sporting critics. It would certainly be interesting for some representative sporting paper to verify this, and set the matter at rest.

* * * * *

The library of the Patent Office is always interesting, not only for the periodicals and books available, but by reason of the distinctive type of "readers." Some good heads are seen, and, as a rare occurrence, a fussy man talking somewhat loudly to himself or companion in total disregard of the recognised silence that prevails. Ladies do not look upon it as sacred ground, for on a recent visit some were working independently in searching out specifications, and others helping the sterner sex.

* * * * *

As some of the complete specifications I wished to look closely into were out of print, the only course open to me was to see the originals, filed in the library, and one of these was that of "W. C. Crofts and another," who in 1889 patented an apparatus for "Improvements in the production and representation of instantaneous Photographic Pictures." To give some idea of the detail gone into, no less than five sheets of illustrations had been made to disclose the invention, and for explanation of the drawings alone five pages of description are given. As the "another" referred to was a barrister-at-law, perhaps this may be an explanation of it; but it is certainly in strong contrast to Mr. Birt Acres' specification, which is a fair specimen of brevity with clearness.

* * * * *

I only hope, for his sake, that the covering power of his patent is good, and he can protect his invention; but to read those already published, and to conjecture from the results on the screen of those provisionally protected, and not yet made public by specification, if any question arises in law, there will be some nice points for the Judges to decide and the counsel and experts to argue and explain. These improved apparatus are developments, and it is difficult to say where the validity of a patent comes in. In those specifications I looked through—viz, Croft's, Acres', and Lumière's—they all are wise enough to describe their inventions as "improvements" or "improved apparatus." Mr. Friese Greene, who was early in the field in this direction, abandoned his patent, provisionally protected in 1892, while Mr. Paul's is not yet completed. I understand, however, by some correspondence that recently appeared, that Mr. Friese Greene has still a patent dated 1893.

* * * * *

If, as current rumour has it, the latter is netting about 120*l.* a week for the use of his apparatus in the various places of entertainments in London alone, it shows how it pays to be early in the field with anything that "catches on" with the public. Where such large interests are at stake, it seems to me only fair to other inventors that a disclosure should be made of the details of the apparatus for which protection is sought—in other words, a complete specification filed, for by the patent law, as I read it, no damages can be claimed for infringement during the time an invention is only provisionally protected. On the other hand, a prior inventor of an apparatus that produces the same result ought to be in a position to ascertain if the later production is an improvement, or only a colourable imitation.

* * * * *

The patent law is so very uncertain, and the cost of testing the validity of patents so great, that business men hesitate to move, and it wants a Cræsus or big company to set the machinery of the law in motion and be prepared to pay the piper. What the Welsbach incandescent gas burner trial must have cost is a matter of conjecture at present, but will, doubtless, be known some day. It can be imagined from the cost of a trial respecting the alleged infringement of a special kind of eyeglasses known as the spiral spring pince-nez, which, after a trial in Scotland, then an appeal, and afterwards being taken to the House of Lords, cost over four thousand pounds, and the decision at last went against the introducer in England of the eyeglasses, and consequently in favour of the defendants as to alleged infringement, for they were able to prove

prior publication in England of an article similar in principle, and closely alike in practical application to that which was the subject of a patent.

* * * * *

As to how many of the hundred-and-one patents for lantern and photographic apparatus annually granted would stand the test of trial it is difficult to say, but I have heard it put as low as one per cent. Certain it is that agents, if they were candid with inventors, would tell them that very few patents are worth anything *as patents* until after they have stood a trial, and the majority taken out do not pay the inventors the cost of the patent and agent's fees, drawings, &c. There is no one so sanguine as an inventor, and a "candid friend," who suggests the possibility of the improvement being *no* improvement, or not likely to be a commercial success, would be thought to have interested motives in saying it, or else lamentably deficient in the proper appreciation of genius.

* * * * *

As to priority for the publication of apparatus for producing animated photographs—not including Muybridge and Anschutz, who seemed to confine themselves to men, animals, birds, &c., in motion, without any attempt at scenes, I see the first is W. C. Croft and Wordsworth Donisthorpe, August, 1889; second, Friese Greene, 1892; third, Lumière Brothers, April 8, 1895; fourth, Birt Acres, May 27, 1895, and Paul, October and November, 1895. It is, I think, only fair to Mr. Acres to state that in the spring of 1895 he photographed the Oxford and Cambridge boat race and the race for the Derby, this being the first time any natural events were attempted, and he showed them in public on January 12, 1896, while they were privately shown as early as September, 1895.

* * * * *

With Midsummer Day past, and cycling, and X ray photography in full swing, there is not much to say on orthodox lantern matters, but, no doubt, the slide-producers are busy getting negatives for new sets of slides, while apparatus-makers are cudgelling their brains for lantern novelties, and an enterprising business man in the lantern way has acquired the plant and premises of gas compression works, and will shortly be able to supply gas. As competition is said to be healthy and promote trade, we shall see what our old friends of the oxygen gas companies have to say and do as regards this. I like to know what is going on, and, as I have had an invitation to look over the works, I shall take an opportunity of doing so, and see if there is anything I can say about it that is of interest to lanternists generally.

G. R. Baker.

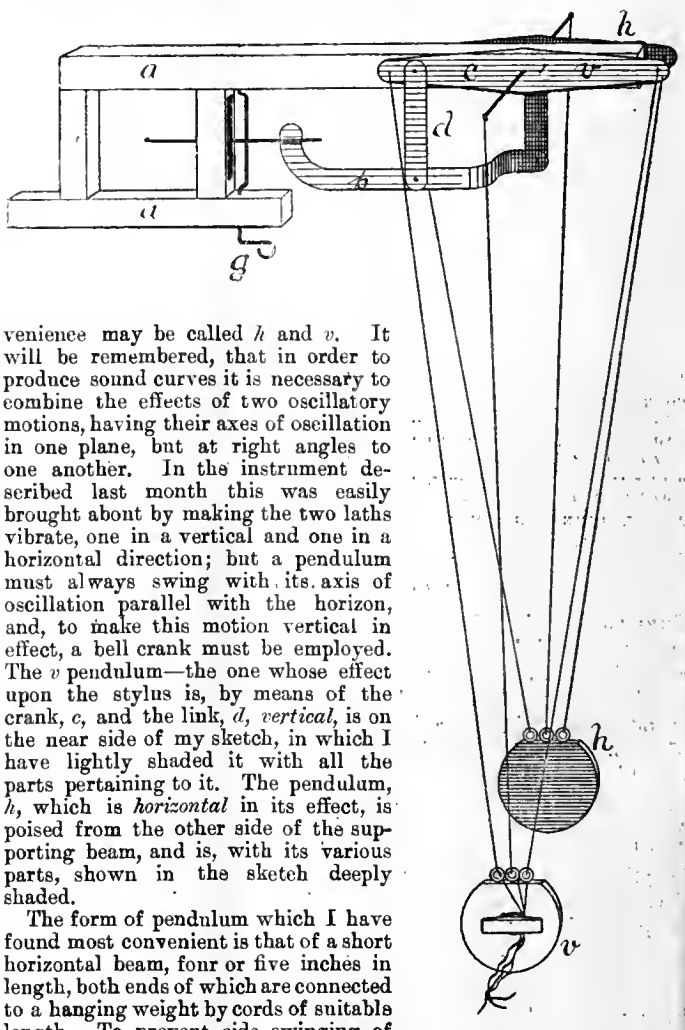
SOUND CURVES WITH A LANTERN.

II.

The apparatus described last month, for projecting upon a screen the beautiful curves resulting from two vibrating rods has this disadvantage as an instrument of education. Its effects are not permanent, and they are not cumulative—two results which militate against any careful study of the phenomena. Of course, it goes without saying that the curves so produced are not shown with anything approaching the frequency with which they would be formed by bodies vibrating fast enough to produce sounds appreciable by the human ear. To appreciate the movements of an elaborate piece of mechanism—say a steam engine, one must watch it when it is running at low speed, but, to really understand the reasons for its various motions, it should be studied carefully when the steam is shut off, and it can be put through its paces very slowly indeed, by hand. It is the same with these sound curves; to really comprehend the lesson which they are capable of teaching, they should be made to form very slowly, and when once formed they should not immediately fade, but should remain for comparison with the figure formed by the successive oscillations.

Such a result may be brought about by employing a compound pendulum in place of two vibrating rods, used in connexion with some device for recording its movements above a sheet of paper, such as a pin, or a small box depositing a trail of sand, but obviously such an arrangement as this is not applicable to an ordinary optical lantern, or, indeed, to a lantern of any kind. However, two pendulums, swinging independently of one another but each acting upon one stylus which traverses a piece of lamp-blacked glass, will do all that is required, and do it well, and, as will be seen, the combination can be used in conjunction with an ordinary lantern.

In the diagram, *a* represents that portion of the apparatus which is placed in the slide stage of the lantern, and which carries the square of blackened glass to be operated upon by the stylus carried at the end of the arm, *b*. The upper beam of the "carrier" portion is prolonged to form a support for the two pendulums, which for convenience may be called *h* and *v*. It will be remembered, that in order to produce sound curves it is necessary to combine the effects of two oscillatory motions, having their axes of oscillation in one plane, but at right angles to one another. In the instrument described last month this was easily brought about by making the two laths vibrate, one in a vertical and one in a horizontal direction; but a pendulum must always swing with its axis of oscillation parallel with the horizon, and, to make this motion vertical in effect, a bell crank must be employed. The *v* pendulum—the one whose effect upon the stylus is, by means of the crank, *c*, and the link, *d*, *vertical*, is on the near side of my sketch, in which I have lightly shaded it with all the parts pertaining to it. The pendulum, *h*, which is *horizontal* in its effect, is poised from the other side of the supporting beam, and is, with its various parts, shown in the sketch deeply shaded.



The form of pendulum which I have found most convenient is that of a short horizontal beam, four or five inches in length, both ends of which are connected to a hanging weight by cords of suitable length. To prevent side swinging of the two pendulums, which are, of necessity, hung very near one another, and which would therefore be very likely to collide, a third cord from each weight may be connected to either end of a transverse beam in a line with their two centres. This will have the effect of confining the oscillations of the pendulums each to its own plane, which planes will be parallel to one another. Moreover, the distance between the weights can be increased to any reasonable extent, and the risk of collision between them reduced to a minimum.

One of the pendulums must be variable in length, just as was one of the vibrating laths, in order to get the different effects which are produced by a difference in their periods. This variability may be brought about by passing the three cords of one pendulum through the three eyelet holes of the weight, and thence round a cleat provided on one of its faces, or a finer adjustment may be obtained by substituting a violin or banjo peg for the cleat, and then the pendulum may be tuned just as a stringed instrument would be. Of course, the other pendulum may have a fixed length—it is only necessary to tune one. Both, however, should be considerably longer in proportion than in my sketch, in which, to suit the exigencies of space, "I've been obliged to draw them small."

There is no necessity to employ a mechanical arrangement to keep the pendulums swinging. If they are long, and their weights heavy, and if all the links and motions used to combine their actions and cause them to describe the resulting curves upon the blackened glass be so arranged that there is only the least possible friction—and this is most important—the amplitude will only diminish very

gradually as the complicated curve is slowly formed, and indeed I think the gradual loss of amplitude adds considerably to the beauty of the resulting figure.

Referring again to the diagram, *y* is a piece of bent wire which serves the purpose of preventing the stylus from coming in contact with the lamp-blacked glass while the pendulums are being started. The method of using the whole instrument, will now hardly need any explanation, but here is a rough outline of the *modus operandi*.

First place the instrument in the lantern, and see that the pendulums swing properly and quite clear of one another. Then with very great care, the stylus being held out of harm's way by the bent wire, G, place in position the piece of previously prepared glass, which has been blackened by holding it for a short time over a smoking lamp, and then the light in the lantern may be turned on, for none of it can now reach the sheet. Set the pendulums to *almost* equal length, and gently and carefully start them both swinging. At the moment when they are "in phase"—starting and finishing their swings at the same time—turn the little handle, *y*, so that the stylus is free to act upon the blackened glass, and a streak of light will shoot across the sheet from corner to corner in an almost perfectly straight line. At the next swing the line of light will be doubled upon itself, although it will not follow exactly the same path; at the next it will diverge still more, and the straight line will be seen to be developing into an oval, which will become fatter and fatter until, when one pendulum has gained half a swing upon the other, it will have become a true circle. Then, again, it will take an elliptical path, though the ellipse will be smaller than before, owing to the loss of amplitude, and its greatest length will be at right angles to the former oval. If the pendulums have sufficient energy left—and they certainly should have—they may be allowed to swing until the stylus again traverses the straight line it originally made. The operation may then, with advantage, be terminated. One cycle of changes will have been completed. Speaking musically, the figure upon the screen is the graphic history of a single "beat," produced by the interference between two sounding bodies which are almost, but not quite, in unison.

The octave, the fifth, and all the other musical intervals may be made to tell their tale in the same manner, and the discords compelled to leave permanent records of their writhing contortions, but it is not necessary to give any further description of the manner of doing it.

CECIL M. HEPWORTH.

LANTERN-SLIDE MAKING AS AN ART.*

THE qualities to be looked for in lantern-slide making processes are: fineness of deposit, freedom from granularity, absence of any tendency to fog, transparency, and good colour. Both the albumen and the collodio-bromide processes possess all these attributes in a high degree. The former process, notwithstanding the beauty of the slides produced by it, is by no means an easy one to master; moreover, its slowness precludes the possibility of making the slides by reduction, and restricts the user to contact printing. Collodio-bromide in capable hands produces results which, if not superior, are certainly equal to those produced by any rival method, but the preparation of the emulsion is an art which comparatively few have fully mastered, and those who have done so deserve high praise for their skill.

Wet collodion, though capable of producing fine results, requires skilful handling, for probably no process so readily lends itself to the production of bad slides. That it is almost exclusively employed by commercial slide-makers must be attributed to the fact that it is cheaper, more expeditious, and possibly also more certain than other methods, rather than to the superiority of the results produced by it.

The carbon process is simple, yields beautiful slides, and gives the slide-maker, with an eye to artistic effect, a fine command of colour; but, with most tissues, a stronger negative than is desirable for general purposes is necessary in order to obtain sufficient vigour in the slides; and this reason, coupled with the fact that the slides can only be produced by contact, probably accounts for the process not being more frequently employed.

In discussing the relative merits of processes applicable to lantern-slide making, the question of contact printing *versus* reduction is naturally involved. It is still, I believe, the popular opinion that slides made by contact are inferior to those produced by reduction. I at one time held the same view, and formerly made all my slides in the camera irrespective of the size of the negatives; but, after some carefully conducted experiments in which slides were produced by each method from the same negative and compared, I have come to the conclusion that, so far as technique is concerned, one method presents no advantage over the other. The two slides I now show you were produced, the one by contact the other by reduction, from a $3\frac{1}{4} \times 3\frac{1}{4}$ negative, and, in regard to quality, it would be difficult to detect any difference between them. Pictorially considered, very different considerations, however, arise, and printing by contact from even a quarter-plate negative may, by altering the original composition, entirely destroy the artistic qualities which the slide would, if made by reduction, have possessed. The converse, however, in some cases, also holds good, and a negative originally defective in composition may be considerably improved by utilising a portion only for the slide. The following slides will perhaps illustrate my meaning. This slide, which was reduced from a quarter-plate negative, I venture to think, is of fair artistic merit, and does not sin in any very marked degree against the ordinary canons of pictorial art. The same, however, can scarcely be said of the next slide, which was made by contact from the same negative. These two slides are a practical illustration of the loss of quality which may ensue when contact printing from negatives larger than the slides is resorted to. The next slides, however, prove that this is not an invariable rule, and demonstrate that, in some cases, where the original composition is defective, a positive gain may result from the exclusion of unnecessary subject matter. It will be seen, therefore, that, from an artistic point of view, the question is one upon which no arbitrary opinion can be given. Neither method can be said to possess superiority. In some cases the slide-making process chosen will decide the matter for us, but, where the process permits of either method being adopted, good taste will alone enable us to decide which will enable us to obtain the best result from a given negative.

It is not possible, in the time at my disposal, to give more than a cursory glance at the various processes employed in slide-making; but I cannot conclude even this brief reference without a word or two upon the gelatino-bromide process, which, amongst amateurs at any rate, is now the most popular of all. This process, with which even the youngest worker is familiar, will yield under suitable treatment slides which, from a technical point of view, will be, if not superior, at least equal, to any produced by the older and more highly extolled methods. This opinion, not hastily arrived at, nor based solely upon my own work, but formed after a critical examination and comparison of the best representative work of others, will not, I am aware, be shared by you all; it is probably one of those points upon which no amount of argument will carry conviction. Some photographers, in a good old conservative spirit very refreshing in these regenerate and radical days, still refuse to believe that perfection in a lantern slide is possible of attainment, unless its production be associated with either the albumen or the dry-collodion process; but, as I have already said elsewhere, they belong to a class which still affects to regard the gelatine process as a retrogression rather than an advance. Gelatine, I must admit, is probably responsible for more bad slides than any other process. Those of you who are in the habit of attending Society Lantern Evenings are, doubtless, only too well acquainted with the frightful examples of "how not to do it" which are always to be met with upon such occasions. Such undesirable results are, however, in no way attributable to, or inherent in, the process, but are solely due to lack of skill upon the part of those who work it. One great advantage of the gelatine process is its rapidity, combined with the enormous range of colour obtainable, ranging from black to yellow—a very important point, as I have already said, to the artistically minded slide-maker.

Commercial lantern plates vary greatly in quality, some being very much better adapted to their purpose than others. I cannot here, of course, make specific reference to particular brands, but the observant worker should have but little difficulty in making a wise selection. Freedom from granularity is one of the most important attributes of a lantern-slide emulsion, and, given a suitable exposure and system of development (upon which, of course, to a large extent, the physical condition of the image will depend), the plate showing least granularity will make the best slide. Great rapidity is inimical to the obtainment of these conditions; therefore, as a rule, rapid lantern plates should be avoided, though it is only fair to add that there are some such plates in the market capable of giving fine results. For reducing, a plate containing bromide of silver is almost a necessity; but, for contact work, a plain chloride plate may be used with advantage. The latter plates—for some reason not easy of solution—have never met with the popularity they deserve. Possibly their indifferent keeping qualities may have had something to do with this want of popularity; at any rate, when freshly prepared and skilfully developed, slides may be produced upon them possessing all the fine qualities usually associated with the albume process.

* Concluded from page 47.

Given a good plate, the excellence, or otherwise, of the result obtainable upon it depends to a very considerable extent upon the mode in which it is developed. In this respect commercial lantern plates vary very much, and treatment that would produce a successful result with one brand might, from a critical point of view, altogether fail with another. I do not advise adhering too rigidly to makers' formulæ; and in very many instances solutions far too strong are recommended, and better results will often be obtained by diluting the developer. The attributes which constitute perfection in a lantern slide may be summed up as follows:—Its colour, whether warm or cold, must be pure, and not dirty or degraded; the range of gradation must be as perfect as possible from high light to deep shadow, but the latter must always be luminous, never opaque, and free from granularity; nor must there be the slightest degradation or veiling of the high lights. In this latter respect, collodion, both wet and dry, has a marked advantage over gelatine, for, try as one may, it is impossible to stain a collodion film, whilst a gelatine one is very prone to this defect unless steps are taken to avoid it. Almost any developer employed for negative work may be used for the development of gelatine lantern plates, though some are more suitable for the purpose than others. It is impossible to weigh the *pros* and *cons* of the legion of developers that now exist. For warm tones I am of opinion that pyro, if it be properly used, is still unrivalled. Many published formulæ give too large a proportion of pyro, and do not contain sufficient sulphite to prevent a slight staining of the film, when, as is often the case, development is protracted. With the following modified pyro developer, and giving what, with a more normal strength of solution, would be a very full exposure, I find it is possible to obtain a rich, warm, brown-coloured slide, possessing in a high degree those technical qualities to which I have adverted:—

Sulphite of soda	240 grains.
Distilled water	35 ounces.
Citric acid	30 grains.
Pyro	40 ,,

To use, take two ounces of above, adding from 30 to 40 minims of ten per cent. soluble bromide of potash, 40 to 60 minims of ten per cent. ammonia, and, for very warm tones, 20 to 30 minims of ten per cent. carbonate of ammonia.

The colour of a lantern slide is very much a matter of taste. I confess myself to a preference for a warm colour whenever the nature of the subject permits. Good taste here is the only reliable guide. A warm brown will suit most subjects—landscapes, interiors, or figures; but a winter scene, particularly if snow or frost is depicted, would obviously demand a cool grey or black. One does, however, even now occasionally meet with such an anachronism as an ice-bound river portrayed in ruddy brown, as, for example, in the slide now upon the screen; when the same view is presented to you in cool grey, I think I shall have sufficiently emphasised my point. Let us take another illustration. Although black is a safe colour in which to render almost any subject, and there may be nothing objectionable in so portraying such a subject as the north door of Calder Abbey, yet those who have visited that beautiful ruin know that its principal charm lies in the rich warm red sandstone of which it is built, and will consequently prefer the subject treated in the way I now show you, though, technically, and apart from colour, the slides are, I think, of equal merit. From a purely technical point of view, there is much to be said in favour of warm-coloured slides, for we know that the conditions which are essential to their attainment —*i.e.*, full exposure and a restrained development, with a weak developer —tend to the production of a fine deposit and freedom from granularity, the ultimate result being a finer and more delicate slide.

Hydroquinone is perhaps the most popular of all developers for lantern transparency work, probably chiefly on account of its non-staining properties. But a cleanly developer, which does not stain the hands, is not the only desideratum for which to look, and in unskilful hands hydroquinone is apt to give results which are very bad indeed. It is true that a wide range of colours can be obtained with it, but its use should be restricted to the production of warm colours, for with many commercial plates, if blacks or greys are aimed at, far better results, both in purity and tonality, will be obtained with ferrous oxalate. Although one of the caustic alkalies is generally recommended as the accelerator in formulæ for transparency work, I much prefer carbonate of soda, which seems to work more evenly, and possesses several advantages. With hydroquinone there is, at any rate in my hands, a decidedly greater tendency to block or clog in the shadows than is the case with pyro, a difficulty which it is not always possible to successfully overcome by dilution of the developer. These I consider to be the chief failing of hydroquinone as a developer for lantern slides. These are examples of slides developed with hydroquinone.

Eikonogen, either alone or in conjunction with hydroquinone, produces good results on some plates; and, in parenthesis I would say, a plate should not be condemned because with a particular method of development it does not give just the result desired, for a different treatment may result in the production of the finest possible slides. The next two slides were developed with eikonogen.

Metol and amidol have found favour with some workers for lantern-slide work. I have had but limited experience with the former; the latter, amidol, produces blacks of very great purity, and has little tendency to block or clog the shadows, but with most plates it is necessary to push development rather far in order to get sufficient density. It is an excellent developer for this reason when slides have to be produced from very dense negatives.

I am reminded by this allusion to negatives that I have not yet referred to this very important branch of the subject. The excellence of the slide will, of course, depend primarily upon the quality pictorially and technically of the negative from which it is made. Although much may be done in the way of improvement by skilful manipulation, I need hardly say that, although it may not be impossible to get good slides from bad negatives, it is certainly a difficult matter, and it is equally certain that the best slides will only be producible from perfect negatives. There is at the present time a tendency to produce thin, soft, weak negatives, probably brought about by the general adoption of gelatino-chloride paper, a degenerate tendency which, if carried to extremes, is not likely to improve the status of photography from any point of view. Such a type of negative is unsuitable for the best transparency work. A good plucky negative, with a full range of gradation, not so dense that the high lights will not show printable detail, nor so clear that the shadows are devoid of detail, will be found to give the best results. In both taking and making the negative, we cannot be too careful, for, from both a pictorial and technical point of view, defects that would perchance pass unnoticed in a paper print, will become glaringly obtrusive when magnified many diameters and projected upon the screen.

Whilst dealing with this part of the subject, I should like to say a few words upon proportion, because it has a most important bearing upon it from a pictorial point of view. In showing views of different kinds of subjects, more attention should be given to their relative sizes, and care should be taken to avoid as far as possible exaggerating the natural relative proportions of the various objects depicted. For example, it seems almost absurd to show some flowers from a bush of syringa magnified to the dimensions of prize cabbages, whereas we know that each blossom is little more than an inch in diameter, and where possibly the very next slide may be a figure study in which the figure is represented as being very much less than life size, which in its turn may be followed by a child of Brobdignagian proportions.

One word upon a matter which seriously affects lantern-slide makers. I refer to the judging of slides at open competitions. Medals are usually offered for pictures and for lantern slides, but there is no doubt that in selecting Judges regard is almost always had to the pictures and not to the slides, the result being that gentlemen are frequently appointed who, though eminently qualified to judge of the merits or demerits of the former, take but little interest in the latter, the result sometimes being that at the last moment the slides are judged hurriedly, and in an almost perfunctory manner. I would suggest, for the consideration of the promoters of Exhibitions, whether it would not be to their own interest, as well as in the interests of lantern-slide making as an art, that some one recognised as an expert in this branch of photography should be entrusted with a task which is certainly as difficult as that of judging of the merits of photographs on paper.

I have reserved the mounting of the slide for my concluding remarks, but it is by no means the least important aspect of the subject. Although a few clever amateur slide-makers fully recognise the importance of paying attention to this part of the preparation of the slide, it is astonishing how little regard is paid to it, not only by the general run of amateurs, but also, I regret to say, by the majority of professional lantern-slide makers. It must be apparent to the most superficial observer that the shape of the mask of a lantern picture will as much influence its effect upon the screen as would the mount or frame of a paper positive. Very conservative notions appear to prevail in commercial slide-making circles, and squares, circles, domes, and cushions are still the ruling shapes, the prevailing idea being, apparently, to include as much as possible of the subject upon the area at command. $3\frac{1}{4} \times 3\frac{1}{4}$ has now become the recognised standard size for lantern slides in this country, and it is, upon the whole, a most convenient size; but

that we should be limited to ugly squares and circles in our commercial slides passes my comprehension. I think, if those who cater for our wants in this direction were to give their customers the option of oblong openings, a mutual gain would result. The picture now upon the screen is the production of a well-known firm of slide-makers; technically it is a good slide, but pictorially it is entirely spoilt by its inartistic mount. To emphasise my point, when I take the liberty of substituting an oblong mask for the unsightly square one, the improvement from a pictorial point of view will be manifest.

No rules can be laid down for the guidance of the slide-maker in the selection of suitable masks, the matter is essentially one for the individual exercise of good taste and judgment. Squares, circles, domes, and ovals will rarely be found suitable, though each may in exceptional circumstances produce the effect desired. Eccentricity of any kind should be avoided, oblong openings will be found to best suit the majority of subjects. The incongruity and bad taste of fancy shapes, such, for example, as that now upon the screen, will be obvious to you all, though the fact that such masks are commercially obtainable would appear to indicate that a demand (let us hope a small one) exists for them.

The shape which sins most against the artistic is the oval. It is, at any rate in a lantern slide, but rarely to be tolerated. It may be said that it serves a useful purpose in cutting off an uninteresting foreground, but where its employment for this reason would seem to be indicated a more pleasing effect will often be produced by vignetting. The practice of vignetting has been very strongly condemned, but in some cases a very pleasing and artistic effect, difficult to obtain in any other way, may be secured.

Mr. Tulloch, in the paper to which I have already referred, advocates printing lantern slides with a white margin, and his remarks upon the subject are so telling that I take the liberty of quoting them:—

"Everybody, I presume, understands the meaning of tone values. Briefly, it means the degree of black, say, which must be used to represent different colours in a composition. Say that a drawing has to be made in black chalk, or pencil, of such a subject as a plate of fruit, consisting perhaps of lemons, green grapes, and black or blue grapes. How dark must these various objects be to roughly represent the intensity of colour carried to the eye from the lemon and the two kinds of grapes. None of them will be white, of course, and, assuming that the lemon will be the lightest, it will yet be darker than pure white, the green grapes will be slightly darker than the lemon, and the black grapes darker still. These and the tone value, and this is what I am driving at. A white margin will show that the lemon was not white, but a pale tint less luminous than white; from the value of the lemon you can determine the value of the grapes. Suppose, now, we remove the white margin. What happens? You have lost the key to the tone values. . . . . All must have noticed how very frequently sunshine effects are mistaken for snow scenes when shown upon the screen. Dust on the road looks like snow, sunlight on the leaves looks the same. Why is this? No doubt some of the pictures are bad, but not all such. The road is not absolutely white, neither the high lights upon the leaves; but, having no absolute white wherewith to judge, they *seem* to be white, and hence the snow effect."

With every word of Mr. Tulloch's in this connexion, I most cordially agree, and, although I cannot show you the actual slides to which his remarks refer, the next two slides, which I have somewhat hastily prepared, will, I think, demonstrate the truth of his remarks.

I need scarcely point out what an important influence upon the pictorial effect of a lantern slide the introduction of a suitable sky has in those cases where, in its absence, there would be an expanse, more or less large, of blank, white screen. Many photographers who would not dream of letting a paper print go forth without a sky never attempt to introduce one into a lantern slide. The difficulty, however, of double printing is really no greater, indeed, I think it is less, in the case of a slide than a print, and may be reduced to a minimum by printing sky and landscape on separate plates. When this last method is resorted to, care must be taken to secure a similar colour in both landscape and sky A word of warning whilst upon the subject of skies. At the present time moonlight effects, so called, generally produced by and against the light exposure at or near sundown, are very popular with the public, and when exhibited generally elicit applause. Many, indeed the majority of, such effects are grossly untrue to nature, the tonality altogether false, the "catchy" effect being due to an excessive contrast of light and shadow, as offensive to a trained eye as it is false to nature. The high lights in such pictures are often far too brilliant and devoid of tone, and the dark clouds with which they are contrasted are far blacker and denser than any clouds ever are in nature. Let those who are fond of such effects (and, when rendered with some approximation to truth, more beautiful subjects for lantern slides could not be found) not forget that cloud forms, however heavy in themselves, are but vaporous masses, and in their most thunderous and forbidding aspects, always luminous. The caution being given, the evil may be easily avoided, both in the development of the negative and of the slide by following the golden rule, "Keep the shadows luminous and avoid undue opacity." I will now show you one or two examples of difference in rendering of the same subject, as a practical illustration of my remarks.

I have now completed, though, I fear, in a very inadequate manner, the task which has been allotted to me. I cannot say that I regret that the opportunity has been afforded me of putting my views upon the subject in a concrete form before you, though, doubtless, abler hands than mine might have been intrusted with the task, for the subject is one in which I take the keenest possible interest. Slide-making and the use of the optical lantern have always been a pet hobby of mine, and I am glad of the opportunity of endeavouring, however feeble may be the attempt, to raise the status of a branch of photography than which I believe none other has a greater educational value. Where a positive on paper may be seen and admired by dozens, the same picture, when projected upon the screen, can be seen and admired by hundreds. Where the one imparts its lesson to the few, the other instructs the many; therefore of a lantern slide it may be truly said, "It gives the greatest pleasure to the largest number." I do not profess to teach you a process. There are many here who are far abler exponents of the different processes applicable to the production of lantern slides than myself, by whom practical information will be ungrudgingly given. JOHN A. HODGES.

THE MAXWELL THEORY OF LIGHT.

[Photographisches Archiv.]

THERE was once an island, and all its inhabitants were blind. It had no means of communication with the rest of the world. None of its inhabitants had ever heard anything about the eye.

Nevertheless, there were many things they knew concerning light, as their other senses were well developed, and from time to time they felt round about them, that it was uniformly warmer. They were aware of this by touch, and they knew it was here, and that it was not there. It could be distinctly felt, and consequently it must be something material.

Then their learned men drew attention to a remarkable fact, a solid body, placed at some distance from the hand feeling warmth, caused the sensation of heat to disappear; consequently warmth could not be a solid body, it must have some resemblance to a wind proceeding in a straight line from some very distant moving body, because objects placed in its way stopped further progress.

In course of centuries the science of this warm wind became more and more developed. New experiments were constantly being made. Much had been learned from them, and very fine instruments, extremely sensitive to this wind, thermometers, &c., had been constructed. By their means the movement of this distant body, which they called the sun, as well as many other facts, were scientifically established.

But, some centuries ago, great objections had been made to this wind theory. No one had ever succeeded in applying this force as a motive power to an instrument resembling a windmill. On the other hand, however, it had been shown, that there were certain solids, that this force could penetrate. Yet, what it was, nobody knew.

Then somebody invented a theory, and gave it an attractive name, fluidum. Fluidum was something incorporeal. Enthusiastic followers took it up, although none of them could imagine what an incorporeal body could be.

In later years this fluidum theory was followed by another. It was maintained that light, that mysterious power, might resemble sound. The latter also had been thought a fluidum. But, with their delicately sensitive fingers, they had noticed the harmonious vibrations of a plate with music. Even a record of this motion had been made in wax by means of a pointed instrument, and it was thus demonstrated, that sound must be a vibration of the air. Amongst the younger men the sound theory found many followers, but the elder still maintained the fluidum theory, because the younger could not succeed in adducing direct proof, that this other power, known as light, could also produce vibrations.

The younger men sought for experimental proof, and found it in the following manner: By means of a perforated disk, that could be made to rotate, an instrument was constructed, which rendered it possible to project rays of sunlight upon an ebonite plate, and to cut them off in alternation. The ebonite emitted a dull tone. The quicker the disk was rotated, and the quicker the intervals succeeded one another, the higher was the note.

In this way was proof adduced, that sound and the other force were essentially the same. Former explanations were abandoned, and every one adopted the new . . . . .

We will now return to facts.

For light substitute electricity, and for men blind to light, men blind to electricity.

The power of the magnet and electrified bodies to affect others at a distance was noted in early times, and at first a fluid theory was propounded. The progress of optics, however, rendered it necessary to abandon this view. Then Maxwell came, and propounded his electro-magnetic wave theory, to which light waves should also belong. Light should be a manifestation of electricity, and electricity an undulation.

The celebrated experiments of Hertz seemed to prove this theory. He made electric vibrations, which, though enormously larger than those of light, had otherwise all the properties of the latter. They were refrangible, gave interference phenomena, &c. The quicker his oscillator worked, the smaller were the waves. From this it was inferred, that electric colours existed, which differed from one another in the same manner as the colours of light, by their different wave-lengths. Since that time the undulatory theory of radiant electricity, and consequently the electro-magnetic theory of light also, has received increased acknowledgment.

But are these inferences justified?

Our parable narrated how the blind wished to prove by the photophone the sound theory of light; but no educated person, who can see, would believe it, because he knows that these photophone waves consist of a complex of light waves. The more rapidly the light is intercepted, the less will be the number of the actual light waves, of which each photophone wave is composed. But, though the latter are complex, reflection, refraction, and interference may be observed.

It is precisely the same with Hertz's waves.

Nevertheless, it is probable, that electricity is transmitted in an undulatory manner through the air, but Hertz and his followers have not adduced positive proof of this. What they have observed is, waves composed probably of complexes of much smaller waves. These smaller ones may be the actual electric waves.

Until the latter is thoroughly established, optics should not be subordinated unduly to the teachings of electricity. AHRIMAN.

ACETYLENE AND INSURANCE.

AT a recent meeting of the Philadelphia Fire Underwriters' Association, Mr. Charles A. Hexamer gave his views on acetylene gas, viewed from the insurance standpoint:—

"Acetylene gas burns with an exceedingly luminous flame of much greater candle power than the best city gas. If furnished to the consumer through underground pipes in a manner similar to the present system of city gas supply, there would be no greater risk from its use than from the use of city gas. In order to cheapen its use, however, it is proposed to supply acetylene gas to the consumer in cylinders, in a liquefied state, under a pressure variously estimated at 750 to 1000 pounds. It is stated that a cylinder of gas, four inches in diameter, four feet high, will contain enough gas in a liquefied state to supply an ordinary ten-room dwelling with gas for three months. These cylinders it is proposed to connect directly with the gas pipe in a building; when empty, to be disconnected and a new cylinder substituted. It is necessary to reduce the 1000 pounds' pressure in the cylinder to a small fraction of a pound at the burners. This is done by a Pintsch valve, a rather complicated mechanism.

"Two important questions present themselves at this point:—

"(1) What would be the result if a possible fire in the building should reach the acetylene cylinder?

"(2) What would be the result if the reducing valve failed and the entire gas pressure in the cylinder were suddenly thrown into the gas pipes in the building?

"It is stated that, while it is true that an increase of temperature involving the gas cylinder would produce increased pressure, before the pressure would cause a rupture of the cylinder (which is said to be tested to 3000 pounds), decomposition of the acetylene gas into carbon and hydrogen would result, with no explosive effect. This result, it is claimed, has been obtained by heating a small cylinder of liquefied gas in a fire to a cherry-red heat. While this may be true (and similar decomposition of gases—notably hydrogen sulphide, which in a cylinder subjected to heat deposits free sulphur and liberates hydrogen—are known), it remains to be demonstrated whether cylinders of liquefied acetylene gas can safely be heated without disastrous results, the fact being that the quantity of hydrogen liberated equals in volume the acetylene decomposed; the danger of a rupture of the cylinder, therefore, is not eliminated by the decomposition of the acetylene. The result of failure of the reducing valve, which operates automatically, can be easily imagined. The liberating of a gas at nearly 1000 pounds' pressure into gas pipes not intended to carry more than a few pounds' pressure must necessarily produce disastrous results.

"From the above it will seen that the points of interest to the underwriter are the presence of cylinders of liquefied gas in buildings in case of fire, and possible failure of the valve intended to reduce and regulate the slight pressure of gas necessary at the burner. There is no reason why the objection from these points should not be overcome. Cylinders of compressed gas can and should be located outside the building, and a safety valve can be provided to empty the cylinder, discharging the gas into the open air outside of the building, in case the reducing valve fails to act.

"Besides furnishing acetylene in liquefied state under pressure, it is proposed to introduce small gas machines intended to generate acetylene directly from the calcium carbide. Apparently no special hazard attaches to this plan, provided the gas machine be located outside the building, and provided the calcium carbide be stored in a dry place and free from an accidental contact with water, which, generating the gas, might cause a fire or an explosion by coming in contact with an open light.

"It is too early to formulate rules and requirements for safe introduction of acetylene gas for illuminating purposes. The subject has hardly passed the experimental stage. The result of an accident to a cylinder of the compressed gas brought it forcibly to the attention of the underwriter. That the disaster was the result of the accidental and possibly careless breaking of a valve being experimented with cannot be allowed to modify the deduction to be drawn. As an illuminant, acetylene is so far superior to ordinary city gas that, if the claim made as to the relative cheapness of its production can be substantiated, its general introduction may be expected. A careful consideration of the subject by underwriters' associations is necessary. In the mean time, underwriters are wise who carefully consider each application for the use of this new gas in its present state of development, and, until proper regulations and requirements have been formulated for its safe introduction, refuse to grant permission for its use in buildings covered by their policies."

THE VIVISCOPE.

[Scientific American.]

A GREAT deal of ingenuity is devoted to the production of entertainment devices, and many most ingenious ones have been illustrated in our columns, but it is seldom that one more interesting, from the scientific as well as amusement standpoint, can be offered to our readers than the one termed the viviscope. Supported on a standard is a circular stage. Concentric with the stage, a circular block, about eight inches in diameter, is rotated by a hand wheel. This block is surrounded by a cylinder secured immovably to the circular stage. Attached to the disc are two wires projecting nearly radially from it, and carrying at their outer ends a block of crescent shape, and which depends directly over the perimeter of the stationary cylinder. As the hand wheel is rotated, this block whirls around and around the cylinder.

With the viviscope are supplied a number of endless bands of paper with coloured pictures of figures in progressive stages of movement, drawn on the zoetrope principle, the same as is followed in securing the photographs for the kinetoscope and vitascope. These bands have their ends pasted together, and are of such length as to fit rather loosely over the stationary cylinder and the depending block. A screen with a hole is provided, which is mounted on the perimeter of the circular stage, and through this aperture the spectator is supposed to see the figures. One of the beauties of the instrument is that the screen is not really necessary, and that without it the movements can be seen by an entire room full of people. When the hand wheel is turned, the block whirls around between the stationary cylinder and the endless band with the figures on it. As the block passes under each figure, by a very peculiar principle of wave motion, the figure is shifted one space forward. Thus, for each rotation of the block, every figure on the band, which, of course, means the whole band, is shifted one space ahead, so that a perfect zoetrope effect is produced, and the figures seem endowed with life.

The easiest way to figure to one's self the mechanical principle evolved is to imagine a rope secured to the floor at one end of a room and reaching clear across it exactly to the door sill opposite the wall, near whose base it is attached. Now let a footstool be placed beneath the rope near the fastened end. It is obvious that the free end will be drawn back, say a foot, from the door sill, and, of course, all the rope in front of the footstool will share the same displacement. Now let the footstool be moved forward toward the door. The rope will pass over it, and, as it is left behind by the footstool, it will regain its original place upon the floor. Each particle of the rope is left one foot in advance of the position it occupied when in front of the footstool. As the footstool is pushed out of the door, the end rope will leave it and regain its original position with its end at the door sill a foot in advance of its position when the footstool was beneath the rope back of it. The difference between the rope illustration and the mechanism of the viviscope is that in the viviscope an endless band takes the place of the rope.

It will be obvious, we think, why this ingenious toy seemed worthy of a

far more than passing consideration. It represents a most ingenious mechanical movement, one which may be termed paradoxical, and which really is a good subject for the exercise of ingenuity in reaching a full and satisfactory explanation of its principle. Independent of this feature, it forms an excellent entertainment device, one whose principal charm consists in the fact that the figures are directly seen without the intermediation of any slot The band is perfectly fixed in position, except such parts of it as the block passes under; the block being but one-seventh of the circumference of the cylinder, the band is stationary six-sevenths of the time. This gives the requirements for a kinetoscope, and the viviscope must, we think, be recognised as such. It is peculiarly timely now when the public has been so much interested by the exhibitions of the kinetoscope and vitascope, which have been witnessed by so many. Considered as a toy, it marks the only radical advance ever made on the construction of the old slotted zoetrope. It is manufactured by E. B. Koopman, 33, Union-square, New York.

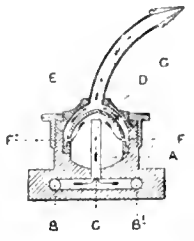
A NEW JET.

Mr. C. W. Locke is the patentee of this invention, which has for its object the more perfect and intimate association of the two gases in the mixing chamber by simple mechanical means, thereby increasing the power of the jet with silent burning of the gases.

The jet slides consist of two tubes connected by a suitable piece of metal at one end, which carries the jet pin; these two tubes telescope into two other tubes which are attached to the lantern body for which the jet or jets are intended, ready adjustment being thereby obtained with greatly increased steadiness of the jet, which hitherto has been impossible with ordinary tin trays.

Mr. Locke says: "In order that my invention may be clearly rendered, reference may be had to the accompanying sheet of drawings, in which fig. 1 is a sectional view of the jet chamber; fig. 2 is a plan and part section of jet slides; fig. 3, perspective elevation of jet slides. Similar letters of reference are used to indicate like parts.

FIG 1



"In constructing a mixed gas jet I employ the two usual tubes, B and B1, to conduct the two gases to the chamber, A; but, instead of leading the gases direct into the said chamber, they are caused to intermix underneath it, at C, and to enter the mixing chamber together through the vertical orifice, D. Over this said orifice is placed a deflecting cone, E, which causes the gases to descend and to issue into the upper part of mixing chamber, A, above the cone, E, through a number of fine perforations, F and F1, around the base of the cone; the gases are then passed on to the nozzle or burner by a tube, G, of special length and bore. In constructing the jet slides, I employ two tubes, H and H1, fig. 2, and connect together at one end by a piece of metal, I, which carries the jet pin, J. These two tubes are made to telescope into two other tubes, K and K1, which are attached to the lantern."

FIG 2

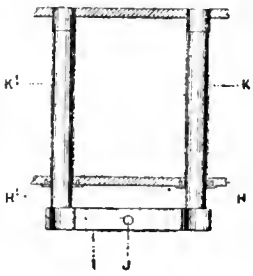


FIG 3

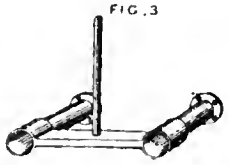


The claims are, in the case of the jet:—

1. A more perfect intermixture of the two gases.

2. The prevention of the gases reaching the nozzle imperfectly mixed, by compelling the gases to enter the chamber together through one orifice, instead of two as usually employed.

3. The vertical orifice and perforated cone, causing the gases to be split up into fine streams and finally bringing them together in the upper part of chamber.

4. Compelling the gases to travel through a longer course than usual in close association.

5. Greater intensity of light, with absolute steadiness and silence in burning.

In the case of the jet slides:—

1. The means of entirely dispensing with the usual tin lime tray.

2. The means of leaving the bodies of lanterns entirely open from bottom to top, allowing the ready escape of heat.

3. Ready adjustment, with great steadiness of the jet, which hitherto has been impossible with the ordinary tin trays.

THE SKIRT DANCE.

The famous skirt dance may be defined as peculiar in the sense that it is not, says the *Scientific American*, a dance as generally understood in stage parlance. The performer standing on the stage and dressed in voluminous attire, requiring, it is said, over a hundred yards of material, by slow motions comprising more arm movements than foot movements causes the light drapery to wave about in most graceful curves. The variety of shape and contour that can be produced by a skilled performer is endless. To add to the effect, wands are used to extend the reach in the direction of the lines of the arms, and the greater control thus obtainable adds immensely to the effect. This dance was made famous by Miss Loie Fuller, whose reputation is now world-wide. During the past season refinements and improvements introduced in it have made of it a new thing.

The performance is executed in a darkened theatre. A number of projectors are distributed, four in the wings and one below the stage, so as to be adapted for flooding the figure of the danseuse with light. A pane of heavy plate glass set in the floor of the stage permits the projector beneath it to produce its effects. Each projector has mounted in front of it a disc about three feet in diameter, perforated near its periphery with a number of apertures. Coloured gelatine is fastened over most of these apertures, a different colour being used for each opening, except where one may be left for white light. The operators at the projectors follow the movements of the performer, and can produce an almost infinitely extended range of effects by varying the colours thrown by each projector.

The theatre being pitch dark, the figure can be brought slowly into view, and can be made to slowly disappear by manipulation of the projectors. She can appear in any colour or combination of colours, and can die away in similar manner. It is needless to say that it is a composite performance, in the sense that the dancer fills only a part of the functions; skilled operators are absolutely essential at the projectors.

One of the prettiest effects is produced by a magic lantern operated from the front of the stage, and shown in the cut on the left hand. The operator projects upon the drapery different figures and designs, using regular lantern slides, making the flowing, misty drapery act as the screen for his projections. It is obvious that he must give great attention to his focussing.

The skirt dance has won the attention of artists, and some very beautiful statues have been based upon its cloudlike variations of form. The slight idealisation required in representing the soft forms of waving drapery in the solid material of the sculptor's art has given most graceful and characteristic effects.

One of the most startling effects is the flame dance. The filmy veil is pure white, but, as the dancer approaches the opening in the stage floor, the veil turns to a fiery red, and the flames wave to and fro as if they were being blown by the wind. Shadows are then thrown on to the veil, which produce an exact reproduction of heavy black smoke, which suddenly changes to an ardent flame again, as if the fire had broken out anew.

HAND-CAMERA WORK.

This is a month of great activity among outdoor photographers, and the hand camera will, doubtless, be largely in evidence everywhere. The bicycle offers a means of rapidity, reaching places that possess pictorial interest, and the bicycle and the camera are closely related, since the one furnishes the means for the outing, and the other the excuse. The hand cameras of to-day are readily carried, being light, compact, and of a shape that is the most convenient for the traveller. Some few points in connexion with the camera may here be noted. The finder should be fully understood and marked, so that the relation that the image on it bears to that on the ground glass may be accurately known. The lens should be taken care of. It is not an uncommon thing to see the front of the camera pushed back for closing, accompanied by a rough handling of the lens. The latter, being the nearest or most projecting part of the front, is seized and used as a handle to force the front of the camera to the rear of the box. In addition to the danger to the rackwork or focussing gear, there is, especially when the shutter is between the lenses and no cap is used, a danger of smearing the front lens with perspiration from the hand, or even of loosening the screws holding the lens to the front board. The camera should be opened and closed by using the device supplied for that purpose; and, while on the subject of lenses, it may be well to note that these should often be examined as to their cleanliness, especially in hand cameras, which are subjected to somewhat rougher treatment than tripod boxes. Again, the diaphragm numbers should be verified. Many photographers with whom we come in contact have not the slightest knowledge of the significance of the diaphragm numbers, and, on attempting to use an exposure meter, find that they are unable to carry out the calculations because of their ignorance on this point. In the majority of cases the value of the diaphragm, given in the directions accompanying the exposure meter, is expressed by a fraction which gives the number of times that the diameter of the diaphragm is contained in the equivalent focus of the lens. The diameter of the diaphragm is accurately measured, and the equivalent focus of the lens divided by it. For example, supposing that the equivalent focus of the lens is twelve inches, and the diameter of the diaphragm is one-half an inch, then the diaphragm number is *f*-24. Should the diaphragm be marked after the U. S., or uniform system, this may be found by squaring the number

obtained after the above method and dividing by sixteen. Thus, in the example given above, the diaphragm *f*-24 would be marked U. S. 36; for $24 \times 24 \div 16 = 36$.

Hand cameras that are fitted with swing back, swing front, sliding and rising fronts, require especial care, that error be not made by the inadvertent use of either of these conveniences. It is best to make it an invariable custom to restore the camera to the normal condition before closing it up.

A tripod should, whenever possible, be taken along. While it is true that many excellent pictures have been made with the camera held in the hand, it is also true that a close examination of the ground glass, possible only when the camera is supported on a stand, will facilitate the obtaining of truly artistic results. The hand camera is no longer an instrument for snapping here and there at moving objects. It has practically displaced its tripod-holder brother, and is capable of doing all that has been done with the latter. The hand cameras of to-day are simply compact and portable modifications of tripod cameras, and, whenever possible, the stand should be employed. Held in the hand, approximation only is possible; placed on a tripod, accuracy is obtained.

Exposure meters furnish a useful guide, and should be given careful consideration. Correct exposure is necessary for the production of perfect negatives, and any instrument that will help in the gauging of this important factor should not be despised. Of their efficiency we can speak from personal experience.—*Anthony's Photographic Bulletin.*

THE DRIFT OF THE AMERICAN LANTERN TRADE.

It is doubtful if any business more forcibly illustrates the remarkable growth of this country than the magic-lantern trade. Twenty-five years ago, says *The Exhibitor*, only three houses were engaged in the business, two of these three being offshoots from the first; to-day there are two dozen deeply interested in the business, together with an endless number of opticians, variety stores, and others, that more or less handle the lanterns and views. The fact that they "do" is a sufficient answer to the question that naturally arises as to how they all can exist. This business differs not in its laws from those that govern all trades; unceasing efforts to improve the quality, vary the stock, and wisely regulate the prices are the tests that determine the success or failure of any trade; as regards quality, one who has studied the drift of this trade must have forced upon him the value of the advice to keep the "BEST." Keen competition, that of necessity follows such a spread of business, has forced down the prices of all goods; the margin is very small but the goods that have been kept up to the best have not been forced into the competition as deeply as the cheaper grades. The slide section of the business has suffered more from the competition in quality than the lantern. Up to a few years past the coloured slide business was controlled by parties who felt that, when a thing is to be done, it should be done in the best manner; this sentiment became a reality with them, and the American public had a line of lantern pictures that far excelled any other stock.

True the variety of subjects was very limited as compared with the English market, but the quality was infinitely better, better by reason of good originals, and better by reason of better painting. There has never been any earnest effort made by the American manufacturers to furnish plain views of scenery such as has been shown by the French and English makers, and consequently there is not in the market to-day a full set of the natural scenery of this country of first-grade slides. This shows a lack of enterprise that is remarkable, considering the opportunities offered. We are patriotic enough to think our scenery and wonders excel all others.

The plain slides in the market, of American make, covering all other subjects, such as Bible history, sentiment, hymn illustrations, intemperance &c., are so far above the English grade as to be beyond comparison.

This is owing to the fact that nearly all of such American slides have been furnished by the maker of the best coloured views, and in their production artistic skill and liberality have been the potent factors.

The advent of the English slides in the market has given the public a greater variety with a much lower grade; such an influx necessarily had its effect on the trade, new things always attract attention, but a public which had been educated as this has been could not fail to soon recognise the vast difference in quality, and the reaction has already set in, so that the demand for the better goods has already made the past season better than for several years. Right here we would impress the fact that there is a wide field open for slides to suit the American public, the mass of the imported stock deals with scenes, characters, habits, and customs that are entirely foreign to the American ideas.

CUTTING AND MOUNTING STEREOSCOPIC PRINTS.

Cutting and mounting is the most troublesome part of the business, but, though rather tedious, it becomes easy with practice. I use an ordinary half-plate cutting shape, with a series of horizontal parallel lines ruled upon it, and also the vertical height of the print marked at each end; I cut upon a thick sheet of glass, with a convex-edged knife.

The prints, it must be borne in mind, have to be transposed on the mount, or else a *pseudoscopic* effect would result, distant objects being brought near, and the foreground thrown into the distance; in fact, the whole scene is turned inside out. So, before the halves of the print are separated, it is well to turn them over and mark on the backs L and R, and then, when they are turned face up, the letters will come right. The R will be on the half which was originally the left, and will indicate that it now has to go to the right. I don't trouble to do this myself, for, before pasting them, I just give a stereoscopic glance to see that they are right, and again, when they are on the mount, to be sure that they coalesce properly.

Another important thing to note is that the distance between the same point in each picture should not exceed $2\frac{7}{8}$ inches. It is easier for many persons to unite them in the stereoscope if the separation is only $2\frac{3}{4}$ inches.

I believe that some people have never seen a stereograph properly, and that the atrocious way in which some commercial slides are mounted has discredited the stereoscope. I have found some slides as much as $3\frac{1}{2}$ inches. No ordinary eyes can unite these without the greatest strain, and they soon get weary of it even if they do succeed in seeing the picture stereoscopically.

I have seen a method of measuring the prints described by means of parallel vertical lines, ruled on the cutting shape and numbered, but from the method I use in cutting I do not require to measure at all. I print on P.O.P., the sheet cut into sixteen. This gives more height than is necessary, but I like to have plenty of margin to decide where to cut my top and bottom lines. If printing half-plate negatives at the same time, I fold for the last cut unequally, making the one an inch wider than the other for the single views. The paper, however, only cuts just long enough for the stereo prints, and, if one is not very careful in folding, some will turn out too short.

Now, if any of you can cut P.O.P. sheets with perfect accuracy, I shall be extremely obliged if he will tell how he does it. So far, I have found it the best plan to fold the paper *lengthways* for the first cut; owing to the spare width of the paper, it is not of so much consequence if there is a little creep in that direction, and the subsequent foldings are easier to make accurately. I also clip the corners together with American clothes clips before creasing down. The paper must be laid carefully on the negative in the printing frame.

Having decided where the bottom of the picture shall come (and you can have more foreground than would be artistic in a single picture), I lay the shape in position, so as to cut through the same point in each half; or, if no object is sufficiently visible there, I set it by one of the parallel lines on the glass. The top is then cut in the same way. I usually make the picture about 4 inches high. I then cut each end as close as I can to the edge of the paper without nicking or gapping the print, which is sure to happen if the knife is at all dull, and not enough margin is left for a continuous strip to be taken off. It is a good plan not to begin this cut at the edge of the paper, but to leave about $\frac{1}{8}$ inch uncut; otherwise, as you finish your stroke, you will probably tear away the corner at the lower end. Having trimmed the double print all round, it then has to be divided, and there will be a strip of $\frac{1}{4}$ inch or so to come out of the middle.

I pass over the prints to another pair of hands to brush the mountant on, and receive them back to place them on the mounts myself, having first marked with a pencil from a gauge on a T-square the dividing line between the two halves—not quite in the centre of the card. I place the left hand print first in position, bringing it up to the marked line, and about $\frac{1}{8}$ inch from the bottom of the card. See that it is squarely on, and squeeze it down. I then similarly place the right-hand one, leaving a space of $\frac{1}{16}$ to $\frac{1}{8}$ inch between them. I then sit on them till I have completed the batch, using, of course, a flat-bottomed chair and a board or a book to equalise the pressure.—Judge Docker in the *Australian Photographic Journal.*

Recently, while taking a flashlight photograph in the store of A. C. Satterlee, 3422, Germantown-avenue, Otis Wheelock, aged 28 years, of 154, North Eleventh-street, was severely burned on the arms and face by the explosion of the powder he was using. The force of the explosion threw both Wheelock and his assistant out into the street, but the assistant escaped without injury. Wheelock was taken to the drug store of M. Sonntag, 3415, Germantown-avenue, and it was found that his left hand and forearm were severely burned. But for the glasses he wore it is probable that his eyesight would have been destroyed, as the glasses were black with the burnt powder, while the left side of his face was also badly burned. M. Sonntag dressed the injuries, and on his advice Wheelock was afterwards taken to the Samaritan Hospital, where he was also treated. Wheelock is a travelling photographer from New York City, and has been in Philadelphia for about three months plying his vocation. He stated that he usually purchases the powder for flashlight purposes by the pound, but being out of the material, he had bought a single ounce at a store which he said he can locate, and believes that the boy who served him gave him an explosive by mistake for the powder he asked for. He stated his intention of holding the proprietor responsible for the mistake which resulted in his injuries.

MONTHLY SUPPLEMENT

TO THE "BRITISH JOURNAL OF PHOTOGRAPHY."] [*August 7, 1896.*

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

IN another month lanternists will, so to speak, "be putting their houses in order," and the first thing to engage their attention will naturally be, if they use the limelight, the supply of gas. The decision of the Home Office Committee on the safety of cylinders of compressed gas has caused one of the gas-compression companies to issue a circular to the effect that certain types of cylinders will, in future, be filled to three-fourths of the previous pressure only, viz., ninety atmospheres, instead of 120, as heretofore. This, as stated, is to ensure a uniform factor of safety.

* * * * *

MOST users of gas, who are near the filling centres, or have a reserve of cylinders, will not object to this regulation, and those who are purchasing new cylinders, if they do not mind a little additional weight, can still have the full pressure of 120 atmospheres. There have been quite enough changes in the regulations as to testing, and in the condemnation of certain types of cylinders previously supplied and filled, that I think the company are wise not to cripple the industry by condemning the lighter make of cylinders entirely, if they are sound and fulfil the requirements in other ways.

* * * * *

THE whole of the practical suggestions of the Committee, as far as they affect the conduct of the trade, as in vogue last season, seem to be in the working-stress limit, which has been fixed at eight tons per square inch for seamless steel cylinders, and seven and a half tons per square inch for lap-welded steel cylinders. The older type of cylinders, while considered by experts in engineering perfectly safe at a higher working stress, will not now fulfil these conditions, hence the filling to a lower pressure, so as to reduce the working stress.

* * * * *

NERVOUS people will be doubly assured if they have their cylinders filled to only ninety atmospheres, and, as they will still have thirty cubic feet of gas in the forty-feet-size cylinders, and nine feet of gas in the twelve-feet size, they can easily arrange their supply to suit the consumption, according to the kind of jet they use and the average duration of the entertainment or lecture. In inexperienced hands the lower pressure is, no doubt, more manageable, especially for use with sulphuric ether, or where no automatic regulator is used but some system of fine screw adjustment.

I FANCY a good time is coming again for the Biunial and Triple lanterns, as audiences are looking for something different to a succession of plain photographs. The animated pictures have given a zest for movement, and now is the time for those who have really fine dioramic effects to show the general public what can be done with properly registered well-coloured photographs, having effects or fine hand paintings. I believe I am quite right in saying that not five per cent. of the audiences at the halls where the animated pictures are being exhibited, and who nightly show so much appreciation of the results, have ever seen a really high-class entertainment of dissolving views and dioramic effects.

* * * * *

THE mechanical branches of the optical lantern world have not been idle during the last two or three months, and the consequence is that simple and practical apparatus will shortly be available for taking and projecting photographs of real life, and that can be purchased for sums that are within the means of private enthusiasts and lecturers who cater for mechanics' institutes, schools, &c. I know of two or three such apparatus, and when I have seen the latest patterns at work, which I hope to do shortly, I will give some details of them.

* * * * *

I HAVE been away from town for three weeks, and have thought little of lantern matters, for my mind was fully occupied with questions of refraction, elevation, trajectory, and bad ammunition affecting the marksmen who have been shooting for the Queen's and other valuable prizes at Bisley Camp. The temperatures of 85° to 90° Fahr., which one had to bear in the open and under canvas, was trying in the extreme, but, if I understand the description of the sufferings of those in town, my *confrères* there were certainly worse off, for the splendid air of the place and the breezes from the Surrey hills made the evenings and mornings delightful. The intense light was at times very trying, for the sun's temperature, as registered by solar radiation thermometer with blackened bulb *in vacuo*, reached 155° Fahr. I was impressed more than once with the necessity of men not used to outdoor life protecting their eyes with suitable tinted preservers, and, as this is a subject photographers, as a rule, do not pay sufficient attention to, I mention it here with the hope that those who make rapid changes (as is necessary in the profession) from the dark room to brilliant daylight will guard against shocks to their sight, and not be afraid to put on a mild, neutral-tinted pince-nez or spectacles directly they emerge from the dark room.

* * * * *

IN my own case I found it absolutely necessary at times, in order to get proper definition when reading, to put on my tinted glasses, and I feel sure that any one, like myself, suffering from mild astigmatism (and there must be thousands among photographers and lanternists) will do well to keep this matter before them.

* * * * *

I HAVE been pleased to get recently some reports of excellent results in amateur hands of the working of the small-size electric arc

lamps: among them the Lantern Society, with the new type of independent and geared adjustment for controlling either or both carbons at will, from India, where it has been used in the palace of one of the native priuces and in colleges, also when working at our own medical schools and scientific and social institutes. Wherever current is available, I say to lanternists, Try the electric arc light, and, if any of the agents for electric light installations tell you there are difficulties in the way, don't be denied, but take an early opportunity of seeing the practical result of the light being used in an optical lantern yourselves. In one of the instances referred to above the apparatus would have been put aside, and not used, if the engineer's report had been accepted as final, for it was stated that, if the light was used in the lantern, no other light in the building could be used. However, a scientific gentleman known to the possessor of the apparatus was consulted, with the result that a way was soon shown by which the current could be used, and that successfully, without injuriously affecting the other lights. G. R. Baker.

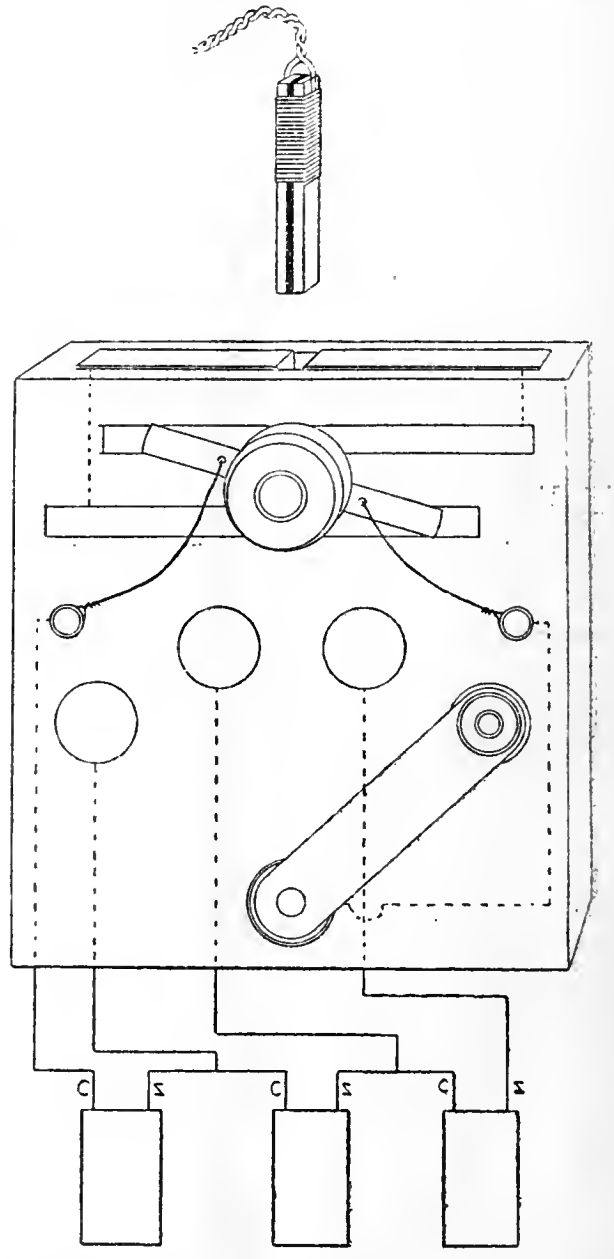
ELECTRICAL EXPERIMENTS WITH THE OPTICAL LANTERN.

All experiments which have the elucidation of a scientific lecture for their object require considerable care in preparation, and no little skill afterwards to ensure everything "going off" all right. More especially is this the case where electricity, or some allied science, is the one being treated of, and more especially still when the experiments are to be performed upon the stage of an optical lantern. Lecture-table experiments, unless performed for the benefit of very small audiences, are usually too insignificant, on account of the small scale upon which they are shown; or, if, expense and other difficulties being set aside, they are performed upon a sufficiently large scale to make them fully intelligible to every member of a large audience, they are apt to be proportionately clumsy and unmanageable. Therefore the lantern is the best means of making the experiments, though occupying but little room, appreciable to others besides those in the front row of the audience; but, if the lantern be used, everything must be done so delicately—for every fault is magnified a hundredfold—that, as mentioned before, the very greatest care must be exercised, both in preparation and actual manipulation.

Another great advantage of utilising the magnifying power of the lantern to make very small experiments in electricity serve the purpose of much larger ones is that the current required for producing the phenomena is proportionately small, and consequently the battery to produce that current need only be a fraction of the size and weight of that which would be required for lecture-table demonstrations. For instance, an electro magnet eight or ten inches high, and capable of supporting a mass of iron of sufficient size to be properly convincing to the audience, would require a battery of seven or eight Bunsen cells to work it; but a tiny magnet, the size of a halfpenny, when placed in the lantern, will appear several feet across, and will lift, apparently, a couple of tons of French nails of two feet in length by the power of a single dry cell.

I have found that a battery of three dry cells of moderate size is quite sufficient for the purpose of most of the experiments which may be performed on the lantern stage, and, if they are associated with some convenient arrangement of switches, so that one, two, or three cells can be thrown into circuit at will, it will do much to ensure the success of the various experiments. Another very important item too, where several experiments have to be performed in rapid succession, as is often the case, is a quick and ready means of making electric connexion between the necessary apparatus and the battery power, for nothing is more troublesome, or more likely to flurry and upset the operator, who has all the time the unpleasant consciousness that he is causing a "stage wait," than a number of loose wires, which *will* get entangled, and sundry screw terminals, whereof the wire holes are as elusive in the darkness as a keyhole preverbially is to him who has dined.

I have for my own use combined these desirable appliances—a multiple switch for the battery, and a plug and socket arrangement for making speedy connexions—with a current-reversing device, which last is an item of very great importance where electrolysis experiments and demonstrations in electro-metallurgy are on the tapis. The sketch shows the general arrangements, and also the battery connexions, I think, with sufficient clearness to make further description unnecessary, but a word or two about the plug and socket may not be without use. The plug consists of two strips of brass or copper, about two inches long by three-eighths of an inch broad, and of appropriate thickness, between which is sandwiched, by way of insulation, a similarly sized strip of vulcanite or vulcanised fibre, and the three are securely bound together along half their length by strong twine, which may afterwards be varnished. The lower half of the compound peg thus formed comprises the



plug proper, and to the upper half are soldered, one to each metallic strip, the two conductors of a short piece of flexible cord. The socket consists of a small square hole or pit in the top of the switch board, the two opposite sides of which are lined with brass of the same width as that employed for making the plug. Two strips of this brass, about five inches long, are bent into the shape of an L, one arm of which covers one side of the hole, the other laying along the top of the switch board, to which it is attached by screws. If each of these L-pieces form an angle of slightly more than 90°, there will be spring enough in the brass to ensure good contact with the plug when it is inserted, but care must be taken that the two arms hidden in the hole do not stand out enough to touch one another when unseparated by the plug, for, if they did that, the battery would be short-circuited, and would very soon be ruined.

A separate plug will, of course, be required for every experiment, but they can be very quickly made, and the great comfort and sense of security they give to the operator, and the certainty that they will

contribute considerably to the success and the general "go" of the experiments, will amply repay the little extra trouble which their previous preparation entails.

The two arms projecting from the socket which, by the way, may carry ordinary screw terminals, for convenience, in connecting up any "slide" which by chance is unprovided with a plug—are connected by wires at the back of the board to the two metallic bars of the current reverser, and this, in its turn, is connected—each arm by a piece of flexible conductor attached to a convenient place on the face of the board—with one pole of the battery and with the lever of the multiple switch, as shown in the diagram, while the three first studs of this switch are joined, electrically speaking, with the other pole of the first, second, and third battery cells respectively, the fourth stud being a dummy, reserved for the "off" position.

The "slides" should, whenever possible, take the form of a "cell," such as those which are sometimes used for projecting live water beetles and suchlike sensational subjects, but, of course, for most of the experiments they need not be water-tight. I am speaking of slides intended for use in an ordinary projection lantern. A science lantern, made with an open stage for experimental work, will, of course, give more room for the necessary apparatus: but, even where such an instrument is available, the cell form of slide is preferable to another, because it will confine operations, to a great extent, to one plane, and thus keep the various parts in focus upon the screen—a thing which is not at all easy to accomplish unaided. The majority of lanterns have stages deep enough to admit a slide from three-quarters to seven-eighths of an inch thick; thus there is plenty of room for a cell whose two glass walls are separated about half an inch, and in this space most of the magnetic experiments can be performed.

One slide may take the form of a cell, in which are a dozen or two of small iron nails, which, when a tiny permanent magnet is inserted, will cling to it, and can only be detached by the vigorous use of a brass rod, or some other implement; then a similar slide, but fitted with a horse-shoe electro magnet, may be used, to show that soft iron is only magnetic by virtue of the electric current circulating round it, and that, as soon as that current is broken, the magnetism ceases. A pinch of iron filings in the cell, by clinging to the poles, even after the current ceases to flow, will demonstrate the existence of that residuary magnetism, which acts an important part in modern dynamos. For such experiments as these an erecting prism is a great advantage, for to see an electro magnet drag *down* a mass of iron nails from its place on the roof is not, at first sight, so convincing as it would be if the operation were shown right side up.

The familiar experiment, so important in treating of magnetism, whereby the "lines of force" are made visible by means of iron filings sprinkled upon a plate immediately over the magnet, requires a vertical attachment to the lantern, if it is to be performed in the usual manner; but there is another plan, which should answer almost as well. Support the magnet in a water-tight cell, which can then be filled with glycerine, or other heavy, transparent fluid (how would carbon bisulphide do?) in which a sufficient quantity of iron filings (not turnings) have been mixed. The specific gravity of the liquid being very high, the filings will only sink to the bottom slowly, and, when the magnet is excited, they will rise and form the characteristic curves and festoons. In this way the usual round of experiments may be arranged for the lantern, and bar, horse-shoe, and annular magnets, or magnets in pairs, with like or opposite poles in juxtaposition, be made to exhibit their characteristic curves. In the same way magnetic fields, such as are found around conductors, within helices, &c., may be shown.

So much for magnetism. I have said nothing about the experiments appertaining to static electricity, although, according to the arrangement of most text-books on the subject, "frictional electricity" is usually disposed of before the "voltaic" is touched upon; but the very simple appliances necessary for the explication of this branch of the subject are so obviously applicable to the lantern, that it is unnecessary to say anything about the manner of application.

Electro-chemical decomposition can be well shown in the lantern, but for experiments of this kind an erecting prism is necessary, for without its aid some of the effects are exceedingly puzzling. For the electrolysis of water a simple cell is required containing the liquid—which must be acidulated, for water by itself is not a conductor—into which the current is led by means of two strips of platinum foil about an inch apart. With one battery cell no effect will be apparent, for the voltage is insufficient; with two, bubbles begin to make their appearance—they look like huge boils upon the screen—and, with the full complement of three cells, the bubbles will form very rapidly, and rush to the surface of the water, which looks as if it were boiling violently. If all this must be shown upside down—for the slide cannot be inverted—the bubbles look like mercury falling to the bottom, thus giving quite a wrong impression. Tiny inverted test tubes can be used, one over each platinum electrode, to show that hydrogen is evolved at one in just double the quantity that the oxygen is detached at the other, a condition of things which is immediately reversed when the electricity is sent through the cell in the opposite direction. Other electrolytic experiments which can be performed with equal ease will rapidly suggest themselves. Electro-metallurgical operations of a practical kind are not so easily shown, because the layer of metal deposited by this small electric current would not sufficiently affect the total thickness of the electrodes in a short space of time to be apparent on the screen, but the principle can be demonstrated by means of an analogy. Thus the gold or silver plating bath, or the copper sulphate solution, may be replaced with a saturated solution (filtered) of lead acetate (sugar of lead), in which leaden electrodes are immersed, and, when the current is switched on, the effect is a very beautiful one, a treelike growth appearing all over the cathode, while the anode slowly wastes away to keep up the supply of lead in the solution. On reversing the current, the tree will immediately droop and begin to dissolve, while that which was before the anode will at once begin to sprout with the same fernlike structure.

There are very many similar experiments which can be performed with equal ease in the lantern, which are now usually laboured through at the lecture table, unconvincing to the audience, and unsatisfactory to the demonstrator. Transferred to the lantern stage, their performance only occupies half the time, with barely a tithe of the trouble, and to the audience they will all be instructive, and many of them beautiful.

CECIL M. HEPWORTH.

SOME FACTS ABOUT ACETYLENE GAS.

[Photographic Times]

ALTHOUGH, during the past year, the daily press, as well as journals and magazines, scientific or otherwise, have teemed with articles relating to this brilliant new illuminant, it is not a little curious that an infinitesimal amount only of real information on the subject has been imparted by any of them. The appetite of the public, ever alert for something new, has been whetted by prophetic stories of its unrivalled brilliance, its wonderful cheapness, its adaptability to every demand for "light, heat and power." We have been told of its discovery in the laboratory of the chemist more than a half century ago, and how it "burned with a luminous yellow flame and volumes of smoke;" how, after slumbering useless during those long years, the accidental production of *crystalline* calcic carbide (CaC_2), in the modern electric furnace, had made possible the production of this gas on a commercial scale, how all the hitherto methods of lighting were to be superseded and night turned into day by its sun-like brilliancy. We were also told of the fabulous sums which had filled the pockets of the fortunate inventors and promoters of the new process, but the information and facts which the public were most interested in were totally wanting. Is this light what it is represented to be? Where can we see it? How can it be obtained? In what manner or form will it be made available? Is *anything* being done *anywhere* toward placing it on the market, or within the reach of those who are anxious to see and to use it? These, and a host of similar questions, were continually asked, but no reply was forthcoming. Is it any wonder that the dear public became sceptical, and the *interested* opponents of acetylene found ready listeners to their depreciating utterances?

But a good thing cannot be permanently injured these latter days, even in the house of its friends, and acetylene is emphatically "a good thing." Its production on a commercial scale is one of the most important of this century of wonderful discoveries. Its possibilities have scarcely been dreamed of as yet. I venture to predict here, that not only will it light the world, now illuminated to so great an extent by the rapidly diminishing petroleum or coal oil, but, within a decade, steam vessels will navigate every sea with coal bunkers replaced by cases of calcic carbide, the gas from which will fire their boilers, in place of the bulky and more costly coal now used for that purpose.

What is acetylene? It is a hydro-carbon gas (C_2H_2), the richest in carbon of any other, its components in volume being 92½ parts of carbon and 7½ parts of hydrogen, in 100. It is highly inflammable, igniting at a considerably lower temperature than ordinary illuminating gas, and burning with a very brilliant white flame when supplied to proper burners. The most satisfactory of these will not deliver more than one-half cubic foot per hour under a pressure of three inches of water, the light being equal to that of four burners of five cubic feet capacity each, using ordinary city gas of the best quality now supplied. The flame is essentially a cool one (owing to the small amount of gas consumed), but extremely hot at the point of ignition, as it must be to ensure the complete combustion of the large percentage of carbon which acetylene contains. This combustion is perfect; no carbon monoxide and but a small percentage of carbon dioxide are emitted, and the temperature of a room in which it is burning is raised no higher than it would be by a sufficient number of incandescent electric lamps to produce an equal

amount of light. It has been completely demonstrated that twenty such acetylene lights will not vitiate the atmosphere to a greater extent than one five-foot flame of ordinary street gas. The quality of the light is simply perfect—"a chunk of sunshine," as some one has aptly termed it. It is, indeed, daylight. The spectrum is almost identical with that of the sun; the most delicate colours are unchanged beneath its rays, and can be as readily distinguished as by daylight. It is more diffusive than any other artificial illuminant, the corners of a room being lighted equally with the immediate circle about the burners in its centre. For reading and writing it is ideally luxurious; brilliant yet soft (when properly shaded), causing no feeling of weariness or discomfort from the most prolonged usage. The flame, however, should not be gazed upon by the unprotected eye, being too brilliant for comfort or safety, and it should always be shaded in some manner. The light being of such potency that a very small burner, consuming not over one-eighth cubic foot per hour, will give the light of twenty-five candles, it may be burned in a great variety of shades and devices hitherto used only with electric incandescent lamps. No other illuminating gas can be thus used, and many new features in artistic lighting become possible with it. But it cannot be used in the large burners of five or more cubic feet capacity required with ordinary city gas. Passed through these, it burns with a brilliant yellow flame accompanied by volumes of smoke which quickly deposit a shower of soot on everything within reach. If, therefore, acetylene be used through the ordinary gas piping of a house the burners must be changed for those of a capacity suited to it. As these cost but a few cents each, the change is of no moment, and can be made by any one.

Pure acetylene gas is not *explosive*, and cannot be made to explode under *any* circumstances; but, if mixed with air in proper proportions, it will, *in common with all other illuminating gases*, explode with a violent detonation and destructive effects. These facts should be clearly understood by every one. A mixture of acetylene with 1·25 times its volume of air is mildly explosive, the energy increasing up to twelve times, after which it decreases until, with one volume to twenty of air, the explosive quality has entirely disappeared. Indeed, the addition of twenty-five to forty per cent. of air to the gas in no wise impairs its luminosity, whilst, of course, decreasing its cost; and an apparatus has been devised for adding any desired percentage to the gas, at the point of ignition. For heating purposes a much larger percentage of air must be used.

If taken into the lungs of an animal, acetylene will produce asphyxiation or suffocation by the exclusion of oxygen, but it will not poison. This has been abundantly proved by exhaustive experiments made on guinea pigs and other animals. When confinement in an atmosphere thoroughly charged with the gas was continued long enough to actually produce death, no change was noticeable in the blood upon microscopic examination, nor was any other symptom of poison apparent. Death was, in every instance, the result of the deprivation of oxygen. In other cases, when the animals were removed to the outer air before death had ensued, they quickly recovered from the effects of the gas, as they would have done after inhaling ether or chloroform. This is in marked contrast to the well-known poisonous action of the carburetted-water gas now supplied in most of our cities, and a very strong addition to the other advantages of acetylene. A comparatively short exposure to the deadly effects of ordinary street gas is sufficient to cause great changes in the blood, and the fatalities attending such exposures are increasing to an alarming extent, as every physician can testify. The general substitution of acetylene for these noxious and, at times, almost non-luminous gases would greatly lessen the dangers attending the careless opening of keys, or the "blowing out of the gas," by those still ignorant of its use. And this, not only through the non-poisonous nature of the gas, but also from the fact that the acetylene burner, with the stop cock fully open, would discharge only one-half of a cubic foot of gas per hour into an apartment, whilst the street gas burner would pass at least tenfold that amount, or five cubic feet in the same time. It would seem unnecessary to call further attention to the importance of these facts.

From the economic standpoint, acetylene compares most favourably with street gas, even at the present cost of calcic carbide. This is now procurable at twenty cents per pound, making the cost of the gas four cents per cubic foot, a pound of carbide rarely yielding less than five feet of acetylene. Used in a burner of one foot capacity, the cost of consumption is four cents per hour for a light at least equal to that obtainable from twenty-five feet of ordinary illuminating gas. At $1·50 per thousand the latter would cost three and a half cents for an hour's consumption, rather less than that of the acetylene, but also vastly inferior to the latter in the *quality* of the light afforded. If air be added to the acetylene to the extent of thirty or forty per cent., as may be done without diminution of light, its cost is cheapened by that amount, thus bringing it below the average of that furnished by the gas companies. With calcic carbide at five cents per pound, which it is sure to fall to at no distant date, acetylene will become not only the best, but also the cheapest, of all artificial sources of light.

Next to the gas itself, the most important factor in the use of acetylene for lighting purposes is the burner. It may be safely asserted that perfection in this direction has not yet been reached by any means, though one which is a great advance upon any heretofore made, and which promises to be a perfect success, is about to be placed on the market. An insuperable objection to all burners hitherto made has been the formation of a mass of unconsumed carbon around the orifice when the flow of gas was turned down low; and, further, that at one point reached in turning down it would smoke, sometimes furiously, requiring constant watchfulness and care to prevent these annoying occurrences. Acetylene is so rich in carbon, that a very high temperature is necessary for complete and perfect combustion, and this cannot be maintained with the lava tips in common use, especially when the flow of gas is reduced to a very small amount. Metal tips obviate these difficulties to a great extent, and those to which reference has been made seem to be almost perfect.

It has been conclusively demonstrated that acetylene cannot be used in the ordinary burners of five feet or greater capacity without smoking to an intolerable degree and wasting gas as well. It is, therefore, necessary to divide the light between a number of small burners. The limit of usefulness seems to be reached at about one cubic foot capacity, though I have seen burners passing as much as 1·74 feet with perfect success, being smokeless and the flame steady. But the most generally useful and successful burner is that of half-foot capacity—a true half foot—not those which being so rated consume in reality a foot or more per hour, as do Bray's 00000. Very many complaints have reached me from parties using these burners that the carbide furnished them was inferior, producing not more than two and a half or three feet of gas to the pound, instead of the five feet promised for it, the facts being that their burners passed a foot or more per hour, and the calcic carbide gave forth its full quota of five feet to the pound.

The highly actinic quality of the acetylene light renders it particularly valuable for photographic purposes, and nothing is risked in predicting a wonderful future for it in this direction. Indeed, much has already been accomplished. In connexion with one of Chicago's leading photographers a series of experiments was made during the past winter, clearly proving its adaptability to work in the studio. With exposures from two to four seconds, fully toned and perfectly lighted negatives were made, the results not being distinguishable from the best daylighted sittings. So well satisfied was he with it, that he is now having his studio fitted with acetylene apparatus for night work, probably the first in the world to adopt the new light for this purpose. It has also been successfully used in photographic printing. With several of the leading makes of printing-out papers, excellent work was done in about the time required for the same on a cloudy day. Thus all phases of studio work are made possible by night as well as by day through the discovery of this wonderful and cheap light. It is also particularly adapted to photo-micrography and the illumination of objects under the microscope. A little lamp which I devised some months since for the latter purpose consumes only one-twentieth of a cubic foot of gas per hour, and gives a solid column of intensely white light the thickness of a small lead pencil. Photo-micrographs with the highest powers may be taken with it in less than one-fifth of the time required with the most powerful oil lamp, and it has been highly commended by many of the most distinguished workers in this department of photography, who are using it in preference to all other sources of illumination.

Acetylene is the ideal light for a bicycle lamp, and already several methods of using it for that purpose have been devised. One of these, the invention of a Chicago man, seems to be eminently practical, and it will, doubtless, come into general use. It maintains a brilliant, steady light for twelve hours without replenishing, cannot be extinguished by the strongest wind or the roughest road, and is easily manipulated by any one.

For lighting railway and street cars it has no equal, either in efficiency or economy. One of Chicago's great street railway companies is about to equip its five hundred cars with the acetylene light, it being vastly brighter than any other, and the cost less. It will be furnished liquefied in cylinders under compression, four half-foot burners to each car affording greatly more light than the usual eight of the Pintsch system.

In no other field of lighting will the great capabilities and advantages of acetylene be more quickly realised than that of the optical lantern and stereopticon. Nearly as bright as oxyhydrogen, it is vastly cheaper, both in first cost of apparatus and in running expenses. The cost of operating a pair of dissolving lanterns, at present price of carbide, is not more than twenty-five cents per hour, while the light is quite equal to the most satisfactory illumination of a fifteen-foot screen. It is being used now by many lanternists with all sizes of lenses, from quarter size to whole, and at all distances from screen between ten and fifty feet. A small portable generator, weighing not more than twenty pounds, with suitable burners and a pound or two of carbide, completes the necessary outfit. No skilled attendant is necessary. It can be set up and put in operation in five minutes, and dismantled in as many more. The light is absolutely steady, clear, uniform, white, and satisfactory. Once started, it requires no attention whatever until the close of the exhibition. In short, it will prove (nay, even now *is*) a most formidable competitor of both lime and the electric arc lights; the Welsbach incandescent gas light bears no comparison with it, while as to the foul smelling and altogether unsatisfactory coal oil lamp—*it* is of the past, dead beyond resurrection.

The economic capacities of acetylene as a source of heat and power have yet to be fully developed, but sufficient progress has been made to demonstrate that they are on a par with its excellencies as a lighting medium. It may be burned in a modified Bunsen burner without smoke and with intense heat. Used in the compound blowpipe, in place of

pure hydrogen, a temperature of 4000° Cent. is reached in place of the usual 3000° of the older form. Its expansibility when mixed with air in proper proportions and fired, being greatly in excess of other gases, renders it especially valuable for gas engines, and in this direction alone a vast future of usefulness lies before it. As the object of this paper is simply a statement of *facts* about acetylene, I will not enter further into speculations as to its future, but proceed to glance at the substance from which it is generated or evolved on a commercial basis, and the means already devised for so doing.

Crystalline calcium carbide, CaC_2, the basis from which alone the production of acetylene on a commercially economic scale has been made possible, was the result of an accidental discovery, the story of which has been so repeatedly told that it seems unnecessary to repeat it here. But for the invention of the electric furnace, it would never have been known; thus do great inventions and discoveries hinge one upon another. The materials from which it is made are among the most abundant and cheapest known to man—coal dust and lime; carbon and calcium. In reality, ground coke is used instead of coal dust, as furnishing a larger percentage of pure carbon than the latter. The coke and unslacked lime, having been ground separately to a fine powder, are thoroughly mixed in the proportions of fifty-six parts, by weight, of lime, to thirty-six parts of coke, and submitted to the intense heat of an electric furnace, which fuses them down to a heavy crystalline mass—carbide of calcium. Although this substance is so hard as to require repeated blows from a heavy hammer to break up the mass, it is so susceptible to moisture that it disintegrates in a comparatively short time if exposed to the air even in an ordinarily dry room. It must therefore be shipped and kept in hermetically sealed cans or receptacles, to prevent loss by decomposition. If the finger, slightly moistened with saliva, be applied to its surface, acetylene is at once evolved, burning briskly upon application of a lighted match. A striking little experiment may be performed by placing a piece of carbide upon a plate and allowing a drop of water to fall upon it, lighting the gas at once liberated at the same time. It will continue to burn so long as fresh water is slowly applied, until the gas is all evolved and consumed, leaving a residuum of calcic hydrate in the plate.

Having thus seen some of the *facts* concerning acetylene—what it is, and from what it is evolved or generated—we may pass to a consideration of the means necessary for this purpose. In reality it is merely necessary to bring the calcic carbide into contact with water to ensure an immediate evolution of the gas. If the carbide should be reduced to a coarse powder and thrown into water, instantaneous decomposition would be the result, causing an explosion which would throw the water in every direction with considerable force, the entire volume of gas produced escaping instantly into the surrounding atmosphere; but, when a lump of the material is immersed in water, only its outer surface is subjected to the latter's action. A double decomposition takes place. The oxygen of the water uniting with the lime in the carbide forms calcium hydrate, which falls to the bottom of the receptacle as a residuum. The hydrogen of the water in turn unites with the carbon of the carbide and forms acetylene gas, which in its turn will rise into the air to be dissipated—if the experiment is performed in an open vessel. The evolution of the gas, though rapid, is quite regular and approximately gradual, the length of time necessary for its complete extraction depending entirely upon the size of the lump of carbide. The amount of acetylene procurable from a given weight of carbide is very steady and uniform, varying from 5 to 5·5 cubic feet to the pound. I have never found any that yielded less than the former amount, and occasionally have had specimens that furnished fully six cubic feet.

In order to utilise the acetylene it is necessary that it be generated in a closed vessel. Two *general* types are alone possible; but of *specific* forms there may be no end. In one type the gas is generated and maintained under compression, and the vessel must be made strong enough to resist any possible pressure. Should the latter reach that of forty atmospheres, or about 600 pounds to the square inch, the gas will be liquefied, under its own compression, each pound of the liquid being capable of giving off about fourteen and a half cubic feet of gas—or 400 times its own volume. This allows of its ready handling in strong steel cylinders, such as are used in the distribution of carbon dioxide or liquefied carbonic acid. Supplied with suitable valves for reducing the pressure to that of ordinary street gas, these cylinders may be attached to the supply pipe of a house, and the gas used in a very neat way without any care or thought on the part of its occupants. But this method of distribution will only be possible in towns large enough to support a liquefying plant, and the necessary and careful attendance of skilled workmen to place in position and look after the cylinders. The great bulk of consumers all over the country cannot be thus supplied. They must have a gas-making device at once simple, automatic, inexpensive, efficient, and safe. This belongs, to the second type of generators mentioned above, and it is of the only one as yet placed on the market that I now desire to speak—namely, the "Monitor" Acetylene Generator of Messrs. Walmsley, Fuller, & Co., Chicago, the patentees and manufacturers.

The "Monitor" generators, although made in several sizes, from a capacity for a single light to that of supplying a large house, are all of the same specific form and character—a combination of generator and gasometer, or gas-holder, in one. With the exception of the smallest size, which practically has no gas-storing capacity, they are perfectly automatic, generation of gas ceasing when it is not being burned. The gas is at no time under a greater pressure than that of a three-inch column of water, slightly in excess of that in the pipes supplying street gas, but better adapted to the smaller acetylene burner than the two-inch pressure of the latter. This never varies at any time from the moment the generation of gas begins until the supply of carbide is exhausted, and is the same in each size of generator, the proportions of area to weight having been exactly calculated to this end. They can be loaded and put in operation in a few minutes, and any one who can fill and trim a lamp can care for them.

The generator consists of three parts, namely—a tank, a combined gas generator and holder, and a drying box, or purifier. The generator slides up and down within the tank, and, when lifted out, a galvanised iron pan will be found in the latter, the use of which is to catch and hold

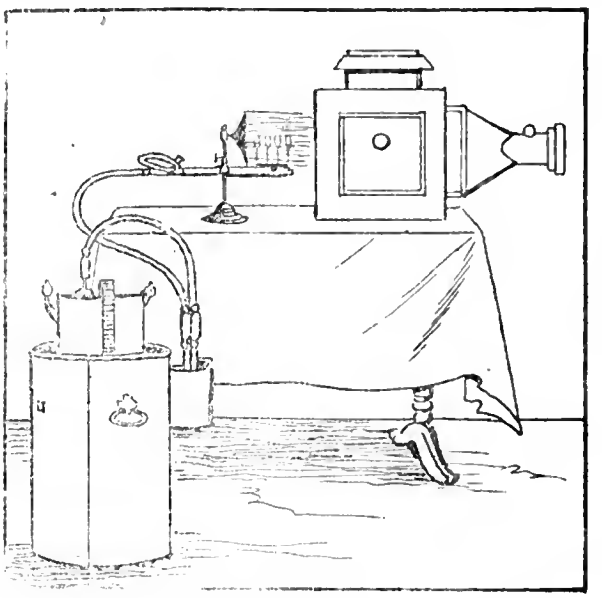


Fig. 1.—Arrangement for employing Acetylene Gas for optical projection.

the calcium hydrate formed during the evolution of gas from the carbide. The top of the generator, through which the carbide is loaded, is sealed by a water jacket. To put in operation, the tank is filled with water to within five or six inches of its top. The water jacket of the generator is also filled, quite to its top, and the generator is lowered into the tank until a catch on its top engages with the top of the former, preventing it from sinking any lower. It will then be found that the wire netting, which is placed in the generator in such a manner as to form a flooring across its entire interior, is about two inches above the surface of the water in the tank, and quite dry. The carbide is then placed on the netting, the pieces distributed over its surface evenly, and the sealing case of the water jacket put into position and pushed down tight, where it is held by a self-acting spring. A gas hose nozzle, with stop cock, rises from the top of the water jacket. The cock being opened, the catch holding the generator to top of tank is released, and it sinks down into the latter, driving out the imprisoned air within through the open stop cock. The moment the wire netting carrying the carbide is immersed in the water, gas is evolved, which issues from the cock in the form of a warm steam. The stop cock is then to be closed, and the generator is ready to supply gas until the carbide has given up its last cubic inch. The loading should not be done nearer than five or six feet to a fire or light of any kind, as a slight explosion might occur if the gas were lighted before the mixture with air is entirely driven out. This is the only possible chance of such an occurrence, and it need be no chance if the slightest precaution to avoid it be taken.

Considerable heat is evolved during the generation of the acetylene, as there is when a piece of unslacked lime is placed in a vessel of water, and for the same reason. The gas consequently comes off both warm and moist, and, if conveyed in this state directly to the burners, will condense in the pipes or tubes, causing an irregular and fitful flame. This is particularly observable in cold weather. The object of the drying box is to prevent this, which it does in a very simple and perfect manner. It is really a double box, one within the other, but with no intercommunication. The outer chamber is filled with cold water, the inner is empty, saving the presence of several metallic fans, presenting a considerable surface over which the warm gas must pass, being cooled and dried on the way. Two tubes, with hose nozzles, lead into this chamber. A short piece of flexible hose connects the nozzle on top of the generator with one of these; to the other is attached a second hose leading to the burners. The stop cock on the generator being opened, the gas flows into the purifier, issuing

therefrom cool and dry, ready for burning, which it will do with absolute steadiness and uniformity from first to last. For convenience, the drying box is hung by a suitable catch to the side of the tank.

The "Monitor" generator, as has been stated, is absolutely automatic in its action. It will furnish gas for one burner of any size, from the tiny microscopic lamp of $\frac{1}{10}$ cubic feet capacity to the Bray ooooo, of over one foot per hour, or as many burners at once of any size as its capacity will supply, with equal steadiness and satisfaction, the pressure not varying a quarter of an inch at any time. If the gas be all turned off, the generator will continue with diminished rapidity until the rising of the holder lifts the load of carbide out of the water, when it will cease altogether. If necessary, it can be left in this condition for an almost indefinite time, ready for instant use. The acetylene is absolutely unchanged by standing in the holder for any length of time. A new form just completed combines generator and lamp in one, without use of hose or drying box, the gas being cooled and dried in a series of capillary tubes, which are not seen. Its general appearance is that of a handsome parlour-table lamp with shade. It is made in a great variety of forms.

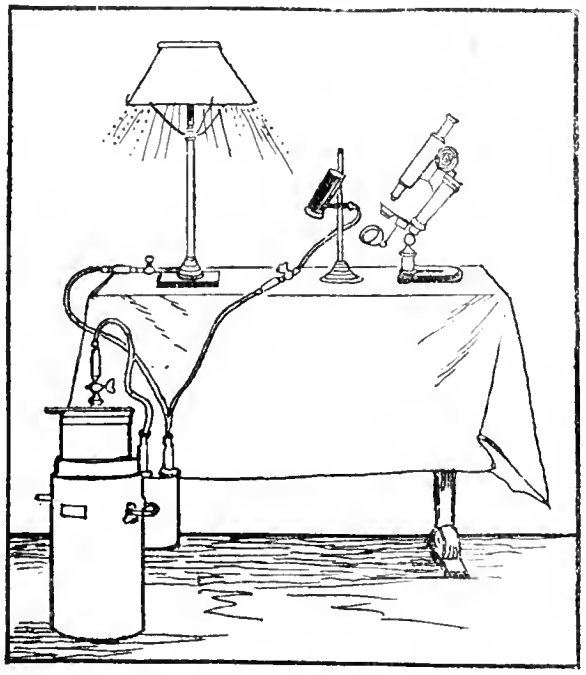

Fig. 2.—Acetylene Gas employed for micrographic work.

The accompanying illustrations, with the foregoing descriptions may possibly convey a tolerably clear idea of the apparatus to my readers, and I trust the facts about acetylene contained in this article may not prove uninteresting or valueless to them. W. H. Walmsley.

LANTERN SLIDES.

[American Journal of Photography.]

A lawyer once offered to give twenty reasons to the judge for the absence of the prisoner in court. After the announcement of the first, the death of the accused, the judge kindly relieved him of the necessity of an enumeration of the other nineteen. And so when the practical slide-maker is asked in what particular is gelatine inferior to wet collodion as a medium for producing transparencies intended for use in the magic lantern, he will perhaps trump up also twenty objections to gelatine, but the first suffices the inquirer, to wit: Slides with gelatine plates do not look as well as those from wet slides when projected upon the screen.

There is apparently a falling off in the virtues of the dry plate when mustered into this special service.

Most of gelatine slides which I have examined thrown upon the screen either show a tameness in the high lights, or, if vigour is secured, it is at the expense of the shadows, which are flat and without gradation.

This is everything but desirable, but probably, admitting the general superiority of collodion, something in the manipulation of the gelatine plate might be held more accountable than the inherent depravity of gelatine itself. I have seen gelatine slides on which it was a delight to look, and on the screen too; but how many a gelatine slide looks perfection itself when examined out of the lantern, a marvel of softness and beauty, but on the screen flat, stale, and unprofitable. Collodion-slide virtues are not always patent to a mere inspection by looking through it. One learns more by experience how to judge of them.

Another objection brought against gelatine slides is the difficulty of securing uniformity of tone.

In collodion the same tone may be had, provided the conditions are the same; but we are not sure that every batch of dry plates will present the same colour. Out of a dozen made with the same plates and developed with the same solution, probably only three or four have the same tone. This is not of much consequence to the amateur, but the commercial-slide maker looks on such capers askance and doubtingly.

Gelatine is so much more convenient, and then we can make slides by contact and at night. It may therefore be acceptable to the amateur to have the experience of one who has worked to try and get what is called a wet-plate effect.

The best results which approach collodion work are produced by making the slide rather thin and then intensifying it.

I at first used bichloride of mercury and cyanide of silver, but resigned it for the following method, which you will recognise as the intensifier which Mr. Cassebaum and I employed to strengthen negatives and which was published in the *American Journal of Photography*. By its use you can strengthen the slide before fixing as well as after, but I prefer to intensify after fixing; it requires more practice to judge how far to carry the strengthening before than after. If you do intensify before fixing, wash out thoroughly all the developer.

Presuming, therefore, that you will strengthen after fixing, I proceed. First:—

Wash out very completely all hypo from the film, then place the slide in a bath composed of

Perchloride of iron	4 grains.
Chrome alum	2 ,,
Citric acid	4 ,,
Water	1 ounce.

This solution not only clears up the slide wonderfully by taking off every trace of fog from development, but also removes the last grip of hypo. It also gives a good colour.

The dish containing the solution should be rocked to prevent the formation of a network on the film, which will show itself if you neglect this precaution.

Do not let it be in the iron solution for more than a couple of minutes, until a slight bleaching is perceptible.

After removal wash well under the tap, and then flow it over with the following solution. Do not lay it in the dish, but flow the solution over it, pouring the solution back into the graduate to flow again, as in wet-plate practice; otherwise, one will be apt to stain the plate and also get a dense deposit of silver on the back.

A.

Gallic acid (best quality)	80 grains.
Alcohol (95°)	1 ounce.

B.

Nitrate of silver	40 grains.
Water (distilled)	1 ounce.

Take one drachm each of A and B, and three ounces distilled water.

When the plate has built up to your satisfaction, wash it thoroughly and dry it.

Lantern slides so made are quite brilliant, and so look very much like wet plates.

The fine quality is obtained by the gradual and slow action, giving such a fine deposit of silver as cannot be equalled by mercury.

Care should be taken in the manipulation not to touch the film with the fingers. I say this because developers of gelatine plates are apt to rub their fingers over the surface to brush off any impurities.

I would even recommend this method to commercial-slide makers, but they, doubtless, would tell me, "Collodion is cheaper."

I also employed Mr. Cassebaum's mixture of hydroquinone as a slide-intensifier.

Stock Solution.

Hydroquinone	60 grains.
Nitric acid	2 drops.
Water	6 ounces.

One-half ounce of this stock solution to two ounces of water, and one drachm silver solution (forty grains to one ounce water).

The slide should be first bathed for a few minutes in acid and water (twenty grains citric acid to four ounces water).

The tones are a rich black and the high lights clear, but I prefer the tone of the gallo-silver.

Window transparencies made with it are particularly fine.

Perhaps this last method will recommend itself to beginners, as it does not require so much care as the former; but this acknowledgment does not imply that you are not to exercise all due care and cleanliness. This reminds me to give a word or two of advice in the development of gelatine lantern slides before intensification.

Did you ever look at a Levy lantern slide and delight yourself with its beauty? There is albumen in the plate, and thanks to Mr. Carbutt for his excellent gelatine albumen slow plates—use them by all means—the Levy slide is made by the so-called Taupenot process, and the development is very slow with alkaline pyro, all detail showing first, after an acid pyro developer is applied which builds up or intensifies the image

somewhat like the gallo-silver intensifier. The grain in both is very fine. Use slow plates, give full time, and develop with solution much weaker than you would employ in negative development, and gradually build up with the gallo-silver intensifier.

On looking over a large collection of lantern slides, I became interested in examining their keeping qualities. A great many of the gelatine slides showed deterioration. Some had indeed fallen in the "sere and yellow leaf," due, no doubt, to defective fixing or insufficient washing, and might have happened to collodion slides if hypo were as hard to eliminate from it as from gelatine. Some, both gelatine and collodion, were jaundiced by mercury. I remember some of the *collodion slides* toned with mercury, which at the time of their genesis delighted me with the beauty of their tone. Now how abject, how fallen!

The collodion slides toned with bichloride of palladium were still brilliant. This is perhaps the most delightful toner of wet slides. If you use it, employ it in a very dilute solution and let the toning proceed very slowly.

Among the most durable were wet slides toned with a weak hot solution of sulphide of potassium. The tones are a bluish-black, too cold for most tastes, mine included.

The slides made according to the method here given, despite the predictions of practical photographers, showed not the slightest change; they are about eight years old. Strange to say, some experimental gelatine slides retained their pristine qualities, although they had been toned with bichloride of mercury before fixing. I attribute this to the bath of chloride of ammonia to which they were subjected after the mercury and a good washing after fixing, the ammonium taking up from the film the unappropriated mercury. This might suggest the bathing in chloride of ammonium of a mercury-intensified negative before fixing, if you must use mercury.

Slides in the collection, not toned at all, were amongst the most brilliant, perhaps on account of the greater thickness of the film. They were varnished; perhaps that contributed something to their permanency.

J. Bartlett.

LANCHESTER'S SYSTEM OF PHOTOGRAPHY IN COLOURS IN THE LANTERN.

The patentee, Mr. Frederick William Lanchester, of Cobley Hill, Alvechurch, states that his invention relates to an improved method of producing photographs in natural colours, and has for its object to so analyse and distribute the light falling on the sensitive plate that the said plate or a print therefrom may be afterwards used in a suitable form of lantern or apparatus to combine and thereby reproduce the colour or colours of the object photographed.

"In one method of carrying this invention into effect I arrange a grating consisting of a number of parallel opaque bars, between a photographic camera and the object to be reproduced, and as close to the latter as possible, the said bars being preferably fixed at an equal distance from one another and leaving spaces between of less width than the bars themselves. The camera is of ordinary construction and a prism is arranged in front of, or behind, the lens with its axis parallel to the bars of the grating, the dispersion of the said prism being such that, when the camera is focussed on the grating, the images of the slots form a series of spectra on the focussing screen or plate.

"When a combination of lenses is employed the prism may be arranged between the lenses, or one or both of the lenses may be ground in such manner as to produce the required dispersion.

"The bars of the grating should be sufficiently numerous to prevent the picture from being unduly broken or disjointed.

"In taking a photograph with this apparatus I preferably use an 'isochromatic' plate and give a rather longer exposure than ordinarily required; the resulting negative picture contains a record of the colours of the object in one form of shaded lines of varying intensity; a print is then taken preferably on an ordinary lantern slide, which, after development, is placed in a similar or identical apparatus as that hereinbefore described, and in the position originally occupied by the photographic plate; the coloured picture is then reconstructed by exposing the slots in the grating to a uniform source of white light, or another method may be employed in which a lamp and condenser are placed at the back of the lantern slide, the light issuing from the grating being thrown on a screen where the original colours are found to be reconstituted.

"The hereinbefore described analysing apparatus may be employed to produce pictures showing interference colours in film backed by reflecting surface as previously used.

"In landscape photography, where the grating cannot be conveniently arranged sufficiently near the object being photographed, a pinhole camera may be employed or the lens may be considerably stopped down, in order that both grating and landscape may be approximately in focus.

"A screen may be employed to absorb the ultra-violet rays, to prevent their reaching the sensitised plate; a cell containing sulphate of quinine in solution may be employed for this purpose.

"Referring to the accompanying sheet of drawings,—

"Fig. 1 shows apparatus suitable for the photographing and reproduction of still-life studies in portraiture.

"Fig. 2 is a modification suitable for more varied work.

"Fig. 3 is an enlarged view of a portion of the grating.

"Fig. 4 illustrates one manner in which a lens may be constructed to produce the necessary dispersion without the use of a separate prism.

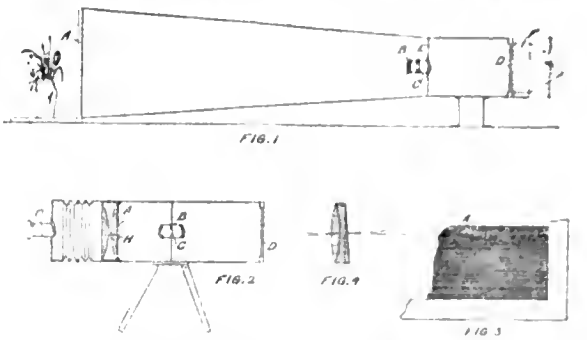

FIG. 1

FIG. 2

FIG. 4

FIG. 3

"A is the grating an enlargement of a portion of which is given in fig. 3. B is the lens or combination with analysing prism, C, forming a dispersed image of the subject on the screen or sensitised plate at D; E is a colour screen as usually employed to obtain truly orthochromatic pictures. F represents a condensing combination used in conjunction with a source of light for reprojecting the picture from the finished photograph, a screen being placed close to the grating at A to receive the picture.

"In fig. 2 the picture is first projected on the grating by an additional lens combination, G, diffusion of the image being avoided by the employment of a condenser, H."

The patentee claims: In a photographic apparatus the combination of a grating and prism.

BLAIR'S CAMERA FOR CONTINUOUSLY PHOTOGRAPHING MOVING OBJECTS.

The following is brief description of this camera:—

In a camera constructed according to this invention the lens is fitted at the front of the body and the shutter at any suitable distance from the back of the lens, the space between the lens and the shutter being enclosed by a light-tight casing.

The shutter consists of a spring-controlled plate or band, having a slot of a size suited to the amount of light required to be admitted when making the exposure. The film extends from a supply roll to a receiving roll, both of which are placed under suitable tension to prevent the film from being unwound from the supply roll, except by the film-operating mechanism, and to ensure that when it is moved by this mechanism it will be properly taken up by the receiving roll.

The film is held close to the shutter by suitable rollers or equivalent, and both it and the shutter are operated by means of a spindle on which is mounted a vane, arm, or equivalent, which may at its free edge or end be provided by one or more points adapted to perforate the film and engage with a projection or slot in the shutter so as to positively engage both the film and shutter simultaneously. The spindle is rotated by any suitable motor, and, if desired, may be provided with a fly wheel.

At each revolution of the spindle the vane or arm first engages the film and shutter, and moves them along simultaneously, and then disengages them, either automatically or by other mechanism, to allow the shutter to be drawn back by its spring, during which backward movement the film remains stationary and the exposure is made, the shutter at the termination of its backward stroke again obscuring the film.

The details of the apparatus may be modified without departing from the essential features of the invention; for example, the spindle may be provided with two or more vanes or arms instead of one as before described, so that two or more exposures may be made at each rotation of the spindle, and, moreover, the shutter may be part of a flexible band which itself constitutes the spring for effecting its return movement. The complete specification is published.

GAUMONT'S IMPROVEMENTS IN PHOTOGRAPHIC ENLARGING APPARATUS.

The patentee says:—

"Ordinary photographic enlarging apparatus is composed of three moveable frames carried by a common base, which frames are connected together by a flexible structure or by a slide, the one of the outer frames carrying the *cliché* to be enlarged, and the other the sensitive surface that is to receive the enlarged image, while the middle frame carries the objective which effects the enlargement. The enlargement obtained is the greater in size, the greater is the proportion between the distance of the objective from the sensitive surface and the distance of the proof to be enlarged from the objective. But it is not sufficient for obtaining the increased size to shift the frame carrying the

objective, because then the focus will not be correct for producing a distinct enlarged image; it is necessary also to shift suitably, by trials, the frames which carry the proof to be enlarged and the sensitive surface, in order to obtain a sharply defined enlarged image. There are, therefore, two variable conditions, namely modifications of the relation of the distances and adjustment of the position of the images.

"According to my present invention, I construct an enlarging apparatus in which the two outer frames are fixed, being connected together by a casing which cannot be expanded or contracted, the objective, situated between them, being alone movable. By this means, however, only one condition is satisfied, namely the alteration of the proportion between the distances. The enlarged image will not be well defined unless a second condition is fulfilled, and, for this purpose, instead of adjusting the frames carrying the images, I modify the focus of the objective by providing a supplemental convergent lens.

"The apparatus is constructed for this purpose as follows:—A box or casing of pyramidal or tapering form carries at its smaller end the photographic proof to be enlarged, and, at its larger end, the frame containing the sensitive surface which is to receive the enlarged image. Frames of various dimensions are provided at either end for receiving proofs or *clichés* of various sizes.

"Between the two ends the box contains the objective, which is mounted in a frame that can be slid either forwards or backward by a rack-and-pinion motion, actuated by an external button. The axis of the pinion carries a second pinion, gearing with a toothed wheel on the axis of which is a disc having divisions on its periphery, so that, on turning the button, the sliding frame can be adjusted to a position indicated by a division of the disc coming opposite a fixed pointer.

"The objective is composed of two converging lenses with diaphragms, in the ordinary manner. In addition, there are provided a series of supplemental lenses of different focus, arranged in a row on a sliding frame sliding through the objective between the other two lenses, so that, according to the position to which the objective is adjusted relatively to the proof and sensitive surface, a corresponding supplemental lens is brought between the other lenses for modifying the focus of the objective. The arrangement employed by preference for moving the slide with the supplemental lenses automatically consists in attaching to each end of the slide a small chain, passing round guide rollers, the chain at the one end of the slide being led backwards and having its end attached to a rear part of the casing of the apparatus, while the chain at the other end is led forward, and has its end attached to a forward point of the casing. Thus, on shifting the objective forwards or backwards, the slide will, on account of the above-described attachments, be automatically shifted transversely so as to bring the proper supplemental lens between the other two lenses. For ensuring the accuracy of position of the supplemental lens, the slide is formed with notches into which takes a spring tooth on the frame of the objective. The supplemental lenses may also be arranged round the periphery of a rotatable disc, instead of on a slide; or the supplemental lenses might be separate from each other, and be placed in position by hand, as may be required, but the other arrangements are preferred."

Details and drawings are given in the complete specification. The claim is:—In combination with variable photographic enlarging apparatus having the objective adjustable between two fixed end frames, the use of additional lenses for modifying the focal lengths of the objective, which additional lenses are preferably all carried by a plate that is automatically shifted transversely when the objective is shifted longitudinally, but which may also be carried on the periphery of a rotatable disc, or be mounted in separate frames.

LANTERN PROJECTIONS IN NATURAL COLOURS.

At the meeting of the New York Camera Club, held Tuesday, June 9, at eight p.m., President Walker in the chair, the subject announced for the evening was an exhibition of stereopticon views in the colours of nature by the projection method of R. D. Gray. Mr. Gray presided at the lantern himself, giving his personal attention to the proper balancing of the colours by skilful manipulation of the lights, and was ably assisted by Mr. Hopkins, of Messrs. J. B. Colt & Co. The presentation of the theoretical part of the subject was left to volunteers from the Club, and was undertaken by one of the members after a short interview with Mr. Gray immediately preceding the meeting. He had, however, attended Mr. Gray's previous exhibitions in New York, and was familiar with all that had been published about his methods of working. A rapid sketch was given of the principles of three-colour photography in general, and Mr. Gray's process in particular, while special attention was called to the various causes preventing the attainment of more than approximate results in the solution of this most difficult problem in photography. That, in spite of these limitations, Mr. Gray produced such exquisite chromatic effects, was attributed to his "personal equation," rather than to his origination or improvement of an automatic method of realising "the reproduction of the actual colours of nature in the true blending of the original." Mr. Gray himself, it should be remarked, does not claim to actually reproduce the true colours of nature in his lantern projections, but rather a harmonious and pleasing imitation of them, enjoying somewhat the same privilege as the painter who, recognising the limits of his materials, follows nature rather than reproduces her, aiming in his work to preserve organic unity, and not to present literal truth. The exhibition of some forty slides, comprising scenes in America, Ireland, Switzerland, and Italy, most of which were shown in public for the first time, spoke most eloquently in elucidation of Mr. Gray's ideas, and fully made up for that gentleman's modest reticence of speech. The slides were freely criticised as they came on the screen, and their beauty as well as their shortcomings pointed out. It was altogether the most successful rendering of natural colour values yet seen in any lantern exhibition in the rooms or before a New York audience, the triple lantern effecting a perfect registration of the three-colour impressions on the screen, while the comparatively small size of the pictures (eight feet) allowed a higher illumination than the twelve-feet screens used on former occasions with Mr. Gray's own apparatus. After the exhibition a discussion followed, in which President Walker, Mr. Stieglitz, and others took part, and Mr. Gray clearly and succinctly answered the numerous questions put to him by the members.

The New Calcium Carbide Works at Niagara Falls.—The new works of the Acetylene Light, Heat and Power Company, formerly the Calcium Carbide Company, are reported complete and in operation. The Niagara Falls Power Company supplies the electric power to drive the plant, 1000 horse power being used. An alternating current is furnished at 2200 volts, and is transformed to 110 volts. The capacity of the works is five tons of calcium carbide per day. The building is divided into five principal parts—a crusher room, a furnace room, a transformer room, a storage room, and a laboratory. Coke and lime, in the proportion of 75 pounds of pure lime to 100 pounds of pure carbon, are separately crushed in a Dodge crusher and a rolling mill, the coke going through a fifty-mesh sieve. They are then thoroughly mixed, and conveyed by a screw conveyer and an elevator to the furnaces on the second floor. There are four crucibles in the furnace, each holding 800 pounds of the mixture. The crucible forms one electrode, the carbon "pencil" the other. A few inches of ground coke are put in the crucible, and the carbon pencil is then let down on it, closing the electric circuit and making an arc of intensely high temperature. The carbon is gradually drawn up as the mixture is dumped in. The chemical action immediately begins, by which the calcium of the lime and the carbon of the coke unite to form calcium carbide. The mixture is allowed to remain in the crucible from three to eight hours, according to the amount of ingredients and the current. A mixture of 1750 pounds of lime and 1130 pounds of coke, making a total of 2880 pounds, will produce 2000 pounds of calcium carbide, The estimated cost is $23 per ton. The products of the factory are all to be shipped in air-tight drums to Pennsylvania.—*Engineering News.*

Acetylene.—Acetylene, C_2H_2, was discovered by Ed. Davy in 1836, and produced synthetically by Berthelot. The preparation of calcium carbide, on such a scale that it can be applied to the production of acetylene, seems due to Moissan and his assistant, Bullier. Acetylene is a colourless gas with an odour of garlic, but agreeably ethereal if prepared from pure material. If a small primer of mercury fulminate is made to explode in the midst of this gas, it is decomposed with a violent explosion and a large flame. It produces in equal volumes sixteen times more light than Paris gas burning in a normal Bengel burner. The amount of heat given out is, however, relatively less. Berthelot has established that acetylene is an endothermic substance. If diluted with atmospheric oxygen, it forms very dangerous explosive mixtures. It is very apt to strike back into the mains or into the gasometers. To avoid this danger, the acetylene is diluted with nitrogen. The maximum explosive power is obtained with a mixture of twelve parts of air to one part of acetylene. Acetylene is not more poisonous than the ordinary carbides forming ethylene, &c., or than coal gas. Coal gas may be enriched by adding small quantities of acetylene not exceeding five to six per cent. At the price of fifty centimes per cubic metre acetylene may enter into practical use at gas works.

I would advise stereoscopic workers to mount their pictures in optical contact, says Mr. F. J. Paterson, of Hobart. The advantages are: No appearance of mount or grain of paper, the image appearing as projected in space; a bright image without burnishing, enamelling, or squeegeeing on ferrotype paper, and perfect protection from atmospheric influence, dirt, or abrasion. Mounting is very simple. A half-plate dish, containing four or five ounces of a two-grain ten-ounce solution of gelatine. A glass plate, taken from its last washing water, is placed in the dish, to one side and end, and a pair of pictures trimmed and put into water until limp, lowered into gelatine over plate, care being taken as to proper position of pictures. The plate is now raised from end or side, the fingers of left hand keeping the pictures from slipping off (do not trouble now as to adjustment). Blot off excess of fluid, and the pictures may now be slid into position. To ensure absence of flaws through air leakage, it is desirable to put under a light, even pressure for half an hour. A piece of opaque backing paper a little larger than plate is then pasted on, and when dry cut down to plate. The gelatine solution is not for adhesion, but that pictures may be slid readily. I use P.O. paper.

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*September* 4, 1896.

THE LANTERN RECORD.

CONTENTS.

THE SEARCH LIGHT.

The vigilant and sagacious "Watchman" of the *American Amateur Photographer* (which, by the way, has gained immensely in practical value under his experienced control) has a note in his August issue in which he pays English—I beg pardon, British—photographic inventors and manufacturers a compliment to which I do not think they are wholly entitled. Remarking upon the opportunity offered by the cheap production of calcium carbide for the utilisation of acetylene as an illuminant, he scolds the Americans for lack of go-aheadness in taking advantage of the opportunity.

* * * * *

"Are we," he inquires, "losing our go-aheadness, or are we becoming generously liberal? Are we content with the honour and glory of having shown the world how economically to make calcium carbide by the ton, and willing to let others reap the fame and fortune incident to the turning to practical account of the acetylene, made possible by our discovery, or are we too busy with what we consider matters of greater importance? In any case, we are certainly lagging far behind. So far as I know, with the exception of Walmsey, Fuller, & Co., of Chicago, no one seems to be making any great effort to bring acetylene into practical use here, while in London alone there are at least a dozen firms each pushing an automatic outfit, costing only a few dollars, and which, with little trouble and perfect certainty, will give a light better for most purposes than either incandescent electricity or the Welsbach mantle; and France and Germany, and even Italy, are ahead of even the Britishers, the latter, having, in Milan, a journal devoted to its development. What are we going to do about it?"

* * * * *

Within a few months I anticipate that several generators will be on the market: but, at the time of writing, "Watchman's" estimate of a dozen firms each pushing an automatic outfit does not hold good. Two—or, at most, three—systems have so far been offered for sale, and of these only one has secured notice in the photographic press. I share "Watchman's" high opinion of the light, and shall be disappointed if it is not largely adopted for enlarging, projection, and illuminating purposes this winter. Calcium carbide is now so cheap, and the generation and combustion of acetylene is a matter of so much ease and simplicity, that a cheap and effective outfit should be neither difficult to make nor expensive to buy. A sovereign should cover the cost of a really good plant—generator, tubing, burner, and all. From the description given in these pages last month of Walmsley's acetylene lamps, I judge them to be superior to anything yet produced this side.

* * * * *

Unabated popularity at "the halls"—that is, the music halls and the variety theatres—still attends the animated photographs that form part of the entertainments provided at those places of resort. In professional parlance, they are "star" turns. I have seen each series several times, and, in my opinion, the best is that on view at the Empire Theatre in Leicester-square. Photographically regarded, the pictures are exceedingly good, being well exposed, clean, and free from spots and light splashes as they pass across the screen, while Messrs. Lumière appear to have succeeded in reducing to a minimum the effects of vibration in projecting the views. They are a vast improvement on those shown last February, and the subjects are very cleverly chosen. Country photographers in town this autumn should certainly visit the handsome theatre in Leicester-square and see these interesting exhibits.

* * * * *

Not a little of the success of these animated photographs consists, as I have hinted, in the careful selection of the subjects; a grotesque and unnatural effect is produced when, in taking a street scene, for instance, vehicles and pedestrians approach to within a few feet of the camera, and jerk themselves out of the picture, so to say. The relatively vast dimensions the figures then assume cause laughter, it is true, but the effect is certainly better without them. I am not sure that the best and most natural effects are not produced when the moving figures *recede* from the camera; certainly in a series I saw the other night (one of Mr. Paul's), a hundred yards' foot race, with the competitors tearing away from the camera, not only struck me as displaying the capabilities of animatography at its best, but appeared to give the greatest pleasure to the remainder of the audience.

* * * * *

It is barely an exaggeration to say that during the last two or three months a camera for taking continuous film photographs of moving objects to be utilised for projection purposes would have sold at famine price. But such an instrument has not been obtainable in the open market for love or money. There were, until a few days ago, probably not more than three or four actually in use in this country, and those who possessed them would not, for obvious reasons, supply would-be rivals. The animated picture "boom" has been skilfully restrained within certain channels; but, if all I hear be correct, within a very few weeks cameras and lanterns for taking and showing the pictures will be commercially available. A firm that advertised one of the former some weeks ago is not yet ready to deliver. Meanwhile, in Paris, the Anglo-American Photographic Import Office, 368, Rue St. Honoré, advertise the De Bedts Kinetograph for taking the negatives and projecting the positives. This costs 40*l.*, and besides the two purposes named is also available as an ordinary kinetoscope.

RADIANT.

LANTERN MEMS.

THE optical-lantern manufacturers in London have been busy during the past month in perfecting the apparatus for projecting animated photographs that they set about making as soon as the Cinematograph was shown in public, and the result is that, besides that of Mr. Birt Acres and Mr. Paul's, there are now on the market two of a less expensive nature that will be found to answer satisfactorily. One is for public lecturers' use in large halls, where the question of portability and noise in working have not to be taken so much into consideration as steadiness of the resultant picture and brilliant effect. The other is of a portable nature, and is capable of being used in any-sized room and conveyed about from place to place in a case very little larger than the ordinary single lantern of best make.

* * * * *

HAVING had the opportunity of witnessing the results obtainable by the latter instrument at a private view afforded me the other evening, I think I cannot do better than describe this first. The original idea of the designer was to combine a cinematograph with a lantern that could be quickly converted into one suitable for the projection of photographs of ordinary size; and he seems to have accomplished the same very satisfactorily, for, in a few seconds after releasing a thumb screw and slipping the band off the driving wheel, the whole of the working part of the cinematograph slides away, and the ordinary front, with lens of suitable focus, can be arranged to take its place.

* * * * *

As I said before, it can be used in any-sized room, for on the occasion of the exhibition referred to the apparatus was about sixteen feet from the screen, and the disc about four feet diameter. The picture was very fairly illuminated, although only a simple blow-through jet of the ordinary commercial pattern formed the illuminant. I should say, with a first-class mixed gas jet, and a distance of thirty-two feet, a very good eight-feet diameter picture could be produced. The films used were both American and French, and there seemed no disposition to catch or falter; in fact, the apparatus was worked very quickly at one time to see if it would in any way fail, but it answered capitally.

* * * * *

THE apparatus shown me was the first completed instrument after the original model, and a number are already on hand, so that the trade can be supplied in a fortnight or three weeks. The price of the apparatus will be 36*l.*, and includes a powerful jet, glass water trough, and case ready for use. The price of the films is from 2*l.* 15*s.* to 5*l.* 10*s.*, according to subject and length. I am very pleased to learn that some of the English workers in the direction of film photographs of animated subjects have been successful in getting really transparent films and also good local and typical subjects for use in apparatus of this class, while, with the demand for kinetoscope films for projection, rather than for the visual kinetoscope, no doubt the American producers will supply the more transparent kind, suitable for use in optical lanterns.

* * * * *

UNTIL the illustrations are published of both the new machines, it will be a little difficult to give the exact technical description of each part; but I think I can convey an idea of the portable one by giving the following particulars:—The driving wheel is attached to the right-hand side of the mahogany body of lantern, and is connected by a band to the cinematograph, which consists of one sprocket wheel, two spools for the films, a revolving cylindrical shuttle, and an intermittent motion, besides a clapper for the film, and spring stages above and below the opening, which can be adjusted for registering with the subject.

* * * * *

THE points I noted as specially ingenious were the intermittent motion, to stop and let the film go on while the shutter was revolving, the method of self-winding of the film on spool after exposure, and the pivoted end of the spindle for the spools which allow the spools to be rapidly interchanged. The spools were kept in position on the spindle by light spiral springs, and, when the pivoted end was turned, it was in line with the rest of the spindle, and so the spool could be drawn off directly. Given a firm table and films with good subjects, the operator of this apparatus ought to have a power in his hands of creating a satisfactory variation to the somewhat cut-and-dried lantern entertainments.

* * * * *

THE other and larger apparatus is also clever in its design and thoroughly well made, the stopping of the film being performed by a star wheel, the whole of the work being very strong and steady, while the stand on which the driving wheel is fixed is framed ironwork. The adjustments are such that great exactitude is obtained, and the maximum amount of light is assured by the system of shutter used. It follows that a certain amount of noise is inseparable from the engaging of the points of the star wheel in the motion, but this is not found detrimental in halls and public places of entertainment.

* * * * *

NEITHER of the apparatus has so far been fitted up as a camera for taking animated photographs, and, as I consider that this will give the great impetus to the sale for private lanternists, I shall be glad to see the necessary adjunct completed, so that employers of labour who have a liking for photography may be able to have permanent records of the work for reproduction and projection at any time. In the same way as the hand-camera craze largely increased the number of lanternists, so a convenient kineoptic camera, with convenient view-finder and portable but firm stand, will give the necessary impetus to the sale of cinematographs and apparatus of that order.

* * * * *

THE question is now and then asked as to how to quickly make designs, write formulæ, or words and figures quickly for projection on a screen, and, although it is probably known to many readers of these "Mems," there are evidently some lanternists who require to know. The first simple method is to smoke with lighted camphor a piece of glass, holding it by one corner with a pair of pliers; this is bound on one edge to a cover glass, and a mat is put between to be ready for use at a moment's notice, as anything can be written on it with a pointed piece of wood. The second method is to have a piece of finely ground glass, write on it with a pencil, and render transparent by paraffin oil.

G. R. BAKER.

ELECTRICAL EXPERIMENTS WITH THE OPTICAL LANTERN.

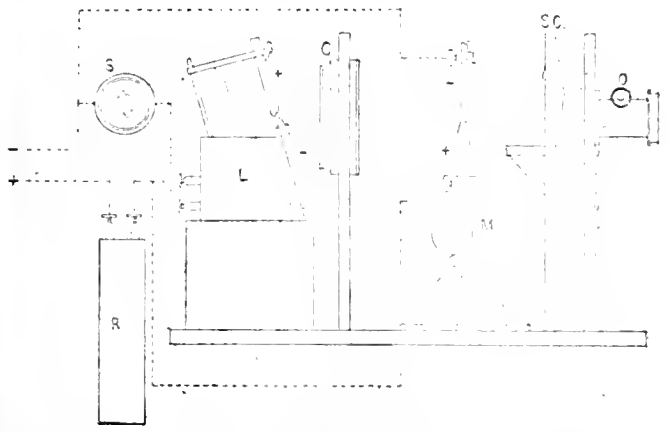
II.

THE experiments described last month were of such a kind that they could be performed with the aid of very small battery power, and the fact that much more effective results could be obtained with two or three simple dry battery cells, with the aid of the lantern, than could be got from twice as many large Bunsen cells at the lecture table, was cited as the chief excuse for employing the lantern. But there are other experiments which absolutely necessitate the employment of some sort of projection apparatus, for, from their nature, it would be quite impossible to demonstrate them without such aid; the electric arc light, for instance. An arc cannot be produced on a large-enough scale for more than two persons at a time to properly study it direct, and, even under these circumstances, the intensity of the light produced and the powerful radiant heat are serious obstacles to comfortable study. But it is peculiarly adapted for projection upon a screen, for its own light is so intense that its image will bear enlargement to almost any extent, and its behaviour under all sorts of conditions made manifest to every member of the largest audience.

Unfortunately, the excuse urged in regard to the magnetic and electrolytic experiments previously mentioned, that but a very small battery power was necessary to supply the motive force, will not hold good in reference to the projection of the electric arc, which, as every one knows, requires a very considerable battery power to maintain it even for a short length of time. But the arc light is now so largely used for high-class lantern work, and is so rapidly extending its sway, that in many cases that difficulty is no difficulty at all, for the one supply to the projection lamp can be drawn upon for the lamp whose image is to be projected—a method which will require no special fittings, except an extra switch, and which will involve no alteration of existing arrangements.

A few years ago, at the last great electrical exhibition at the Crystal Palace, it fell to my lot to operate the lantern for Professor Fleming, in illustration of a series of lectures by him on "Electricity and Magnetism." Many of these illustrations took the form of experiments performed upon the "table" of the lantern, and it was for these that the little arrangement of plugs and switches, described last month, was devised. The arrangements for projecting the image of the arc and carbon points upon the screen, and demonstrating its behaviour under various conditions, although showing nothing of particular merit or novelty, were so successful and effective—though I says it as shouldn't—that a description may serve as a useful hint to others.

The sketch shows the general arrangement of the lantern, which, it will be seen, was of the skeleton variety, consisting of three



uprights—one carrying the condenser, C; another, S C, being a peculiar form of slide carrier specially made for single-lantern work; and the third serving as a support for the front lens, O. Each of these was movable along the base, but the correct positions once found, of course no further alteration was required, except to the slide-carrier portion. To the back of the slide carrier a small shelf was fixed, upon which were placed the cells for the electro-magnetic and other experiments, and when these were going forward the S C portion would have to be shifted bodily forward, so as to bring the object upon the shelf into position.

A condenser of six inches diameter was used, and the objective was twelve inches in focal length. These two were placed about twenty-four inches apart, with the slide midway between, so that the cone of rays from the six-inch condenser was reduced to approximately three inches in diameter at the point where the slide was placed.

In the sketch the slide carrier is shown shifted right forward, to make room for the experimental arc lamp which occupies its place. This was made, if I remember rightly, from an old microscope, whose rack-and-pinion adjustment served for the feeding movements, by which the lower of the two carbons could be gradually raised as they burned away. The projection arc lamp at the other side of the condenser was a Brockie Pell automatic lamp, supplied by Newton, a really excellent lamp, whose behaviour throughout was admirable. The method of connecting these two lamps with the electric current supply is clearly shown in the diagram. The two main (100-volt) leads at the left-hand side are connected—one through the necessary resistance to the negative terminal of the automatic lamp, and the other interrupted by a switch to the other terminal. This positive lead is tapped on the "live" side of the switch by a wire which carries the current to the *lower* carbon holder of the hand-feed lamp, whose image is to be projected. The negative lead for the *upper* carbon holder joins the negative lead to the projection lamp *after* it has passed through the resistance, so that the experimental lamp is always in circuit, and cannot be shut off by the switch, which, however, has full control over the other.

The lower carbon of the experimental lamp is of large size, and is made positive in order that the crater formed in it by the action of the current may be in a suitable position for the reception of various foreign objects, whose behaviour, when subjected to the intense heat of the electric arc, it is proposed to make visible upon the screen.

The manner of performing these experiments was this: The image of the two carbons, about half an inch apart, was first thrown upon the screen by means of the ordinary projection lamp, and, being inverted, it, of course, appeared as if the positive, or cratered, carbon were at the top and in the position most suitable for street lighting and general illumination, the reason for which could be very easily pointed out. The two carbons were then very gradually brought nearer to one another by means of the rack-and-pinion movement, and at the moment of contact, as they are kindled, the main lamp was switched off, and the carbon points then separated to the proper burning distance. In the same manner, the effect of putting small pieces of various metals in the crater could be well demonstrated, and very beautiful some of these effects are. For instance, after all the characteristics of the normal arc had been pointed out, and all the usual deductions made therefrom, the carbon points could be gradually separated, or allowed to burn apart—all the different appearances of the arc, as the distance between the electrodes varies, being duly noted—until, with its peculiarly beautiful dying flickers, the arc suddenly expires altogether, at which moment the projection lamp should be switched on, and the black carbons will appear upon the white ground once more. Then, with a pair of tweezers, a small piece of copper—say, half an inch of bell-wire, crumpled up—should be placed in the crater, and the whole operation repeated: bring the carbons slowly together, switch out the main light at the moment of touching, and then separate again, leaving a vividly green flaming arc between the points. The experiment can be repeated several times with various metals, which, if carefully chosen, will each lend an entirely different character to the arc.

Other experiments, which are very effective upon the screen, are those which demonstrate the influence of magnets of various forms upon the electric arc. The space between the carbons bridged by the current should be about half an inch, so that there will be a long arc, which will then be very sensitive to small bar magnets, being immediately repelled and made to burn on the edges of the carbons farthest away from the disturbing force. Even those little magnets sold at the toy shops, for small boys to lure miniature ironclads to destruction on the edges of a pudding basin, have a very marked effect upon the arc, which will be "blown" completely out if the magnet is brought near enough.

The carbons of the experimental arc lamp may be replaced by metallic electrodes. Two copper rods, for instance, may be used, resulting in a brilliant green arc of wonderfully pure colour. If iron rods be used, the effect of the molten metal, actually boiling in the crater, and occasionally bubbling over and running down the sides, is very interesting and beautiful. Then the changes may be rung by using different metals in the positive and negative holders, or by using carbon for the negative electrode, with one of the metals as positive, or *vice versâ*: but enough has been said to indicate a large number of experiments which, with a little ingenuity, will speedily suggest themselves.

An incandescent electric glow lamp can also be well shown by this method, and the great difference in the apparent thickness of the filament when it is glowing brilliantly, and when its shadow is merely cast upon the screen, is very marked. To show this at its best, a lamp designed for lower voltage than it is used upon should be employed, as by this means a very much more brilliant image will result. A thirty-two candle power eighty-five volt lamp, run on a hundred-volt circuit, will yield a very brilliant light. The resistance inserted in the circuit for the benefit of the arc lights may be disregarded; its influence upon a single incandescent lamp is scarcely noticeable. A separate switch will, however, be required if the filament is to be shown first as a shadow, and then by its own light upon a dark ground, with the arc light extinguished.

CECIL M. HEPWORTH.

PERSIMMON'S DERBY ON THE SCREEN.

MANY people are persuaded that they have seen this year's "Derby" actually run, says the London correspondent of the Photographic Society of India's journal, although they have not been near Epsom. In fact, the "prophets" decided not to go to the "mountain," and "accordingly" the scene on the Epsom sward had to be brought to them instead. This was effected by the enterprise of the Alhambra Management, who came out with a flaming bill on the morning after the race, announcing that the Derby of 1896 in moving reality would be enacted on their screen that evening in the form of an animatograph. And a great stroke of business they achieved. The pictures were most successful, too successful, in fact, to escape a doubting criticism in several of the clubs and society meetings by men who had attempted snap-shots and failed to get any results. These Thomases suggested the great difficulty of distinguishing between one race and another, as the explanation of the immediate appearance of a perfect set of hundreds of instantaneous pictures when they personally failed, owing to the dim light of the moment, in securing a single good snap-shot. However, there appears no adequate reason to doubt the *bona fides* of the spectacle, so that the Derby crowd is likely to

suffer in future by the abstention of that immense number who "only go to study the people, you know," and who will, of course, simply wait a day, and pursue their studies on a large white sheet from a comfortable arm-chair. It is said that the Eastman Photographic Materials Company are receiving a number of orders for long lengths of film on which these kinematographic series of negatives and positives may be made. Considering the elaborate apparatus required both for the exposures before and the projections after development, it is a striking proof of the widespread and influential interest being take in photographic progress. The results are, of course, unapproached and unapproachable by any other kind of pictorial representation for actuality; but one would hardly have expected to find such an amount of private work being prosecuted in this expensive and difficult branch as is evidently the case. The colouring of the pictures is almost a matter of course now, and the mingled effect of the many separately coloured positives makes every tint perfectly harmonious and pleasant.

[In reference to the foregoing remarks touching the alleged doubt of the animated pictures of Persimmon winning the Derby being genuine, we may say in fairness to Mr. R. W. Paul, who took the photographs, that he some time since called at our office and offered to prove the genuineness of the results.—Eds.]

SOME NEW POINTS IN PHOTO-MICROGRAPHY AND PHOTO-MICROGRAPHIC CAMERAS.

[American Philosophical Society.]

Photography in connexion with the microscope, photo-micrography as universally termed, is now such an every-day affair that one unacquainted with the facts can scarcely realise that only a few years ago its practice was confined to a very few enthusiasts at home and abroad, and its results looked upon as interesting and beautiful, but practically valueless. Yet such was the case in the later seventies, when Dr. J. J. Woodward was producing his marvellous photo-micrographs at the Army Medical Museum in Washington. His work was such a vast step in advance of any that preceded it as to attract the attention of the entire scientific world, and in many respects it has never been excelled. Being confined, however, almost exclusively to the resolution and delineation of difficult test objects, as diatoms and rulings on glass, its sole practical value consisted in the improvements in objectives brought about by the efforts of many eminent opticians, both American and foreign, to meet his exacting requirements. "The Battles of the Lenses" will, doubtless, be remembered by most of you, and there can be little doubt that the wonderful improvements in and perfection of modern objectives are due in a large measure to the impetus given by Dr. Woodward in his efforts to obtain the best for use in photo-micrography. Indeed, Nobert saw for the first time the lines of his nineteenth band in a photograph made by Dr. Woodward with one of these object-glasses.

But even more marked in their effect upon photo-micrography than the improvements in objectives have been the changes in photographic methods since Dr. Woodward's day. He worked within his camera itself, his workroom constituting a gigantic camera box, to which no ray of light was admitted during the focussing of the object and exposure of the plate save that which passed through the microscope. The source of light varied according to time and circumstances. Usually he employed that of the sun through an immense heliostat, which is still in use at the museum; but, as a large portion of his work was done at night, he also called in the aid of various artificial illuminants: magnesium ribbon, the lime light, and toward the end of his work the electric arc lamp, each with unvarying success. Not being an expert photographer himself, this portion of his work was done by a professional, and it may not be uninteresting to know that collodion or wet plates alone were used. Gelatine emulsions were as yet unknown, or practically unattainable.

It will thus be seen that, in addition to his own wonderful skill as a manipulator, Dr. Woodward had at his disposal unlimited Government resources as aids to his researches and experiments. Indeed it may be safely said that no other worker in the same field was ever so liberally provided with the means for prosecuting it. The cost in every direction was deterrent to the most of less fortunate mortals, and, as stated before, but for the many radical changes since made in photographic methods, photo-micrography would still be the recreation of the few, instead of the practical realisation of the many.

With the general introduction of gelatine dry plates, of such exalted sensitiveness that the light of an ordinary lamp sufficed for exposures with quite high powers, and portable cameras adapted for use with any microscope having an inclinable body, the making of a negative of almost any microscopical object was brought within reach of every worker. The printing, however, was not so satisfactory, especially where large numbers were required in the illustration of papers or books; but, as in the past, the steady advance in photographic methods speedily supplied the existing need, photogravure and other process methods reproduced the negative in positive form with wonderful exactness, delicacy, and cheapness, so that, at the present day, papers upon any subject may be illustrated in a manner utterly unattainable a short decade ago. By the same means the optical lantern has been brought to the fore as one of the indispensable adjuncts of a well-appointed lecture-room. Ready-sensitised plates of thin glass are now furnished at reasonable cost by several eminent makers, by use of which one can make his own slides and from his own negatives, either by contact printing or by reduction in the camera, if he is provided with one adapted to the latter purpose. In short, the microscopist of the present day finds at his disposal the ready means of illustrating his work at every stage; and one who publishes his notes without illustrations finds himself at a disadvantage as compared with his more progressive brother.

It is not the object of this paper to do more than glance at the new points in photo-micrography which have fallen under the notice of the writer during the past score of years, and to call attention to a new form of camera combining some novel features, which he has recently introduced under the name of the "autograph." It may be not uninteresting, however, if a very brief allusion is made to his preceding work in this direction, as he takes a perhaps pardonable pride in the belief, that to his efforts a considerable portion of the present acknowledged value and popularity of photo-micrography are due.

Without the slightest previous knowledge of photography in any form, I became greatly interested in its application to the microscope by my friend and mentor, the late Dr. Woodward. Many days passed in his workroom during my then frequent visits to Washington gave me a keen relish for and desire to engage in this fascinating pursuit, without, however, the slightest expectation of ever being able to do so. The costly and complicated apparatus and appliances necessary placed it quite beyond my reach. But in a few years, with the advent of portable cameras and gelatine dry plates, I became one of the numerous army of amateur photographers, and very shortly afterward, by means of a make-shift attachment to my microscope produced my first photo-micrograph, a little affair, on a plate scarcely three inches square, and not at all well done, but esteemed as almost a sacred treasure to the present day.

From this crude beginning was evolved the instrument known by the lengthy title of the "Enlarging, Reducing, and Copying Photo-micrographic Camera," which I placed on the market early in 1882. It met with instant and generous recognition, and has maintained its popularity steadily ever since. So far as I have been able to learn, it was the first American camera for this purpose to be produced commercially.

As indicated by its title, this camera is adapted to a variety of purposes. Any microscope with an inclinable body may be used with it in making a photo-micrographic negative, with or without an ocular. The latter is the usual method, since much more light is transmitted by the objective alone, whilst the long extension bellows permits a high magnification with any given lens. Dr. Woodward always worked without an eyepiece. With an ordinary photographic lens, the instrument may be used for enlarging, reducing and copying, the very long bellows rendering it particularly valuable for the latter purpose. It is, however, unnecessary to go into fuller details of the construction and capacities of this camera, since it is already so widely known.

Certain defects or rather want of adaptability to *all* purposes in this camera led to the designing and construction of my latest box, the "autograph." It was somewhat bulky, especially in the larger sizes, which in the too often contracted workroom is a hindrance to its habitual employment. It could be used only in a horizontal position, and the microscope must have a joint permitting inclination of the body, a feature not found in many otherwise excellent instruments, especially those of German manufacture. For use with these stands a vertical camera is, of course, indispensable, as it is when the object is free in a fluid, such as yeast spores, blood, pus, milk corpuscles, &c.; but, for the great majority of work, the horizontal position is the better, especially where it is desirable or necessary to use the direct rays of light from a lamp without the intervention of the mirror. To meet these varying demands, the "Autograph" camera was designed, and it is believed successfully. It may be described as follows, the dimensions given being those for a camera carrying 4 × 5 plates, the only size so far constructed. They would have to be proportionally greater for a larger-sized box.

The base or platform is of polished mahogany or other hard wood twenty-six inches long, standing upon three very short feet, to ensure steadiness on any table or other support, the front end being heavily weighted beneath. At the other end of the platform a stout frame of japanned iron, twenty-four inches in length, with joint close to its base, is firmly bolted. This frame carries the camera, which slides freely in two parallel grooves milled in its upper surface and can be secured at any desired point by a stout screw passing through a slot running the entire length of the frame, in its centre. The joint permits the frame carrying the camera to be placed and firmly held, in either vertical or horizontal positions, or inclined at an angle of 45°. For copying or making lantern slides from negatives by enlargement or reduction the latter position is almost indispensable, and is one of the most valuable "new points" embraced in the "autograph" camera as will be seen presently.

The camera box is furnished with leather bellows of best quality, extending twelve inches, which has been found to be the most generally useful, though double that length can be employed if necessary or desirable. It is fitted with a reversible back, carrying both focussing screen and plate-holder—a most desirable feature, as it greatly facilitates the proper arrangement of the object in relation to its position on the plate where the microscope is unprovided with a rotating stage. The ground-glass focussing screen is mainly useful for arranging the illumination and the object in the field of view, its surface being too

coarse to permit fine focussing with high powers. It may, however, be easily removed from its frame and replaced by a sheet of plate glass, when by means of a suitable lens the nicest adjustment can be made. The plate-holder is double, and fitted with inside kits to carry $3\frac{1}{4} \times 4\frac{1}{4}$, $2\frac{1}{2} \times 2\frac{1}{2}$ or lantern plates, in addition to those of its full size, 4×5 inches.

The front is fitted with a removable plain board, to which an ordinary photographic lens may be attached, and an additional board carrying an extension (which may be oblong or cone-shaped as desired), with an opening in its front end to receive the tube of the microscope. The flange of the photographic lens can be attached to this extension front, if it be necessary to increase the length of the camera in copying and enlarging.

When the camera is used in the vertical or inclined positions, both coarse and fine adjustment screws are within easy reach of the hand, and may be manipulated in connexion with observance of the focussing upon the screen; but, when the horizontal position is assumed, the distance is too great from screen to microscope to permit this, and other means must be provided. A short rod, turning freely in suitable bearings, is attached to the baseboard on right-hand side of the camera. To the end nearest the observer is fitted a large milled head, and to the other a pulley wheel, with V-shaped groove in its periphery, a corresponding groove being also turned in the micrometer screw of the microscope. This pulley wheel slides freely upon the rod or shaft, allowing it to be placed in line with the fine adjustment screw, where it is firmly held by a small set screw. A fine cord passed around the two grooves suffices to move the micrometer screw when the milled head is revolved. This, of course, is an old and well-known device, but, being a good one, has been adopted in this case.

The extension of the iron carrying frame beyond the end of the baseboard, with the additional weight of the camera acting as a lever, having a tendency to tip the front of the base upward, a heavy iron bar, forming one of the short tripod supports, is fitted beneath the front of the board, entirely obviating any such danger. The platform itself is of sufficient length to carry microscope, lamps, and bull's-eye condensing lens on stand, the added weight of which serves also to give increased steadiness to the whole apparatus.

It is not within the scope of this already too lengthy paper to say anything in regard to the making of a negative from a microscopic object. This must be left to another occasion. But it may not be amiss to glance for a moment at the source of light for making the exposures. Diffused daylight reflected from the mirror is probably the most generally useful illuminant, and the various positions in which the "autograph" camera can be placed give the day worker many advantages in its use. But most of us have, perforce, to do our work by night with artificial light. Fortunately there are many of these, some one of which is available to every one. The lime light, the electric arc, the Welsbach gas burner, and the humble, omnipresent, petroleum lamp are all good, varying mainly in the differing lengths of exposure required with each. And, finally, we have the new acetylene gas lamps, which place in the hands of every worker *the ideal* light for photo-micrography.

A few words as to the value of the "autograph" camera in copying and in making lantern slides by enlargement or reduction, and I will tax your patience no longer. For both these purposes the camera, fitted with a photographic lens of not more than nine inches focal length and inclined at the angle 45°, is to be placed near a window, and its base cleared of the microscope, lamp, &c. A carrying frame, with its upper surface parallel with the camera front, takes their place upon the platform, to which the book or print to be copied is fastened. The lighting, focussing, and all such subsequent details are, of course, familiar to every photographer. I cannot even hint at them here, and would suggest that, if the copy is for lantern purposes, it would be well to make it at once of the proper size to permit printing by contact, thus effecting a considerable saving of time.

Negatives of microscopic objects are generally made considerably larger than the dimensions of a lantern slide, though in some cases, as a minute diatom, for instance, they are much too small. In either case the lantern slide must be made by reduction or enlargement as necessary. For these purposes the camera is arranged precisely as for copying, except that its front end must face the window and be close to the latter. A large sheet of white paper is to be laid upon the platform as a reflector, and on this the stand used in copying (and carrying a frame containing the negative) must be placed. A focussing cloth or other covering is then spread over the space between the frame and camera, so that no light may enter the lens save that which passes through the negative. The camera is then moved to or fro upon its ways, until the image projected upon the screen is of proper dimensions, when it is to be fastened in that position, the focus sharpened by moving the bellows; and the balance of the necessary work of exposure and development done in the manner familiar to all who have mastered the simple mysteries of photographic manipulations.

W. H. WALMSLEY.

THE CAUSES OF COLOUR.

[Knowledge.]

THE beauty of the objects of nature around us depends so much on the varieties of colour which they exhibit that it becomes an interesting question, What is the cause of these differences? We have only to think of the blue sky, the green foliage, and the various splendours of flowers and fruits to realise to how great a degree the pleasure we experience in viewing a country scene is due to the many-hued surfaces of natural objects. The pleasurable feelings aroused by the sight of the deep blue of the sea contrasting with the bright red colour of the sandstone cliffs, or the effect of the sunshine when it lights up the splendid purple of the heather on the slopes of the hills, can be forgotten by none who have experienced them; and the striking effect of Eastern scenes is owing largely to the brilliance of the tints which meet the eye. It is needless to enlarge on the part played by colour in this world of ours; the difference between a world of colour and one in which surrounding objects are only distinguished by different shades of grey can be realised by all.

When we come to inquire how the red colour of a rose is produced, and why it differs in appearance from a blue flower, we must consider what happens to the light which falls upon the petals of the rose. We see the flower because the light from the sun is reflected from it, but something has happened to the light before it reaches our eyes; the light we receive differs from that which fell upon the flower. The rays from the sun penetrate to a certain extent into the substance of the flower, and most of them are reflected from particles beneath the surface. Now, the cells making up the petals of a rose contain a fluid which has the power of absorbing certain of the rays of light, and the light entering the eye after penetrating a short distance below the surface of the petals, and coming back, has passed through this fluid, and in its course some of the rays of the sunlight have been abstracted from it. Thus the light reaching us is lacking in certain of the constituents of white light—that is, it is coloured. White light may be considered as made up of the three fundamental colours—red, green, and violet—blended together. The light which has passed through a certain extent of the substance of the rose petals has been deprived of its green and violet portions, and thus the red rays alone reach our eyes. All substances which possess colour exercise this power of sifting the rays of light. Light falling on the leaves of the rose bush passes through their superficial layers, and is reflected from below the surface; thus it has to traverse certain particles, which take from it the red and violet rays and allow the green to pass. The green rays, which escape absorption, are the only ones which reach our eyes, and we therefore call the leaves green.

When white light passes through a prism, it is found that, in the band of colour or spectrum produced, the blue and violet rays are the most bent out of their original course; they are the most refrangible. The red rays are the least bent. It is found also that the vibrations of the ether filling space which produce waves of light are quickest in violet light, and slowest in red light. Some substances absorb the quick vibrations more readily and thus appear reddish in colour; others absorb the slower vibrations, allowing the others to pass through, and therefore have a green or blue colour.

When a substance is heated, its particles are thrown into a state of rapid motion, and soon set up a motion in the ether which, when the vibrations are of a certain rapidity, produces light. If a ball of iron is heated, it first of all gives out radiation consisting of dark rays, which have the effect of producing heat. As its particles become hotter and hotter, and thus vibrate more rapidly, the radiation begins to affect our eyes, and the ball glows with a dull, red heat. As vibrations of greater and greater rapidity take place owing to the further heating, the ball appears bright yellow, and finally white, when vibrations of all the different rapidities which affect our eyes are given out. In this case it is the motion of the particles or molecules of the heated body which is imparted to the ether, and so produces the effect we call light. Now, those molecules which are able to execute certain vibrations and give them to the ether absorb these same vibrations from the ether—that is, absorb certain rays of light. This effect is best seen in the case of gases, and the phenomenon is analogous to that which occurs with sound. A tuning fork or stretched wire, which can give a certain note when it is struck, is able to take up and absorb the note from the vibrating air around it when that note is sounded in its neighbourhood.

It may be noticed that the light from the electric arc, when seen near at hand, has a distinctly bluish colour; but this same light, when viewed from a distance, appears yellowish, as certain of its rays have been absorbed by the water vapour in the air on its passage to the eye. For a similar reason the sun is now considered to be a blue star; his light, which would appear intensely white and rich in blue rays especially, if it could be seen from beyond our atmosphere, appears yellowish after it has passed through that atmosphere, and has lost some of its most refrangible constituent rays.

The effect of absorption in producing colour is seen from the fact that powdered bodies generally appear white. This is accounted for when we consider that a powder consists of particles arranged at all angles, so that the light falling upon it meets various surfaces, and is mostly reflected before it has passed below the surface. Thus the white light reaching it is not deprived of some of its constituents by selective absorption, as it would be if it penetrated the substance that was then reflected. In this way powdered red glass appears white. For a similar reason, the froth of coloured liquids, such as brown ale, appears pure white. The light is reflected from the surface of numerous small bubbles, and does not pass

much through the liquid itself. Thus, also, a cloud is very opaque to light, the light falling on it being reflected at the surface of the numerous globules of water. To this is due the brilliantly white appearance of large fleecy clouds in bright sunshine.

Some substances absorb equally all the rays of light. Such substances, of which soot is an example, appear black. The reason why a flower like a white lily appears white is that the fluid contained in its cells does not absorb one sort of rays more than another, but allows all to pass with comparative freedom. White light, then, reflected from its surface, or from a little below, is not deprived of any of its constituents, but remains white.

The effect of reflection from internal surfaces, accompanied by absorption in producing colour, can be seen by pouring a coloured liquid, carefully freed from floating particles, into a white porcelain basin. Light is reflected from the sides of the basin, passes through the liquid, and its colour is seen. If, now, the sides of the basin be covered with some black substance, no light will be reflected from them, and the liquid will appear black; no light comes to the eye from the interior, and the surface of the liquid reflects all the rays equally. If next we place in the black-looking liquid a white powder like chalk, its colour is at once restored, light being now reflected from the interior at the surfaces of the chalk particles.

From the above considerations we can understand to what causes the colour produced on mixing pigments is due. A mixture of blue and yellow paints has a green colour, because that is the only colour transmitted by both pigments. The blue paint absorbs the red, orange, and yellow rays, allowing the others to pass through it; the yellow paint absorbs the blue, indigo, and violet. Thus green rays alone are permitted to pass through both, and the result is that the mixture appears of that colour.

Some substances appear of one colour when viewed by reflected light, and another when seen by transmitted light. Thus the light reflected by gold is yellow, but a leaf of gold, made so thin that light can pass through it, appears of a green colour. This appearance of different colours on reflection and transmission is also seen with many of the aniline dyes. The colour of the light due to reflection is then made up of those rays which are not admitted at all, but sent back at the surface, together with that light which has been reflected from a certain depth below the surface, and has thus lost some of its constituent rays by internal absorption. The light to which the colour is due when the substance is viewed by light which has passed through it is that which has been derived of some rays by reflection at the first surface, and again of others by absorption in passing through. Hence the difference of colour when viewed in the two different ways.

Variations in colour perception, no doubt, depend on varying sensations in our own eyes, as well as on changes in the light itself. Some curious experiments have been made with a view to testing our different sensations as to colour. It has often been noticed that a bright scarlet uniform would appear perfectly white in a good photographic dark room, with ruby glass windows. With regard to such effects, Herr H. W. Vogel described recently in Berlin some experiments he had made. He used oil lamps, and fitted on to them pure red, green, and blue colour screens. It was found that, when the white light was entirely shut out, no sense of colour was perceptible to the observers, and objects in the room appeared of various shades of black and white. He found that, when a set of colours was lit up by red light, the red pigments appeared white or grey, and this changed at once into yellow, not into red, when blue was added to the light under which they were viewed. Thus a colour was perceived which did not exist in either of the sources of light used. The colour sensation produced by a source of light also depends partly on the intensity of the illumination. From these and similar experiments Herr Vogel comes to the conclusion that our opinion as to the colour of a pigment depends upon our perception of the absence of certain constituents from the light reflected from it. Thus a surface which has a red colour is only perceived as red by us when light of other colours shines upon it, and we observe its incapacity for reflecting these colours.

When a solution of quinine is viewed in sunlight, a remarkable blue shimmer is noticed, extending for a short distance beyond the surface at which the light enters. A similar effect is noticed with many other substances, the colour being different in different cases. The phenomenon is known as fluorescence, as it is well observed in the mineral fluor spar, and is due to the fact that light is absorbed by the substance, and is again given out as light of a different colour. For instance, rays of high refrangibility towards the blue end of the spectrum may be taken in and given out as yellow rays of lower refrangibility. In the case of quinine, invisible rays beyond the violet are absorbed, and blue or violet rays are emitted by the solution. In all cases of fluorescence, a degradation of the rays takes place; those given out are of lower refrangibility than those which disappear on absorption. By painting a screen with a solution of sulphate of quinine, the spectrum beyond the violet can be made visible, as those vibrations which are too rapid to affect our eyes are changed into others of lower refrangibility, which can be perceived when they fall on the retina. The curious blue colour of the solution of quinine extends only a short distance into the liquid, because those rays which are capable of producing it are soon absorbed, and the light which passes onward through the fluid is destitute of such rays. The colour produced in cases of fluorescence has a different origin from that of the ordinary surface colour of substances, for the rays absorbed do not disappear as light, but their place is taken by other rays of a different sort.

The nature of the vibrations which constitute light still remains mysterious, but great advances have been made in recent years in our acquaintance with these and allied phenomena, and we may hope for still greater accessions to our knowledge in the not distant future.

J. J. Stewart, B.A.

HOW TO TAKE STEREOSCOPIC PICTURES WITH THE POCKET KODAK.

Everybody who has looked at stereoscopic prints or transparencies in a stereoscope will readily admit how very lovely and delightfully lifelike they are, and cannot but wonder why more of this kind of photography is not practised.

Fifteen or twenty years ago nearly every house possessed a stereoscope with which to interest and entertain visitors. Now where can one be found, and, when there is one, how many persons look in it? True it is that within the last year or two there has been a half-hearted revival of interest in this manner of showing one's pictures to one's friends, says the *Kodak News*, and many are now enthusiastic stereoscopic photographers, but progress has been very slow. It is difficult to assign a reason for this, but perhaps the costly initial outlay necessary up to now may have been responsible for it.

Whoever heard of a stereoscopic camera for 2*l.* 2*s.*? yet that is the total outlay required in order to make stereoscopic pictures with the pocket Kodak.

The pocket Kodak must convert large numbers to stereoscopic work now a special and expensive camera is no longer necessary, and the operations are so delightfully simple.

All that is required to start this branch of photography is, in the case of those not already possessing a pocket Kodak, two pocket Kodaks. Of course, if you already have one of these little instruments, then another will be needed.

The plan we adopted was as follows:—

The two pocket Kodaks were placed side by side, so that the finders and keys were on top, and the lenses pointing in the same direction. They were stood upon a piece of wood cut to the exact size occupied by the two cameras, and bound together with rubber bands or a strap. Other and better means of keeping the little cameras firmly bound together will suggest themselves to our readers. Our object at present is to describe a simple and inexpensive way of making these miraculously realistic stereoscopic pictures. It is most important that the two cameras should not move independently of one another.

Our plan is greatly simplified by the fact that, when the cameras are joined together, the distance between the lenses is exactly correct.

Having followed the directions above described, we are ready to make our exposures in the usual manner. We will only impress on our readers the necessity, in making snap-shots, of pressing the two buttons *simultaneously*.

In making time exposures, the exposure with each Kodak can, if there is any advantage in doing so, be made independently, but in such a case the Kodaks must not be moved from the original position they were placed in, and the same time of exposure must be given with each Kodak. On the whole, however, we advise that, for obvious reasons, the exposures be made simultaneously with both pocket Kodaks.

The films should be developed together, and for exactly the same period of time, in order that the negatives should possess a common degree of density.

So also should the negatives be printed on one piece of Solio paper.

Our method is to take a piec of Solio slightly larger in all directions than 6 × 3 inches. Cut out from a piece of opaque paper, measuring on the outside edge 6 × 3 inches, a mask having two openings, each measuring $1\frac{5}{8} \times 1\frac{3}{8}$ inches. The openings must be cut out so that the distance between their centres is just under 3 inches—say, $2\frac{7}{8}$ inches. Then mount the negatives film side up, under these openings, attaching them to the mask by means of gummed paper, so that the one made with the Kodak on the user's right hand is, when fixed to the mask, on the left side. To be sure of doing this, it will be necessary that the negatives are kept track of during the process of developing, and we would recommend them to be marked, when first taken out of the cameras, R for right, and L for left, for purposes of identification afterwards.

Now proceed to print, tone, and fix in the usual manner, and mount on stereoscopic mounts, which can be obtained. Before trimming the prints, it is a good plan to place them under a card mount with two openings (the prints can be held in position temporarily with elastic bands), and then examine them in the stereoscope. If they do not coalesce, move one print only, just a little, and examine again. When the exact position is decided upon, mount each print round the openings of the mount, and trim them down to the lines drawn.

MICROSCOPY.

It is stated on some authority that magnifying lenses were not in use till about the end of the sixteenth century. It was known long before then, however, that letters were enlarged when seen through a globe filled with water, but it was thought that magnification depended upon the nature of the water or of transparent bodies, and not upon the lenticular form of the glass. From the gradual deepening of curves, no doubt, the idea originated of producing lenses of shorter and shorter focus, until the combination of a convex lens as an objective with a concave lens as an eyepiece, distanced apart by the hands, led to the discovery of the telescope. Its conversion into a microscope would immediately follow, for, as Herschel says, a telescope used for viewing very near objects becomes a microscope.

"The first microscope would most likely be in the shape of a hand lens," writes Mr. A. B. Steele in *Knowledge*, "and this would soon be improved upon by mounting the lens at one end of a tube with the object held at the focus or attached to a piece of glass. For higher powers some system of focussing would be applied, either by sliding the object cover or the lens, and for still higher powers globules of brown glass would be used. It is said that Huyghens brought microscopes from Holland of minute spheres of glass about the size of a grain of sand, and one of the earliest experts in microscopical observations is said to have constructed an instrument of blown glass and used it in the discovery of minute forms of life. The honour of having produced the first microscope consisting of a combination of lenses is generally ascribed to a spectacle-maker named Jansen, in the small town of Middelburg, in Holland. The date can only be approximately given as shortly before or after the beginning of the seventeenth century. One of Jansen's microscopes was found at Middleburg in 1850, and was exhibited at the Loan Collection in London in 1876. It resembles one of the present-day compound microscopes without the field lens. At the time of its manufacture clear glass was scarcely to be had in Holland, and microscopes were constructed with lenses of rock crystal, and designed to view opaque objects by reflected light.

"In 1637 Descartes published a description of a simple microscope, which was a decided improvement upon the form commonly used before his time. It consisted of a simple lens mounted in a central aperture in a polished concave metal reflector, and was practically the same as the lens constructed a century later. He also designed a machine for grinding and polishing lenses nearly a quarter of a century before practical men had their attention drawn to this important subject. But about this time the man whose fame as a microscopist is best known, and who gave the first real interest to microscopy, was Hooke. He was the first to employ diffused light instead of direct sunlight. He introduced the field lens, and invented the ball-and-socket movement in the construction of the microscope. He was also the first to discover that a drop of water placed on the front lens of the objective would allow more light to pass than a dry lens could in the proportion of unity to the refractive index of water. Such lenses were subsequently known as immersion lenses. So distinguished a person was Hooke that Herschel speaks of him 'as the great contemporary and almost the rival of Newton.' It was not till nearly fifty years after his time that microscopes were provided with mirrors. The early system of focussing seems to have been effected by a 'screw-barrel' arrangement acting on the object, which was clipped between two plates and depressed from the objective by a spiral spring; and 'screw-barrel microscopes,' so named from the objective being mounted in a little barrel, became common in the eighteenth century. Many improvements in the screw-barrel system of focussing were introduced, but all were more or less defective, until a plan was discovered by which the image would remain steadily in the field, and allow the object to be viewed during the actual process of focussing.

"The invention of means to determine the exact magnifying power of any objective is due to Benjamin Martin, who applied a screw micrometer to the eyepiece with fifty threads to the inch, so that the precise number of diameters could be stated. A ruler, divided into tenths of an inch, was placed under the microscope so as to have a tenth in full view on the image; then, by measuring it with the microscope, and counting how many turns were made in so doing, the number of turns divided by five showed how much larger the image was than the object. Martin made a large compound microscope for his Majesty George III., which is now in the possession of the Royal Microscopical Society. The instrument stood on the floor, and was so large that the King could conveniently use the eyepiece while sitting in his arm-chair. The compound microscope of to-day, known as the 'Continental model,' by which most of the scientific work of our time has been performed, was evolved out of Martin's reflecting microscope. In designing and executing microscopes Martin excelled all others of his day, but his fame rests chiefly on his being the first to construct an achromatic objective.

"The possibility of applying achromatism to the microscope attracted the attention of men like Wollaston, Herschel, and Brewster; but, notwithstanding the researches of these, its adoption made slow progress, in fact, there is very little difference in the definition of the image between a microscope made last century and one made during the first quarter of this. It was achromatism that gave the stimulus to the discovery of a more precise means of focussing, and since its application in 1824 by the French optician, Chevalier, the development of the microscope has made greater progress than during the whole former period of its existence. The neglect given to fine adjustment can only be accounted for by there being little or no original investigation done with the microscope, and consequently there was no impetus given to its development. The best designs of fine adjustment were first devised by Englishmen. To Powell we are indebted for a system of focussing applied to the nose piece. In Andrew Ross's instruments the fine adjustment tube was raised and depressed by means of a screw acting upon the end of a lever of the second order, while in those of Powell and Lealand the screw acted upon a lever of the first order. The rival to these was the 'Jackson system,' the fine adjustment of which was deficient in delicacy and precision, chiefly owing to the extreme shortness of the acting lever. Lister's discovery of aplanatic foci led to still greater improvements in objectives, for his investigations were taken advantage of by three of the then leading firms of opticians in London, and very fine objectives were produced after long and persistent experiment.

"The first really practical immersion lenses were made by Professor Amici, of Modena, and were improved upon by Hartnack and others, who succeeded in producing such excellent objectives as to make it possible to resolve the most difficult tests known to microscopists. Water-immersion lenses were constructed by Englishmen about 1860, who made both new lenses and also new front combinations to screw on to old glasses. About twenty years ago a farther greater advance was made by Mr. J. W. Stephenson, of the Bank of England, who induced the firm of Zeiss, of Jena, to construct lenses in which a drop of cedarwood oil was substituted for water. These were termed homogeneous immersion lenses, because, the oil being of the same refractive index as the glass of which the objective was made, the light from the object passes into the optical system without refraction. But for greater improvements still we are indebted to the optical knowledge of Professor Abbé, of Jena University, in combination with the mechanical skill of the late Carl Zeiss. In every achromatic object-glass it is impossible to unite more than two rays of the dispersed light in the spectrum, viz., red and green, the others being left out and forming what is called the secondary spectrum. It occurred to the Professor to construct an objective with the mineral fluorite—which has a very low refractive index—as a component, and so to obtain a greater command over the removal of the chromatic dispersion. He thus devised what are now known as apochromatic objectives, which are slightly over-corrected for colour, while the eyepieces used with them are under-corrected, the result being that three rays of the spectrum are united, and an almost colourless image is produced. The magnification by means of these eyepieces may be carried to a large extent, eyepieces having a magnification of twenty-five times being used with these objectives without any apparent degradation as regards colour, especially with the lower powers. This discovery has been followed by every optician of note, both here and on the Continent, and it may be truly said that no scientific work of any importance with the microscope can be done without an apochromatic objective. The microscope has by this means been firmly established on a footing which the telescope can never, we fear, hope to possess. It "holds the head" in optics, as our French neighbours say. It is much to be regretted, however, that we are so very dependent upon foreign workmanship for the optical tools with which important scientific work is done. Our British manufacturers are no longer leading, but following, for most of the firms are making microscopes upon what is called the 'Continental model,' the instruments with which nearly all real scientific work is done at the present day."

AN IMPROVED METHOD OF JUDGING SLIDES.

[Australian Photographic Journal.]

A most interesting competition of lantern slides was held at the last general meeting of the Amateur Photographic Association of Victoria. This Society is strong in good lantern-slide makers, and the competition was looked forward to with great interest on this account, as, until the slides were handed in, no one knew positively who were the competing members.

Messrs. J. W. Small & Co., in order to encourage the making of slides of a high quality, presented an optical lantern as a prize to be awarded to the maker of the best slide from a given negative. The donors supplied the negative and laid down the rules which were to govern the competition; these, briefly stated, were to the effect that each competitor should have the use of the negative for forty-eight hours, only one slide was to be submitted by each, any plate or process might be used, slides were to be sent in under mottoes, and accompanying each slide was to be a sealed envelope bearing the same motto and enclosing the name of the maker, together with all particulars as to how the slides were produced; judging was to be done by all members of the Association who might be in attendance on the evening of the competition.

The system adopted by the Society for testing was a new one, as far as this part of the world is concerned; the slides were exhibited two at a time, the two lanterns being placed side by side, and five feet apart, and five feet discs were projected by them.

After a pair of slides had been exposed for the time agreed upon, they

were removed from the lanterns and reinserted, with the difference, that the slide which was at first in the right-hand lantern was now shown in the left, and that which had been viewed by the light from the left was changed into the right. A few seconds longer and the scrutineers ordered the vote to be taken, one slide being first voted for and then the other. The slide for which the greatest number of votes were cast remained in the lantern, and the other was removed, being thrown out of the competition; a third slide was then introduced, and so on, until the whole of those submitted had been shown; the operators varied things at intervals, for sometimes they changed the slide which remained in the lantern after a vote was taken, and transferred it to the other instrument before the next slide was inserted (the lenses were kept capped between each two changes), and this increased the interest. The object of changing the slides is said to have been the prevention of one slide having an accidental advantage over another by reason of any slight difference between the lights in the two lanterns.

The limelight was used, and the competition appears, from what we can learn, to have passed off in a very satisfactory manner.

The points to be learned from this competition, which we believe is the first that has been conducted upon these lines in Australia, are worth considering.

In the first instance (and this is a novelty here), the whole of the competitors work from the same negative; thus the holder of extra-good negatives or negatives of attractive or interesting subjects has no advantage over the man who has not the good fortune to possess such, and any accidental preference which some of the voters might exhibit for certain subjects is not allowed to interfere with the result.

Leaving the choice of plate to the maker of the slide is also another good point, as the experienced slide-maker will naturally select that plate which he understands best, or, if he is conversant with several makes, he will choose the one which his judgment tells him will best suit that particular negative.

The second novelty is the showing of two slides on the same screen at the same moment; by thus exhibiting them, the judges are enabled to obtain a clear grasp of things, and are in the best position to weigh the merits and defects of the respective slides one against the other, the discs being absolutely the same size and the illumination as nearly equal in the two lanterns as it was possible for those in charge to keep it. (We were informed some time ago that the projection lenses in the lanterns of the Association are Dallmeyer's Lantern Lenses, which were specially paired to the order of the Society.)

The device of changing the slides in the lanterns previous to the taking of the vote has also much to recommend it, as both slides are then seen under practically identical conditions.

If, instead of allowing the judging to be performed by the whole of the members of the Society, a small jury of recognised experts in the making and criticising of transparencies had been appointed, we think that there would have been no question as to the value of the slide which came off victorious; but, when the votes of the general body of members are taken, this result is by no means guaranteed, as it is extremely unlikely that every member present would be qualified to adjudicate upon a matter of this sort; and, as the members are sure to vote one way or the other, there is every opening left for an improper decision with regard to some of the slides, especially when deciding upon the respective merits of two which happen to very nearly equal. We do not, indeed cannot, assume that this was the case in this particular competition, but that the chance of such errors of judgment occurring does exist cannot for a moment be denied.

Another thing deserving of notice is the small size of the discs employed; though these are quite large enough for the testing of slides in this manner, the light can be made very intense when concentrated in such a small area, and this would give a slide which would be far too dense to look well under ordinary conditions, an unfair advantage over one which had been prepared with the usual conditions in view. The discs were only five feet diameter, now in accordance with the well-known rule, that, if a given consumption of gas per hour and a given pressure afforded a light which would give desirable results when a ten-feet disc was used, the same amount of light would illuminate a five-feet disc with exactly four times the intensity; thus it will be easily comprehended that a very heavy slide would possibly look just correct, whereas one which had been prepared for normal illumination would be swamped.

No doubt, this detail was not lost sight of by those in charge of the lanterns, but still the temptation to obtain as fine a light as possible is always very great, and it would possibly be found surprisingly difficult to resist.

These two matters appear to us to be the only elements of weakness in the scheme, though the manner of judging favoured on this occasion obviously possesses one great advantage, in that it leaves no room for fault-finding on the part of the vanquished, as every man has a voice in the placing of his own work.

Considering the competition, as a whole, we think that it is a step in the right direction, and that the initiation of this system in Australia is a further illustration of the energy of the leaders of this Association, and, taken in conjunction with the valuable papers contributed by some of them to the recent Congress, a proof of the work which they are doing for scientific photography. We anticipate that this method of deciding competitions will be introduced into more of our photographic societies.

Correspondence.

ACETYLENE GAS.

To the EDITORS.

GENTLEMEN,—Knowing the keen interest you take in any advancement in lighting generally, and particularly in *acetylene* gas, we think it would interest your readers to know that we have just very successfully illuminated the horticultural show and floral fête held at Lady Shelley's Park, Boscombe, Bournemouth, on the 19th and 20th ult.

The whole of the large marquees, each about 200 feet by 40 feet (four in number) were most brilliantly illuminated by the aid of our "Incanto" generators—twenty burners of about sixty candle power each were employed in each tent, and there was not the slightest hitch during the exhibition—the light remaining steady and smokeless—and the general opinion expressed was that this light was really superior to an electric installation which would have cost ten times the amount.—We are, yours, &c., THORN & HODDLE.

159, *Camberwell New-road, London, S.E.*

IT is stated that the Acetylene Illuminating Company, of Queen Victoria-street, have concluded arrangements with the British Aluminium Company, who are already located at the Falls of Foyers, by which they will be able to erect works of several thousand horse power, for the manufacture of calcium carbide, using water power. Pending the construction of the proposed works they have obtained the use of a considerable portion of the spare water power of the existing works of the British Aluminium Company at Foyers, and a carbide plant is now being erected there, which it is expected will be in full work during the month of October.

A NEW electric arc lamp has been invented by Dr. Leo Arons which ought to be of considerable use to professional photographers, on account of the steady white light it gives and the fact that there are no carbons to replace. In form it is somewhat like an inverted U, the electrodes being fused through the bottom of the arms, which are filled with dry mercury which has been freed from air; the curved position of the U is evacuated, and, when the current is passed through the mercury, a beautiful greenish-white light is produced. During the burning of the lamp, the mercury distils over from the hotter anode to the cooler cathode, and, when the level of the mercury rises too high in the cathode arm, it simply flows back again over the arch of the U, so that the lamp requires no attendance at all.

THE most extraordinary of all light-houses is to be found in the Hebrides, Scotland, on Armish Rock, Stornoway Bay—a rock which is separated from the Island of Lewis by a channel over 500 feet wide. On this rock a conical beacon is erected, and on its summit a lantern is fixed, from which, night after night, shines a light which is seen by the fishermen far and wide. Yet there is no burning lamp in the lantern and no attendant ever goes to it, for the simple reason that there is no lamp to attend to, no wick to trim, and no oil well to replenish. The way in which this peculiar light-house is illuminated is this, says the *Marine Record*: "On the island of Lewis, 500 feet or so away, is a light-house, and from a window in the tower a stream of light is projected on a mirror in the lantern on the summit of Armish Rock. These rays are reflected to an arrangement of prisms, and by their action are converged to a focus outside the lantern, from where they diverge in the necessary direction." The consequence is that, to all intents and purposes, a lighthouse exists which has neither lamp nor lighthouse keeper, and yet which gives, as serviceable a light, taking into account the requirements of this locality, as if an elaborate and costly lighthouse, with lamps, service room, bedroom, living room, storeroom, oilroom, water tanks, and all other accessories, were erected on the summit of the rock.—*Scientific American.*

ONLY to one little matter will I allow myself to call your attention, and that is, when you see street merchants having in their small stock of goods, stereoscopes, and stereoscopic slides, I think it pretty strong evidence that stereoscopic goods are still in demand. It calls for considerable judgment and good taste to properly compose and make a good stereoscopic picture, be it a group, an interior, or a landscape. These are not by any means as easily made as work under the skylight.

Again, take notice of the amount of capital employed in the optical lantern trade. You have only to look over some catalogues appertaining to that trade to be convinced of its magnitude. See the expensive instruments made by Beseler, Colt, Thompson, Queen, McIntosh, and others. York, of London, and Wilson, of Scotland, send men all over the world, taking negatives for slides. West, of Portsea, came to New York during the yacht race for that purpose alone. Few men dare give a lecture nowadays, no matter what the subject, without it being illustrated, and in some instances have lantern slides made for their especial use. Notice the number of lantern clubs all over the country.—JEX BARDWELL at the American Convention.

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*October* 2, 1896.

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

Variety is charming! Such is the conclusion come to on more than one occasion with regard to Lantern-slide Exhibitions, and, sad to relate in a photographic journal, that portion of the British public who desire recreation have actually expressed themselves satiated with plain photographs, and have asked for coloured slides and dissolving-view effects to give the audience a change.

* * * * *

A beautiful photograph projected on the screen any one with the least possible artistic taste cannot help being pleased with, but 100 or 200 photographs shown in succession is rather apt to be wearying, and I really feel that the time has come when some of the photographic societies, or lantern sections of these societies, should encourage the exhibition of artistically coloured photographic slides. If latitude were allowed artists so that any slide having a photographic basis could be shown, I think it would encourage the art of painting on glass.

* * * * *

At present the artists who can paint in transparent colours on glass, really artistically, can be counted on the fingers of the two hands, but, with the veto removed from coloured slides at the societies, artists, and particularly ladies, would "try their hand" at colouring. That they could succeed without personal instruction as to technicalities I do not think is likely, but for a reasonable fee lantern-slide artists would give the necessary number of lessons to ensure proficiency with practice. In the earlier days of the lantern, pupils had to serve a seven years' apprenticeship, but then the demand for lanterns and slides was not nearly so great as it has been during the last ten years, and photography has made it possible to produce the necessary quantity to supply the demand.

* * * * *

With regard to hand-drawn subjects as so beautifully produced by Clare, Childe, Hill, and others in the early days, and still seen in limited numbers at the higher-class lantern-makers, where hand-painted slides and dissolving-view effects are a speciality, if an artist is really clever at figure-drawing and will take the matter up, he will find, after he has mastered the details and can lay transparent colours on equally or smoothly, there would be a demand for his work. It must, however, be A1; for, if not, when magnified as it is on the screen, it is anything but pleasing to the eye.

At a recent entertainment I was an eyewitness of the pleasure the audience exhibited on some artistically coloured photographs, with effects, being projected on the screen; and I think, if the lantern section of societies would consider the advisability of having one night of the season set apart for coloured views and effects, and take care that the apparatus is capable of properly "registering" the slides, and that the slides and effects are prepared to that end, they would find the members appreciate it, especially if care is taken in arranging the seats so that none of the audience are nearer than one and a half times the diameter of the picture.

* * * * *

I have mentioned it so many times that I hesitate to reiterate that the reserved seats in halls and entertainments with the optical lantern (unless science projections only) should *not* be at the same place as for concerts, &c., as usually placed, but at some distance back, for the angle is too great to include a proper view of the picture, and the general effect is lost by the eye concentrating on some apparent defect due to excess of enlargement on account of nearness. In an otherwise well-arranged entertainment, referred to above, I noticed this defect in the disposition of seats.

* * * * *

I am glad to see that the Cinematograph, or some apparatus of this class, is to be shown at the Royal Photographic Society's Exhibition, and I trust it will be the means of inducing photographers to produce film photographs, so that something beyond the kinetoscope films may be available for projection. I observe that French and American houses are vying with each other in their endeavour to get the first market in England; but, good as some of the subjects are, I have no doubt British photographers, when once fairly started on the track, will out-distance them in popularity of subject, and probably in execution. Three or four English photographers are already at work; but, as far as I can learn, only two of them will sell their films, except to purchasers of machines or licencees; whereas, if a perfect gauge is kept, so that the films may be certain of working in well-constructed machines, there will be a good demand for them.

* * * * *

Regarding the projection of "colour photography" transparencies, I had hoped that Mr. Ives would by now have placed on the market his apparatus for showing the beautiful results he obtained himself by means of three coloured screens and superimposed projection. If he is not sharp, except as a scientific result or example, I fear he will not find much call for it, for I recently saw some beautiful examples in single transparencies projected in colour. At present I am not in a position to give details, but before long a public exhibition will be given, and the inventor and producer of these beautiful specimens promises to satisfy the most sceptical. He assured me that no pigment, dye, or colouring matter of any kind, was used, and, as far as I could see the transparency in the stage of the lantern and the resultant picture on the screen, his assurance seemed fully borne out. A little longer time to complete certain details and secure protection for the process is asked for.

G. R. Baker.

DISSOLVING VIEWS WITH ELECTRIC LIGHT.

A few weeks ago, in the course of a paper on *Painters as Judges at Photographic Exhibitions*, Mr. Alfred Maskell, referring to lantern slides, said he finds it "difficult to be serious in applying the term (art) to these very mechanical and easily made transparencies." I am afraid his opinion of dissolving views would be something appalling, but all men cannot live by art alone, or the animated photographs would not be having such an innings, and the majority of those who go to lantern shows do not consider they are being properly treated unless dissolving views are the order of the evening.

The electric arc light is, *par excellence*, the light for the lantern wherever it can be obtained, and its use is rapidly spreading as fresh tracts of land are being included in the electrically lit domain: for not only is it much brighter and much smaller than its only rival, the lime light, but it is, where suitable current is obtainable, much easier to use, and more satisfactory in its results, provided, of course, a good and reliable form of lamp or regulator be employed. But electric light, as applied to dissolving-view work, has, compared to the lime light, this disadvantage, it cannot be turned gradually off and on. Its intensity cannot be reduced in one lantern and augmented in the other so as to produce the dissolving effect in the manner which is so successfully employed with the lime light. True, by a suitable arrangement of variable resistances, the light from an electric arc can be very considerably reduced—especially if a hand-feed lamp be employed—but a point will be reached when the reduction cannot be carried any farther without the light first flickering and then going out suddenly, and at that point the candle power of the light is still in three figures, so its sudden extinction would mean anything but a gradual dissolving effect upon the screen. Moreover, in the other lantern, where the light is being turned on, it cannot be established at all until sufficient current is applied to produce a light equal to some hundreds of candles: so the question resolves itself to this, that to produce a dissolving effect upon the screen, where electric arc light is concerned—the most brilliant light we have—we must hark back to the appliances used for the purpose when the weakest of our now available illuminants (the oil lamp) was the only one a disposal.

However, there is comfort in the reflection that the double fan arrangement, which became obsolete with the advent of the lime light, and which must now be resurrected, is a far more perfect means of dissolving one picture into another than the turning off of one set of gases while another is being turned on, which at present obtains where the lime light is concerned. It has its disadvantages, undoubtedly, not the least being that both lights must be kept burning at the full all the time the "effect" is in progress. But, with two electric lights, one can be extinguished as soon as the change from one picture to another has been effected, and it need not be relighted until just before the next change is required. However, sufficient electric current must be provided to maintain two lights running concurrently, unless what I may call the "series" system be employed. And this system I will dispose of first, for, though it is undoubtedly economical, there are so many practical objections to its use, that I am afraid it must be regarded as practically "out of the hunt."

When a single arc light is run upon a 100 volt circuit (100 volts is the usual pressure supplied to halls, &c.), an extra resistance has to be employed to absorb the energy which is not required at the lamp. For instance, a lamp taking 15 ampère current would absorb rather under 50 volts out of the 100. The remainder—a little more than half of the total voltage—has to be taken up by the resistance, which converts the energy into heat, that, of course, being quite wasted. Thus, in round numbers, the energy represented by 15 ampères at an E.M.F. of 100 volts—that is 1500 watts—is divided equally between lamp and resistance. So two arc lamps, with the 15 ampères passing through each, and each absorbing its quota of nearly 50 volts, could be run upon the circuit, and the two lights, each as brilliant as the one would be alone, would absorb together only the same power as is required to maintain a single light with its resistance. Consequently it requires precisely the same quantity of electricity—or, in other words, it is just as cheap—to supply a double dissolving-view lantern as a single one.

Now for the disadvantages. In the first place both these lamps must be of the automatic variety, and automatic regulators are, except in the hands of an experienced electrician, very difficult to manage, and very liable to go wrong at critical moments, and even an electrician would find it no easy matter to control the vagaries of two automatic lamps running tandem as it were at the same that he is operating the double lantern. It is practically impossible to keep two hand-fed lamps running in series, for one cannot tell which lamp requires attention when the light burns a little low, for the light of both diminishes equally, and, if the wrong one is trimmed, both are immediately extinguished. With two automatic lamps run in series, all the troubles of one lamp will be quadrupled. Every little flicker or jump which occurs in one lamp—and a few jerks are inevitable with even the best carbons—will be reproduced in duplicate in the other, and, should anything go wrong with the works of one, both will be extinguished. Lastly, both lamps must be kept running during the whole performance, for each serves as a resistance to the other, unless some arrangement of switches be employed by which a resistance can be shunted into the circuit instead of one of the lamps while the other is burning. This would remove many of the disadvantages, it is true, but it might introduce fresh ones, for it is very doubtful whether this shunting could be accomplished without causing a very perceptible flicker of light on the sheet, and many automatic lamps, including the best of all, will hiss and spit in a noisy and most distressing manner for a full minute after they are lighted up. However, here is a scheme for the necessary connexions; it might be worth trying, at all events.

There are more ways than one in which two lamps for working in series, or separately with a resistance, according to circumstances,

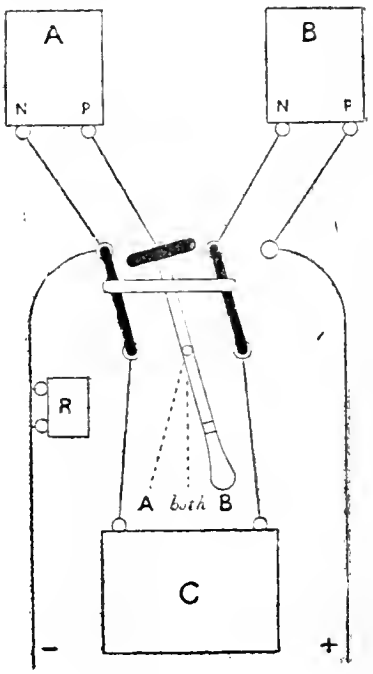


Fig. 1.

may be connected up, but the plan I have sketched out in the accompanying diagram (fig. 1) will, I think, be found to answer all requirements in a satisfactory manner. Referring to the sketch, A and B are the two lamps, which, as before stated, must be automatic. The polarity of the triunials is marked by the letters N and P. The negative and positive leads are shown at either side of the diagram, the former being connected with the negative terminal of one lamp, while the latter is attached to the positive screw of the other. In the centre of the figure is a double, two-way switch, whose two arms are linked together (by insulating material) so that they may be operated together by one lever between them. This lever also carries a junction piece, whose function it is to connect the two central contact pieces with one another when the switch arms proper are not in contact with any of the studs. C is the resistance whose duty it is to absorb the superfluous voltage when only one lamp is burning, and it has to be thrown in circuit with either lamp alternately to take the place of the one which is not in action. The two uppermost contacts are connected with the positive and negative leads respectively.

When the switch is in the position B, as shown in the sketch, the right-hand lantern only is in action. The current enters by the positive lead, passes the stud of the switch, where there is nothing to interfere with it, and enters the lamp at the positive terminal. Leaving it again at the other it flows through the right-hand arm of the switch into the resistance, which, by the way, must be adjusted to exactly the same resistivity as one lamp. Thence it passes through the other arm of the switch to the negative lead, not

entering the lamp A at all, for there there is no return path for it. On the other hand, when the switch is in the opposite position, the lamp B is thrown out of circuit, and the current passes first through the resistance and then through lamp A.

But between these extremes there is a central position for the switch, when the two arms connected with the resistance have no contacts to rest upon, but the two central studs are in connexion with one another. In this case the current will flow first through lamp B, and then, without entering the resistance, through lamp A; and the two lamps will then be burning in series. The small auxiliary resistance, R, is to control the amount of current consumed when the two lamps are running together.

The method of working scarcely needs any explanation. We will suppose lantern B is in action, the switch being in the position shown. Slide No. 2 is ready in lantern A, whose lens is covered with the fan of the dissolving device. A short time before the change is required the lever is shifted over to the central position, and lantern A lights up without interfering in any way with its neighbour. By the way, the switch should, of course, be fitted with some spring movement to give the usual "quick make and break" action, or the operator will have to be very dexterous to avoid half contacts. Now, the lamp in A lantern having settled down quietly to its work, the dissolving fan can be shifted across, and the "effect" accomplished, after which the switch lever may be pushed to position A, and lamp B goes out.

But, as I have said, this arrangement has its very decided disadvantages to be placed beside its one good quality—an important one, that of economy—and, if reference be made to fig. 2, the alternative

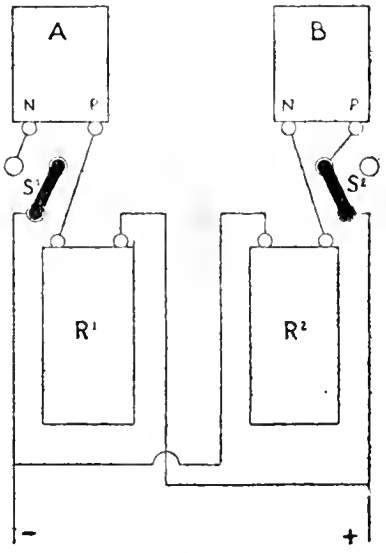

Fig. 2.

method, the *parallel* arrangement as it may be called, will be found set forth in diagrammatic form. The method is so simple that it will not take long to describe it. Each lantern is absolutely independent of the other; each has its separate switch and separate resistance, and each is connected entirely separately with the leads. In this diagram, as in the previous one, lantern B only is in action. Immediately before dissolving—for, as hand-fed lamps can be employed, no time need be allowed for settling down—switch A is turned on, and lamp A lighted up. Then the change of picture is made, and lamp B switched off. It may be preferable, when hand-fed lamps are used, to have each one fitted with an automatic arc-striking device, so that they light up spontaneously directly they are switched on; but in my own practice I do not find this at all necessary. After dissolving, I switch out the lamp which is not required, and immediately turn the switch on again. The lamp, of course, does not relight. When the time comes for dissolving again, a touch of the handle—my lamps are fitted with a "quick striking" device—suffices to re-establish the light, and my hand is ready on the feeding handle, to adjust the length of the arc, if it does not immediately begin to burn satisfactorily.

This system is as simple as it well can be, but it has the disadvantage of not being economical on a 100 volt circuit. It necessitates leads and fuses of sufficient capacity to supply enough current for two lamps, for, though they will only be running simultaneously for a short part of the time, the electrical arrangements must be made as if they were burning together for the whole evening. It remains for the operator to weigh the advantages and disadvantages of the two systems against one another, and to decide upon that whose merits are the greater.

CECIL M. HEPWORTH.

NOTES ON RADIOGRAPHY.

No scientific advance of modern times has called forth such a voluminous torrent of literature, within such a short time of its discovery, as has the Röntgen radiation. The radiographic results produced to-day are a great improvement on those of a few months ago, and many technical advances have been made; nevertheless, we are as far as ever from a solution of the mystery as to what the X rays are, and how they are produced. The number of theories put forward to account for the various phenomena exhibited is growing daily; indeed, they are becoming so bewildering, that to argue the *pros* and *cons.* of each, even in the light of our, at present, limited knowledge, would occupy considerable space. Collective investigation has never been productive of good results, inasmuch as the inferences drawn from the various experiments are in many instances incorrect and misleading; and, even when the results of experiments alone are recorded, they in most cases, have to be repeated before they can be accepted as proven. Not for one moment should the publication of carefully observed facts be discouraged; on the other hand, every inducement should be held out to those workers who are willing to give away the results of their labours. At the same time, no chance should be lost of impressing the willing ones with the necessity of recording the facts as they occur without adding one jot, for the sake of giving verisimilitude to an otherwise bald and uninteresting fact. There can be little doubt that many of the facts (published as such) relating to radiography are not what they appear. I would not for one moment suggest that misstatements have been purposely made with the intention of misleading, but I cannot help thinking that in many instances the wish was father of the fact, and that insufficient care was taken in making records. To those workers who are devoting most of their time to the investigation of this interesting discovery it matters little what statements are made, as they are in a position to pick the wheat from the chaff; but to beginners erroneous statements are a source of great trouble. Only recently I received a letter from a beginner who is in great trouble because he cannot obtain satisfactory negatives of the hand with an exposure of ten seconds. He is using a "focus tube," a coil which gives a continuous four-inch spark, and a very rapid plate, as he had seen recommended in an article. On reading the article in question, I found that the writer stated that under similar conditions he had obtained a negative. What he should have said was that he obtained an image; to call it a negative unintentionally misleads many readers. That he obtained an outline of the hand, and perhaps an indistinct one of the bones, is undoubtedly a fact; but that it was a negative (in the generally accepted meaning of the term) is incorrect, as no amount of intensification or after-treatment would render it sufficiently dense for printing purposes. It is very easily demonstrated that an exposure short of that which is necessary to produce a good, dense deposit, in that portion of the plate which is covered only by the protecting envelopes, is incapable of yielding a negative. A slightly under or over-exposed plate can, of course, be intensified, and may yield a good result.

There are at least two methods of testing the actinic power of the rays, and of finding out the shortest exposure necessary to produce a negative with a given make of plate. The first is by using a Rayometer—an instrument formed of superimposed layers of thin metal, of diminishing size. This I described in the columns of a contemporary a few weeks back. The second method is carried out in the following manner: The outside protecting envelope (quarter-plate) is ruled across with lines a quarter of an inch apart. The covered plate is now placed in position under the tube, the distance between the two being carefully noted. A thick piece of sheet lead, with a straight edge, is now laid over the plate so as to protect all but the first quarter of an inch. This is exposed for, say, ten seconds, when the coil is stopped. The edge of the lead is now moved to the second line and again an exposure of ten seconds is given, and the process is repeated until the whole of the plate has been exposed, when the last quarter of an inch will have had only an exposure of ten seconds, whilst the first will have had 170. The plate should now be developed (if possible with a standard ferrous-oxalate developer) until the least-exposed portion has obtained some density. An examination of the negative will show which portion has been best exposed, granting, of course, that the rays from the tube were sufficiently powerful to produce the best result, in the length of time occupied by the full exposure. If it is thought that none of the exposures have been long enough, the experiment may be repeated, giving exposures of twenty seconds; a half-plate can be substituted; or another quarter-plate can be given an exposure of 170 seconds before the process is repeated. I have found this method exceedingly useful in helping me to form a judgment as to the working of my apparatus, and, if the standard ferrous-oxalate developer be used, together with a timed development, we have a ready means of determining the relative rapidities of the various brands of plates.

In my early experiments I had great difficulty in obtaining a negative from which I could print without some intensification or dodging. Now

however, by making a preliminary experiment in order to test the efficiency of my tube, I can obtain negative after negative from which I can produce excellent prints. I have, moreover, proved that the plate with the highest speed number is not necessarily the best for radiographic work, and that some of the specially prepared ones are far inferior to some of the older and less rapid brands. My best results have been procured upon a plate which is comparatively slow—one which requires from two to three minutes' exposure for a hand. I would most willingly tell my readers what brand I use, but I am of opinion that such advertisements are unfair to other makers, as undoubtedly the personal equation, to a great extent, is brought into play. I may say, however, it is one of the brands which I years ago found to yield the best negative in photo-micrographic work.

The most important subject to radiographers is that of tubes. There can be no two opinions that the so-called "focus tube" is a great improvement upon the older form. There is, however, plenty of room for improvement, and further experiment cannot fail to be productive of good results. The chief faults I have to find with the present tubes are, firstly, that they are too short, hence sparking over and brushing from the terminals is a common occurrence; secondly, that their shape renders them peculiarly liable to be pierced by sparks; and, lastly, that in many instances the platinum loops are too thin. The first difficulty is easily overcome by prolonging the end of the tube to such a length as to render sparking across impossible. This may be done by welding a glass tube into either end, the conducting wire being fixed inside this with some non-conducting material. I have tried this method with success. Under ordinary circumstances, the brushing from the end of the tube is a matter of little moment, but for surgical purposes it should be made impossible, for not only is it painful to the patient, but it is liable to make him jump, and thus to endanger the safety of your apparatus. I see no reason why all "focus tubes" should be made the same shape; and, further, as all those I have spoiled have been pierced by sparks at the angle formed at the junction of the portion which contains the cathode pole with the main bulb, I would suggest that the shape be altered. At this angle the edge of the concave cathode pole comes very near to the glass, and, as the angle appears to exert some resistance to the free passage of the spark over the tube, it might be done away with with advantage. I would suggest that the shape of an elongated egg would offer less resistance, and that the cathode pole need not then come so near the surface of the glass.

It must fall to the lot of very few amateurs to be able to experiment in the manufacture of tubes, hence our progress in this direction is not as rapid as it otherwise might be; nevertheless, there are many makers who would be willing to fall in with any practical suggestion. There is therefore no reason why such suggestions should not be brought forward. A more powerful tube would, at any rate, place increased facilities in the hands of the surgeon, as it would enable him to work at a greater distance from the photographic plate, and one of the chief difficulties in the way of obtaining satisfactory radiographs of the thicker parts of the body would be removed.

Whilst upon the question of tubes, I should like to inquire if experiments have been made with the object of finding the most suitable and best metal for use in the construction of the anode pole. That platinum answers well will undoubtedly be admitted, but there is no reason why some other metal should not be better. Has silver been tried? My experiments have proved that this metal is more opaque to the rays than platinum, hence it might answer better. Again, I would suggest that the metals uranium and tungsten should be tried. That we at present know very little of the conditions which enable us to obtain the best results from our tubes is obvious from the contradictory statements which have appeared in print. That temperature has some effect is certain, but to what degree is a matter for further observation. A few weeks ago I arrived at the conclusion that the height of the barometer had an effect, and I made several experiments in the hope of obtaining conclusive evidence. During this period, always using a spark of the same length, the tube sparked over some days, whilst on others it carried the twelve-inch spark with ease. My calculations, however, have been entirely upset, for, during a later period of ten days, with constant changes in pressure, it has not once sparked over. From these experiments I can only conclude that these variations in the working of the tube are due to some changes in the tube itself. I may say that the tube in question is not a new one, and that it has been in use for upwards of four months. It was originally intended to be used with a two or three-inch spark; it now carries a twelve-inch spark with ease. I have several times seen it stated that the fluorescence of a tube is no guide to its working power. In my experience this is incorrect, as I am invariably able to judge my exposure by noting the amount of fluorescence. The coil I am using has a mercury contact-breaker, which can be so adjusted that any number of breaks can be obtained at will. I at one time imagined that the intensity of the rays was in direct ratio with the number of breaks, and I spent much time in trying to devise an arrangement that would give more rapid breaks. I now find, however, that a certain but variable number of breaks yield the best results. The number varies considerably with the state of the tube, and I find that best suited by noting the amount of fluorescence. This I consider to be an observation of some importance, and shall hope to communicate some further particulars when I have continued my experiments.

The question of shortening the necessary exposure by radiography through the back of the plate whilst the front is in contact with a card coated with some fluorescent substance has been carefully gone into, and with fluor spar, which has been specially recommended, I fail to note any advantage. I have repeated the experiment many times, using a card which only covered half the plate, and I have failed to mark any difference between the two halves. In using the card above the plate there was a slight difference, but this was more than counteracted by the resistance the fluorescent substances offered to the passage of the rays. I find that tungstate of calcium is exceedingly opaque, and offers a resistance nearly equal to that offered by iodoform, which has been mentioned as being unusually resistive to the X rays.

The following experiment, although yielding a negative result, may open up a field of research which is new. I wanted to ascertain if the X rays would act in a similar manner to light, upon a plate which was exposed under the same circumstances under which the colour photographs of M. Lippmann are produced. For this purpose a plate was backed up with mercury, and several pieces of coloured glass were placed upon it. From my previously gained knowledge of the action of the X rays, I expected a negative result, nor was I disappointed. I may mention, however, that the plates were not specially prepared, so that the experiments were not tried under the best conditions. I failed to notice any difference in the amount of deposit in any instance, the various coloured glasses being of the same thickness; and, moreover, when the negative was again backed with mercury, there was no sign of colour. I, however, discovered that the necessary exposure was considerably reduced. I should like my radiographic readers to repeat this experiment and to publish their conclusions, as it seems to prove that mercury has the power of reflecting some of the rays, a phenomenon I have not observed with other metals.

I have made a lengthy series of experiments with the object of ascertaining the penetrability of various metals, but, owing to the extreme difficulty of obtaining the various metals in sheets of the same thickness, I have been seriously handicapped. Sheets have been chosen as nearly as possible of the same decimal gauge, and, although it has, so far, been impossible to obtain accurate measurements, they may be roughly placed in the following order.

List of metals, placed in order of the resistance they offer to the passage of the X rays: Aluminium, steel, zinc, tin, copper, nickel, brass, platinum, lead, and silver.

The brass in the above list is composed of copper, 63 per cent.; zinc, 37 per cent., with slight impurities, in all about ·03 per cent. The thickness of the sheets used was as near as possible 4 metal gauge, or ·012 decimal gauge.

The order in which the above list of metals is placed is only approximately correct, and it will be necessary to make accurate measurements before an absolutely correct list can be drawn up; it is, nevertheless, sufficiently near the mark for all practical purposes.

During the progress of my experiments upon metals, I have noted an interesting point which I have not seen mentioned. It is a well-recognised fact that variations in thickness can be radiographed, and it is quite possible (using great care) to obtain a mixed image of the two sides of a coin. But this is not all; for, if a sheet of metal be dented, even so slightly as not to render one part thinner than another, this indentation can be pictured. If a radiograph be taken through the metal covering from the top of a bottle of pyrogallic acid, for instance, the lettering and trade mark will stand out as plainly as if it were photographed in the ordinary way, with a camera and lens. I at first thought that this phenomenon was due to the fact that, in the process of pressing up the image, the metal was considerably thinned in certain parts. I disproved this theory in the following way. A small piece of thin foil (a mixture of tin and lead) was pressed down upon a medal with the ball of the thumb, not sufficient force being exerted to stretch and thin the metal. I succeeded in radiographing the raised image with ease, and, on carrying out this method, with care, I find I can obtain an image of any medal I may desire to copy. I then came to the conclusion that the production of the image was due to the varying distances of the surface of the pressed metal, from the photographic plate. This theory I still hold, although it is just possible that the phenomenon may be due to an entirely different cause, viz., to some special property exhibited by the X rays in passing through curved substances.

To try and ascertain the truth of the matter, I took two small pieces of sheet lead, about one-fortieth of an inch in thickness. These I lightly pressed upon a brass ring, so as to slightly raise a ring on each piece. I now placed both pieces upon a covered plate. One I placed with the raised ring towards the plate, the other with the raised surface towards the tube. On examination of the negative I failed to find any difference between the two images, and, had they not been marked, I could not have told one from the other, although in both instances the rings were perfectly distinct. This experiment would tend to prove that the last theory mentioned is the correct one.

When radiographing through a number of substances upon one plate, unless great care be taken in making notes, there is always a chance that one may be mistaken for another unless they are marked immediately. This difficulty is, however, easily overcome by marking at the same time as the radiograph is produced. The method I have adopted answers so well that I can safely recommend it to others. Having arranged my

substances to my satisfaction, I then take a strip of thin sheet lead or copper, and cut from it smaller strips, which I arrange under the objects so as to form Roman numerals. These, of course, photograph, and there is no chance of making a mistake. I adopt the same method also in numbering my negatives.

In radiographing the hands, feet, and various parts of the body, it is frequently a matter of some importance that accurate measurements should be recorded at the time of producing the negative. To facilitate this, I have devised the following apparatus, which answers its purpose very well. A square wooden frame is made, round the edges of which small sprigs are driven in at a distance of an inch apart. Thin brass wire is now stretched across from side to side and from end to end, so as to divide the whole surface into inch squares. This frame, which should be considerably larger than the plate it is your intention to use, is placed over the covered plate so that the wire is close to the envelopes. If the hand be placed over this, the resulting negative will plainly show the squares, and accurate measurements can be made at a glance.

From a surgical point of view, radiography is fast gaining ground, and in many instances it bids fair to surplant the older methods of diagnosis.

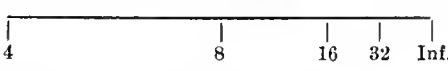
The chief difficulty which at present lies in the path of the surgical radiographer is that of not being able to properly interpret the results when obtained. This, however, will be overcome in time. An extended investigation with the object of ascertaining the varying appearances of radiographs of pathological specimens, the exact diagnosis of which has been confirmed, cannot fail to add to our knowledge, and will render us better able to judge of the condition of things in the living body.

Having already occupied much of your valuable space, I will conclude with the hope that these hurriedly written and disjointed notes may prove of use to some of your readers.

HALL-EDWARDS, L.R.C.P., F.R.P.S.

FOCUSSING SCALE FOR HAND CAMERAS.

IN the *Photographic News* the following rule is given for the construction of a focussing scale for hand cameras: "Focus a low-lying cloud or other object on the horizon, and make a mark to show the extension of camera. Now focus on an object 4 ft. distant, and mark the extension of camera. Exactly midway between these two points will be the extension for 8 ft., midway between the 8 and infinity



marks will be the distance for 16 ft. The intermediate distances can be found in exactly the same way."

This is certainly very simple, but unfortunately the extension for 8 ft. will not he "exactly midway between these two points," neither will the intermediate distances be correct if determined in the same way.

If, for example, we take a 7-in. focus lens and proceed by the above rule, we shall obtain a scale like this:—

The point marked 4 will be 1·195 in. from the inf. mark, therefore, the 8 mark will be ·5975 from it; but the focus of a 7 in. lens, for an object distant 8 ft., is 7·5506; consequently, the 8 point, as determined by the above rule, is about $\frac{1}{20}$ in. too far from the inf. end of the scale. If examined, the other points will also be found to be improperly placed, because, if these posterior foci are in a geometrical progression, their conjugates will not be so.

To correct the above rule.—Instead of writing 8 at the $\frac{1}{2}$ mark, put 8 *minus* focus; instead of 16 at the $\frac{1}{4}$ mark, put 16 *minus* 3 foci; and, instead of 32, put 22 *minus* 7 foci, and so on.

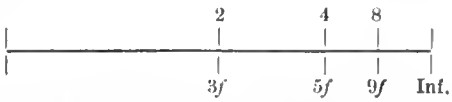
The number of foci to be deducted may be easily determined, because they are always unity added to double of the preceding figure; thus, 1 *plus* twice 3 = 7; 1 *plus* twice 7 = 15; 1 *plus* twice 15 = 31, &c.

The corrected scale for the 7-in. focus lens will be, therefore,

instead of	8 ft.	put	8 ft.	*minus*	7 in.	=	7½ ft.
„	16 „	„	16 „	„	21 „	=	14 „
„	32 „	„	32 „	„	49 „	=	28 „
„	64 „	„	64 „	„	105 „	=	55 „

Another accurate and more simple rule, which only requires the focal length of the lens to be known, is as follows:—

Lay off the focal length of the lens from the focal point (inf. mark), thus—



Then halve and quarter it, &c., as before, writing over the divisions, 2 for the half, 4 for the quarter, 8 for the eighth, and so on. Below these write a figure which is one more than the one above it; thus, under the 2 write 3, under the 4 write 5, and so on. Then the focal length of the lens (in inches), when multiplied by these lower figures, will denote the respective conjugate foci in inches.

Example.—Construct a focussing scale for a hand camera, the focus of its lens being 5 in.

As in practice, the marks at 2 and 4 will hardly be required; we may begin by laying off at once the $\frac{1}{8}$ of the focal length for the 8 point, and halve it for the 16 point, and so on. Thus—

Distance from Inf.			Number.	Conjugate focus.		
$\frac{5}{8}$	=	$\frac{1}{8}$ of focus	8	9f	=	3¾ ft.
$\frac{5}{16}$	=	$\frac{1}{2}$ the preceding	16	17f	=	7 „
$\frac{5}{32}$	=	$\frac{1}{2}$ „	32	33f	=	14 „
$\frac{5}{64}$	=	$\frac{1}{2}$ „	64	65f	=	27 „
$\frac{5}{128}$	=	$\frac{1}{2}$ „	128	129f	=	54 „

EDWARD M. NELSON.

FLASHLIGHT PHOTOGRAPHY.*

[Australian Photographic Journal.]

THE framework having been made or purchased, a few words about the lamps may not be out of place. Although most of my pictures have been taken by means of penny pipes, I by no means undervalue the various flash lamps now upon the market. The pipes will give sufficient light for all ordinary purposes, their only drawback being the extra trouble necessary in preparing them for work. The chief point in their favour is their cheapness, so that, if one has a desire to "try his hand on" flash-light work, he has a very inexpensive mode of procedure. Should he succeed, he can then "launch out" as extensively as he pleases. Latterly, I have had some simple lamps of my own design made by a tinsmith which work with less trouble, although the results are no better than before. Each experimenter must choose for himself the lamps which give the best results in his hands.

I will suppose the reader desires to "take a flashlight." Having chosen a good brand of instantaneous plates, it will be necessary to "back" the same before use, otherwise every highly polished piece of furniture, mirror, glass, or white article in the room, will most certainly cause halation and ruin the photograph as a picture. I have used several methods, but for simplicity I think nothing beats the following: Expose sensitised paper—P.O.P. preferred, although albumen will do—to daylight until very dark. Do this in the shade, or it will bronze and cause a reflecting surface. Over-exposed prints might be treated thus and saved for the purpose; cut paper to size of plate and wash for ten minutes to remove all free silver. Partially dry between blotting-paper, and dissolve a little fish glue or gelatine in warm water, just sufficient to make it tacky. Having sponged the surface of darkened paper with this, lay the plate face down on any dark smooth material before a dull ruby light, place paper in position, cover with blotting-paper, and squeeze the two surfaces into contact. Do not use too much moisture or it will run under the edge of the plate. Should the paper overlap, it may be easily removed by drawing the edge of a knife along that of the plate and pulling off surface paper. If the plates are to be exposed and developed the same evening, they may be placed in the slides at once, otherwise they must be thoroughly dried in a dark cupboard or chest before use. If used wet, the paper is easily peeled off before development; but the plate must be placed in water for a few minutes to soften backing if dry.

The next thing is to arrange your picture, and here a difficulty may arise. If in your own house, and you are the "white-headed boy," you may possibly do as you please and turn the room inside out, if necessary. If so, get rid of all the furniture not absolutely necessary to the proposed picture, or introduce other pieces from somewhere to make the surroundings more appropriate; but, when "flashlighting" in other people's homes, you may not feel so much at liberty to give the necessary trouble. However, by a little tact one can get his own way within reason. First

* Continued from BRITISH JOURNAL OF PHOTOGRAPHY, p. 584.

choose the spot for the camera. This, for an ordinary sitting room, will be in or near the corner from which the prettiest picture will be obtained. Then remove all large objects out of range, especially if they be in the foreground and likely to obstruct the view or throw deep shadows across the room. The less furniture the better. Having arranged this to your satisfaction, set up the camera so that it stands about four and a half feet from the floor. If higher, you will have too much wall and ceiling, and not enough floor space. Carefully level camera, and see that back and front are both perpendicular with the walls. A universal camera level placed on the baseboard will greatly assist in this matter. Any good R.R. wide angle lens will do provided it is suited to the size of plate used. My whole-plate flashlights are taken with a one-sixteenth inch wide-angle Voigtlander; the half-plates, with an ordinary Watson's half-plate R.R.

If possible, the camera should be set up, and focussing done by daylight, as it is rather difficult to do it at night. Failing this, get a friend or assistant to hold a lighted candle in several parts of the room at different distances from the camera; at the extreme edges of picture as seen on ground glass; in the centre of foreground, and at the extreme distance. The flame must be brought into sharp focus in all these spots, the lens being stopped down until this is so. Use as large a stop as possible consistent with sharp definition. The larger the stop the softer the picture, but too large a stop tends to flatness, fog, and fuzziness. Experience will soon enlighten one on this point. Have as much gaslight as possible, both while focussing and during exposure, so that the flash will not startle the setters so much as when it takes place in a darkened room.

Having arranged the camera, &c., the lamps next claim attention. Erect the framework and connect up the lamps with tubing as directed in last article. Its position should be from ten to twelve feet to the right or left of the camera, but not right in the corner of the room. This will not occupy many minutes, as the lamps, having once been affixed to the arms, will always remain in position. The lower arm (with the two lamps) should extend towards the camera, the upper (with three lamps) extended nearly parallel with the side wall, slightly tending toward the same. The object is to throw a good *side* light with a weaker one from the front. This will prevent harshness and give roundness to the figures. Should commercial lamps be used, full directions for charging them will accompany their purchase. CHAS. GRUNCELL.

ACETYLENE.

AT the last ordinary meeting of the South London Photographic Society, held at Hanover Hall, Hanover-park, Peckham, Mr. W. F. Slater (Vice-President) in the chair, Mr. C. Hoddle attended, and gave a demonstration of the uses of

ACETYLENE GAS.

He said calcium carbide (Ca C^2) was a very hard, greyish substance showing a purplish lustre when freshly broken. It was composed of common lime and carbon in any form such as hard or soft coal, coal dust, or coke, fused in an electric furnace at a temperatnre of between 4000 to 5000 degrees for about eight hours. The carbide so produced had only to be brought into contact with water, when a double decomposition took place, the oxygen of the water combining with the calcium forming white lime which is left as a residue, and the hydrogen of the water combining with the carbon forming acetylene. Acetylene is a rich hydrocarbon gas (C^2H^2), its component parts being 92½ carbon, and 7½ hydrogen in 100. "In my first experiments I used Bray's 000 burners, which were fairly satisfactory, but later on I succeeded in getting 0000 and 00000 burners. Bray's are now making a special burner for use with acetylene, but I do not consider them perfect, as there is always a deposit of black carbon on the nipple when it has been in use a little time, but that can be cleaned off with a pin or penknife, or, better still, a rather hard tooth brush." The demonstrator then charged up a generator specially designed for use with the optical lantern, and explained, in detail, the various steps for the production of the gas, and the essentials for obtaining a good, steady light. The uses of the gas for portraiture and other photographic processes were also explained, and in conclusion the demonstrator stated that, in his opinion, acetylene would eventually supersede gas and electricity for lighting purposes. Samples of Gem lantern plates and Argura paper were distributed.

KINETOSCOPIC PROJECTING APPARATUS: MR. G. RICHARDS' IMPROVEMENTS.

THE patentee states that his invention relates to a machine for enlarging and projecting small pictures on to a screen. The machine is used to enlarge that class of pictures taken on what are known as films, on which a large number of small pictures are taken consecutively of an object generally while in motion. As a rule, about 450 of these pictures are taken of an object, thus forming a picture in its complete shape. "The object of my invention is particularly to obtain extreme accuracy of register and movement of the film, so that the pictures projected on the screen and enlarged generally about one hundred times will not present the unsteadiness which is now usual in this class of machine. It further relates to the movement of the films by improved mechanical methods. It also relates to means of dealing, or moving, or handling the films to advance and stop them at stated periods of time in such manner that there are no strains brought to bear on the films, to elongate them or distort them or destroy them, or in any way to cause the wear and tear of the films which is now common in these machines. In order to assist in the care of the film and to reduce the wear and tear of it, my invention relates to an improved form of spool for carrying and protecting the film both before being shown and after it has passed through the machine. The film or a number of films are wound on to a spool having side plates of sufficient diameter to suit twelve films each fifty feet long. The side plates of the spool are loose, to revolve independently from the spool. When the spool is placed in position on the machine, the side plates are held from rotating, by which means the film has only to revolve the light spool. My invention also relates to the arrangement of the frictional device for moving the spool to carry the film so as to combine the motions of unwinding and winding of the films as they pass through the machine."

After describing and illustrating the mechanism, Mr. Richards claims:

In machines for enlarging and projecting small pictures on to a screen:—

1. The employment of two wheels or rollers over which passes a film bearing a series of pictures, and between which rollers the film is brought opposite a lens, such wheels or rollers being driven by a gear wheel common to both.

2. Mounting one of the wheels or rollers referred to in the preceding claim upon an adjustable arm pivoted on the centre of the wheel by means of which both wheels or rollers are driven.

3. The combination with the arrangement set forth in Claim 1 of a "drunken worm" for actuating the gear wheel which drives the two wheels or rollers over which the film passes.

4. The employment of a friction device for driving the spool on which the film carrying the pictures is rewound.

5. Making the body of the spools separate from the sides, and mounting the latter on the body so that the body can turn independently of the sides, in combination with means for locking such sides when the spools are mounted on their spindles.

ANIMATED PHOTOGRAPHS IN NEW YORK.

THE public interest in the Vitascope and Cinematograph Exhibitions, alluded to in our August issue, shows no signs of abatement. A recent visit to the New York theatres, where these instruments are in operation, reveals the fact that the exhibition of motion on the screen is the most appreciated part of the whole performance. "The theatres are packed at the time announced for the exhibition," says *Anthony's Bulletin* "and it looks as if the interest would be maintained throughout the whole of the coming theatrical season. The great advantage, of course, lies in the possibility of varying the programme from week to week and illustrating events that are occupying public attention. The troubles arising from vibration in the camera have been overcome, and all that now remains is for more careful attention to be given to the development of the positive films. A little filling up of transparent spots would be beneficial. But this successful portrayal of motion on the lantern screen is an immense advance, calculated to stimulate inventive genius, and to have no little effect on the future of photography. The vitascope creates a demand for a perfect rollable film, and a demand that will have to be met with an article beyond reproach. The amateur photographer, who made the vitascope possible, will thus benefit by it. In the future, instead of a photograph with a frozen and fixed expression, such as are the vogue today, a band of pictures some 150 feet long, on an extremely thin flexible film, will be presented to us by the photographer. This will be placed in our table kinetoscope, and a picture showing some life and expression will be at our command. A stereoscopic table instrument for viewing objects in motion would be a success."

EXPLOSIVE PROPERTIES OF ACETYLENE.

A PAPER on the *Limiting Explosive Proportions of Acetylene and the Detection and Measurement of the Gas in the Air* was read at the British Association by Professor F. Clowes. The detection of small proportions of the gas would not, he said, be readily effected by its smell when prepared in a state of purity, and the smell would not in any case furnish a means of measuring the proportion present in the air. The method applied by him to the detection and measurement of fire damp and coal gas in the air, however, served for detecting and measuring acetylene as well. A small hydrogen flame showed a pale but well-defined "cap" in air containing any proportion of acetylene less than the lowest explosive proportion. When the hydrogen flame was exposed to the air to be tested for acetylene in a darkened space, it was at once tinged yellowish-green. In determining the limits of explosibility, acetylene was mixed in gradually increasing proportion with air and kindled. Air must contain at least three per cent. of acetylene before it could be kindled by flame and the mixture caused to burn throughout. As the proportion of acetylene

was increased the explosive character was augmented. When twenty-two per cent. of acetylene was present, carbon began to separate during the burning. The amount of carbon which separated increased until the explosive character of the mixture disappeared; this point was reached when eighty-two per cent. of acetylene was present in the air.

SNAP-SHOTS AT LIGHTNING.

THERE is just a chance in 25,000 that you will be killed by lightning this summer.

These figures are based on carefully collected statistics, but it need not disturb your coolness during the next thunderstorm to contemplate them. Although the season has already been marked with several notable and tragic accidents, and the prospects are that this year's lightning fatalities will number more than usual, you are in far more danger from trolley cars, and other engines of violent death, than you are of being struck by a bolt from the heavens.

The United States Government keeps tab on lightning as well as on many other things, and it has been ascertained that the average number of people killed in this country by lightning every year is 200. Some other interesting facts have been collected by the weather bureau. In eight years 3519 fires have occurred which were attributed to lightning, and the damage to property was something like $13,000,000. The records show that barns are more often struck than houses, and that houses suffer more than churches. The records also show that more barns were struck in New York than in any other State in the Union. Pennsylvania comes next, and Michigan third.

Many old ideas about lightning have been discarded of late years, since scientific observations have been made of the results of lightning strokes. One old saw that has gone over the board is the familiar one that "lightning never strikes twice in the same place." Lightning not only strikes twice, but many times in the same identical spot, and is the usual, rather than the unusual, thing for two or more strokes to follow the same course during a storm.

The scientific sharps of the weather bureau also tell us that there is no use trying to dodge lightning, and that the time-honoured precautions which our grandmothers solemnly advised us to observe are entirely useless. They say that it is a popular delusion that it is unsafe to stand under a tree, or in an open doorway during a thunderstorm, and they absolutely sneer at the feather-bed and the middle-of-the-room idea. They must be in league with the dreaded lightning-rod agents, however, for they declare that those almost abandoned devices are very useful, and should be placed on all exposed buildings.

Only a few weeks ago one of the most notable tragedies of the season occurred in the upper part of New York. A young couple had taken refuge from the rain under a tree. They were lovers who had quarrelled, and had but a few hours before kissed and made up. A lightning stroke sought them out, and both were killed. Senator Tillman's daughter and a minister who accompanied her were killed in much the same manner only a couple of weeks ago. They were members of a party of excursionists who ascended a mountain near Asheville, N.C., and they stopped under a tree to avoid a wetting from a passing shower. Both were killed by a single stroke.

Another popular idea concerning lightning that has been proved false is in regard to the shape of its course. Until a few years ago every one believed that the path of a lightning bolt was an irregular zigzag, with sharp angles where the bolt took a notion to alter its direction. In all old pictures, where lightning was depicted, a zigzag streak of white was used. For centuries artists stuck to this method, and no fault was found with it.

But photography has shown that there are no angles in the course of a lightning flash. There are curves, but no sharp corners. It is not an easy task to take a snap-shot of a thunderbolt, as you may imagine, but within the last ten years it has been done frequently.

Professor McAdee, of the weather bureau at Washington, is probably the most expert photographer of lightning in the world. For the last two years he has devoted a good deal of time to the work, and he welcomes a thunder shower as enthusiastically as a small boys does a circus. He is well situated for the work, for the Washington monument is sure to draw out an angry flash every time an electrically charged cloud passes over it. Professor McAdee has three cameras trained on the top of the monument every night during the summer, and, whenever there is a thunderstorm, he and his assistants get snap-shots of the bolts.

Were it not for the fact that the shaft is protected by a most elaborate system of lightning rods, it would probably have been shattered long ago. There are four copper conductors, with gold-plated and aluminium-tipped points running from the tip of the monument into a well under the foundations, 600 feet below the capstone.

Professor McAdee has invented appliances for anticipating lightning, and has even made calculations as to the dimensions, horse power, and direction of the stroke. Still, there are many things about lightning which are understood no better than 100 years ago. These are put down as freaks, and the scientific men are puzzling their heads to solve their meaning. They know that lightning always follows the path of least resistance, yet they cannot explain some of its antics.

For instance, at Wooster, O., a two-story bay window was cut away from the main structure of a house as if by a giant's knife. At Norwich, Conn., in 1892, a bolt went into the earth, and jerked out 100 feet of iron water pipe. There have been several instances where bolts have played havoc with gas pipes, melting the iron pipes and igniting the gas.

There is an instance on record of the killing of a man by a lightning stroke where the reason for the course of the bolt was afterwards discovered. The unfortunate victim was sitting in the centre of a large room with all the windows and doors closed, but the bolt came through two upper stories, struck him down, and went through the floor under his chair into the cellar. Upon investigation, it was found that in the attic, hanging from a rafter, and pointing directly toward the man in the chair, had been a saw, while below the man, in the cellar, was an iron crowbar. This unfortunate man simply formed a link in a broken conductor. Upon such incidents as these, story-writers found tales in which the assassin's knife is knocked from his hand, and he is stricken dead by a providential bolt from heaven. Such incidents may have occurred, but there is not one well-authenticated case on record. Still, the lightning stroke is a great help to writers of fiction in disposing of heavy villains.

Lightning is as erratic in its results as in its course. Sometimes it scars, again it shatters. Men have been struck by bolts which have stripped their clothing into rags, melted watches and coins in their pockets, and pulled the nails from their shoes, yet left them but little injured. In other cases persons have been instantly killed, and the bolt has left no sign of its fatal visit, save a small bluish spot on some part of the body. Again, the bodies of victims have been marked in a most curious manner.

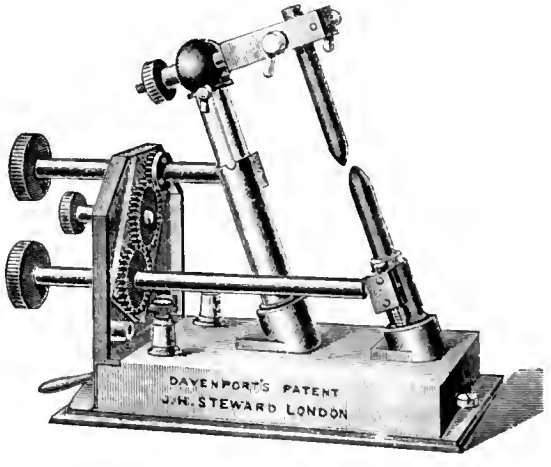
Persons are not always "stricken down," as the much-used phrase has it. They are sometimes lifted up by lightning. An instance of this sort happened in Missouri last summer. Two children were struck in a group of several persons composing a picnic party. The children were lifted three or four feet into the air, and fell back dead. This is explained by the fact that the discharge is sometimes from the earth towards the clouds.

It is also known that a bolt does not always reach the earth, but sometimes returns to the clouds from whence it came. A photograph was taken by an enthusiastic amateur in Michigan of such a return stroke. In the course of another decade, perhaps the scientists who are now making a study of lightning will have discovered all about its wonderful force, and will be able to explain the reason for all the freaks which it now plays on wondering humanity.—CYRUS SYLVESTER, in *Brooklyn Times*.

STEWARD'S IMPROVED ELECTRIC ARC LAMP.

J. H. Steward, 406, Strand.

AN improved model of Davenport's patent arc lamp has been made by Mr. J. H. Steward, of 406, Strand, London, and recently placed upon the market. It has been designed by the inventor to cover all possible uses for projection purposes, and will safely take the stronger



current necessary for high-power illumination. The size of carbons can be either 8 × 10 mm. or 10 × 12 mm., and the method of feeding them by geared wheels is such that they can be made to approach each other at the proper ratio, or, on slightly drawing out the central rod, each carbon can be moved independently. All necessary adjustments are provided to the carbons, and to the base, for perfect centering. The lamp, or regulator, is strongly made, and aluminium is employed for the back and base, to reduce the weight. We understand the Lantern Society use one for the latter part of last session, and the report on its working was most satisfactory.

BUTCHER'S IMPROVEMENTS IN OPTICAL LANTERNS.

Messrs. Butcher, of Blackheath, have patented an improved form of lantern, made entirely of metal, supported on a metal stand that will hold the apparatus firmly on to any beam, joist, tie, chair back, ladder, or any object usually found in rooms used for entertainments, and that will yet allow the light to be thrown in any direction, either upwards, as from a floor to a stage, or downwards, as from a roof to the stage, also from right to left.

The body of the lantern consists of a cylinder of Russian iron, or other suitable metal, of sufficient diameter inside to take the lens to be used. It is long enough to accommodate the jet at the back of the lens. A slot is cut through half the diameter to allow the tinters to slide in front of the lens.

The lens is held in position by a flange inside the cylinder about two inches from the front, against which the back of the lens rests. It is secured by a projection at the bottom, and by a screw passing through the top.

Inside the cylinder or body at the bottom two strips of metal are riveted, to form grooves that will hold the tray firmly that carries the jet. On both sides of the body is a projecting screw fitted with a milled nut, for clamping the body at any angle to the stand.

The stand consists of a metal fork with two prongs upwards. Through the end of each prong is a hole, into which the above two projecting screws fit. The lower end of the fork fits into a tube or socket that is attached to a strong cramp by means of a movable elbow joint clamped by a thump screw. A screw is provided at the top of the tube or socket that will either fit the fork or allow it to revolve freely.

The features claimed in the invention are as follows:—A limelight box made entirely of metal; its cylindrical form; the use of a metal stand as described, for limelight boxes or optical lanterns; for either one or more parts, or for the apparatus used as a whole.

LANTERN NIGHTS AT THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

Slides will be exhibited during the continuance of the Exhibition as follows (the displays commence at 7.45 p.m.):—

Saturday, October 3, slides sent in by Mr. John Gray, *A Photographic Ollapodrida.*

Monday, October 5, slides sent in by Mr. Harold Baker, *Warwickshire Towers and Towns.*

Wednesday, October 7, slides sent in by Mr. Edgar G. Lee, *North Country Scenery.*

Saturday, October 10, slides sent in by Mr. W. D. Welford, *The Hand Camera as a Pictorial Recorder of Holidays.*

Monday, October 12, slides sent in by Mr. Eric Bruce, M.A., a Demonstration of the Aerial Graphoscope, showing Lantern Views in Space.

Wednesday, October 14, slides sent in by Mr. E. Dockree, *Odds and Ends.*

Saturday, October 17, slides sent in by Mr. John Carpenter, *Still Life*, and Mr. George Hankins, *Miscellaneous.*

Monday, October 19, slides sent in by Mr. R. B. Lodge, *Birds Photographed from Life, and Nests.*

Wednesday, October 21, slides sent in by Mr. J. H. Gear.

Saturday, October 24, slides sent in by Mr. Henry Sandland, J.P., *Animal Pictures.*

Monday, October 26, slides sent in by Mr. J. A. Hodges, *Through North Devon with a Camera.*

Wednesday, October 28, slides sent in by Mr. T. M. Brownrigg, *Here and There.*

Saturday, October 31, slides sent in by Mr. F. H. Evans, *Lincoln Cathedral* and *Woodland Pictures.*

Monday, November 2, slides sent in by Mr. G. E. Thompson, *Life in Tripoli.*

Wednesday, November 4, slides sent in by Members of the Photographic Convention of the United Kingdom.

Saturday, November 7, slides sent in by the Manchester Photographic Society.

Monday, November 9, slides sent in by Members of the Amateur Photographers' Field Club.

Wednesday, November 11, slides sent in by Captain W. de W. Abney, C.B., D.C.L., F.R.S. (President).

Leeds Camera Club.—An able and instructive lecture on *The Wet-collodion Process for Lantern Slides* was given by Mr. J. W. Carbutt before the members of the Leeds Camera Club on Wednesday, September 16. The simplicity and inexpensiveness of the process were fully demonstrated. A plate was coated and sensitised, and a slide afterwards produced by contact from a negative the lecturer had brought with him, the development and toning of the same being done during the lecture, the picture being afterwards thrown on the screen. The production of the different tones of slides was fully explained and illustrated on the screen, to show the action of the different chemicals used during the toning process. An interesting discussion took place, and much valuable information was vouchsafed to the inquirers. At the close a hearty vote of thanks was accorded to Mr. Carbutt. On Wednesday evening next, the Rev. J. Beanland will give his popular platino demonstration for beginners.

Catalogue of Magic Lanterns and Accessories.—The London Photographic Supply Company, of 63, Great Dover-street, send us their Lantern Catalogue. It consists of forty-four pages, and is devoted to describing single, double, and triple lanterns of great variety, dissolving lamps, jets, carriers, lantern-slide-making cameras, and numerous accessories required in optical projection work.

An illuminated bird's nest is to be met with in India. The baya bird of that country spends his spare time catching mammoth fire flies, which he fastens to the sides of his nest with moist clay. On a dark night a baya's nest is said to look like an electric street lamp.

Intensity of Daylight.—Mr. Wiesner has communicated to the Academy of the Sciences at Vienna a note on the comparative chemical intensity of daylight at Vienna, Buitenzorg (Java), and Cairo. His observations were made by the Bunsen-Roscoe method, in which the activity of the light is estimated by its power of causing the combination of hydrogen and chlorine. Mr. Wiesner finds that at Vienna the greatest chemical intensity of daylight is represented by 1500 Bunsen-Roscoe units, while in Java it was 1812 units. At Vienna the intensity at noon is on the average less than the maximum for the day in the ratio of 1 to 1·08, whilst in Java the corresponding figures are at 1 to 1·22. The annual range of light intensity at noon is, under similar conditions, 1 to 2·14 at Vienna, whilst in Java the range is only between 1 and 1·24. In both places the light is less intense in the afternoon than in the morning. At Cairo with a perfectly clear sky a considerable reduction in the photographic intensity occurs near noon, the maximum being never at that period of the day.

Royal Photographic Society's Exhibition.—Our readers should note that during the Exhibition there will be demonstrations of X-ray photography given daily at 3.30 p.m. The Birt Acres Kinematoscope will be shown every evening that the Exhibition is open, at 8.45 p.m. This instrument enables lantern pictures to be projected upon the screen with all the movement of life. Exhibitions of slides by means of the optical lantern will be given every Monday, Wednesday, and Saturday evening, at 7.45 p.m. The Exhibition opens to the public on Monday, September 28, and closes on Thursday, November 12.

Utility in Radiography of Screens of Phosphorescent Zinc Sulphide; the Emission by Glowworms of Rays traversing the Needle Paper.—"I substitute for the simple fluorescent screens of barium platino-cyanide, calcium tungstate, &c., a screen of my phosphorescent zinc sulphide," says Mr. Charles Henry, "covered with a leaf of 'needle paper,' and I lay on the paper the object to be radiographed. After some minutes' exposure to the radiation of the Crookes' tube I remove the screen into the dark chamber; the depressions of the objects, opaque to the X rays, appear black, and the transparent parts appear light. I can study the minutest details of the image for a quarter of an hour at least. On gently heating the screen with a source of dark heat, I can continue this examination longer. This method, which allows of a great economy of electric energy and of tubes, may be recommended for exhibitions, lectures, and all cases where it is not required to preserve the radiographic specimen. Phosphorescent zinc sulphide is incomparably more sensitive to the X rays than is calcium sulphide. If we expose for five minutes to one and the same radiation from the tube, a plate enamelled with calcium sulphide and a screen of zinc sulphide, the former scarcely shines, whilst the latter is near its luminous saturation. During the last evenings I have had occasion to place, during times varying from half an hour to several hours, some glowworms upon photographic plates wrapped up in needle paper; on developing, we could distinguish on the plate black-and-white tracts which reproduced exactly the course pursued by the subventral lanterns of these capricious animals."

From recent researches by Captain Abney, it appears that the light energy obtained from the sun is about 13,000,000 times as much as that obtained from the stars in both hemispheres, and that the moon gives about forty-four times as much light as the stars.

To Remove Red Spots from Plate Glass Slides.—These are due to the oxide of iron polishing powder, left adhering to the bottom of the deeper pits, made in grinding the glass surface, and which have not been removed in the polishing operation. Sometimes they are too numerous and conspicuous to be tolerated. A short rubbing with whiting and water will clean out the red matter more quickly than acid treatment. The pits will be left, but they will not be so noticeable as before, and, in case a mounting medium is used having nearly the same refractive power as the glass, they might escape observation.

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*November 6, 1896.*

THE LANTERN RECORD.

CONTENTS.

LANTERN MEMS.

The number of societies has been reduced by one, for the Lantern Society has ceased to exist. In many respects this is a pity, for it should have found a useful place in the optical lantern world. Its failure was due, first of all, to coming into existence too late, when so many photographic societies had already formed lantern sections; and, second, the subscription being set too high for a distinctly technical society, where research in connexion with it was very limited. It is easy to be wise after an event, but it would probably have served a more useful purpose as a school for operators, where members in rotation would have the opportunity of manipulating biunial or triple lanterns, as well as making demonstrations with special apparatus under competent guidance. One thing is certain that if attention and enthusiasm on the part of the Chairman and Executive counted for what it was worth, it should have succeeded as a Society.

* * * * *

The calls on the time of most men in the scientific world, such as literary men, opticians, &c., is such that they cannot possibly attend all the societies' meetings they would like to, or desire, even in order to keep *au courant*, and so it comes about that, unless some distinctly marked demonstration is to take place, they do not attend. In the case of the Lantern Society, it was thought that, if certain members would guarantee to introduce a new member annually, or be responsible for another subscription, it might give the necessary vitality for its continuance, but only a small number (I think) acquiesced, and therefore nothing remained but to wind up the affair, the apparatus being sold by auction.

* * * * *

This result brings forcibly home to one the thought, often expressed, that there are too many societies for practically the same purpose, and I should like to see an amalgamation of some of the societies at a really convenient meeting house in a central position. This would obviate the necessity of the same paper being read at several societies, or new apparatus being taken to, and described at, several places to a certain percentage of men three or four times over because they belong to a club and those societies as well.

* * * * *

That colour photography is creating some interest in the pages of this Journal the editorial and Correspondence columns show; and, in order that my "Mems." may be up to date as far as Mr. Bennetto's process goes, I wrote to him at Newquay, asking if he had anything to add to the information he gave me personally when there in September, and I have the following notes, which I have no doubt he will not object to my publishing, for, although they set matters in a clearer light than anything hitherto made known, they do not give details that will enable any one to anticipate the publication of his method.

* * * * *

He says: "Regarding your query, I do not know there is much more information I can give you, except that the method described by Mr. Ives, and communicated in The British Journal of Photography, does not in any way resemble my own. I worked the same thing out in 1891, and have written and told the Editor so. It is useless, the images (three) produced by the bichromate alone making quite a strong positive, and producing a monochrome effect upon the colours, destroying the colours and their truth to the original, besides which, the image cannot be perfectly sharp."

* * * * *

Regarding the colour transparencies that I saw in the optical lantern and projected on the screen with really beautiful effect, he adds: "The perfect pictures by my improved method are less in thickness than an ordinary positive film on a lantern plate, and will not be on glass at all, but supplied or produced as fine films." Mr. Bennetto has also designed and produced a suitable support and frame for using them in the lantern, so that the heat does not affect them. I feel sure all lanternists and photographers are looking forward to the time when Mr. Bennetto can either supply some of these films or grant concessions for making them.

* * * * *

I said to a lantern-slide artist the other day, when telling him of these results, that his occupation, like Othello's, would soon be gone. However, from the class of work that finds its way into slide-painters' hands, there is not much fear of this happening, for numbers of subjects are still required that cannot be taken from nature, and these would keep them well occupied, besides which there would be the preparation of dissolving views and effect slides.

* * * * *

It was only natural that Mr. G. A. Storey, A.R.A., should at his lecture at the Camera Club on *Colour* speak in favour of his art; and, as I understand, the paper was listened to with great interest by a large number of members, I trust that a fair percentage of them reciprocated the feelings of the lecturer when he said he considered "colour as necessary to a picture as gold was to a guinea." If they did, it will produce a good effect, I trust, and remove some of the prejudice often expressed—something to this effect, "I would not have a coloured photograph on any account; colouring simply spoils it."

* * * * *

Some kinds of colouring may spoil photographic transparencies, but I contend that, when a good photograph is artistically painted

by an artist who knows the colours in nature, very beautiful results are obtained, but the floating on of colour indiscriminately over buildings and everything else is not at all likely to bring about a pleasing, much less an artistic, result, and this must happen if the so-called colouring has to be done for a few pence each slide.

* * * * *

THE animated photographs are not in any way losing their popularity, but I am sorry to see, in some instances, a disposition to unduly enlarge the tiny photographic representations of life. It would be far better to have a smaller and brighter picture, with better definition, than a large area covered with an indifferently lighted picture, notwithstanding a powerful arc light is employed. Then, again, the love for novelty is such that photographic monstrosities are projected on the screen in some of the street scenes, because the point of view was unsuitable and the perspective abnormally rapid.

* * * * *

TAKEN altogether, the animated pictures are giving satisfaction, and are likely to be popular for some time to come. I learn of at least one large-size film apparatus having been made and successfully employed for taking photographs of historical events, and I trust, by the time the photographic weather comes next spring, several instruments of this type will be available for professional and amateur photographers' use. It would be interesting if some one would read a paper or describe the technique of developing and printing these long-film photographs, and the steps to be taken to obviate frilling or stripping of the transparent films used for projection.

* * * * *

ACETYLENE gas seems to be "under a cloud just now. It will be interesting to have all the facts in its favour and its drawbacks put in a convenient book form, or as notes for reference. At present lanternists who were interested in the light are nervous about it, and are asking for information. G. B. BAKER.

RADIOGRAPHY.

Now that the excessive exacerbescence of the X-ray excitement has waxed somewhat extenuated—excuse me—and the ordinary average man and even woman is able to look upon his or her own skeleton excarnate or rather upon its X-raygraph with equanimity, those photographers who have been waiting until the first mad rush was over may be glad of a few practical particulars as to how to set about the production of those curious photographs.

I call them photographs because that word conveys a more definite idea of their real character than do any of the multitudinous names, fancy and scientific, which have been proposed by their well-meaning godmothers all the world over, and, while the rays by which they are produced are certainly not light of the kind that we can appreciate, and very probably are not light of any kind, still no one has actually proved that they are not, and, as they behave to the sensitive photographic plate precisely as if they were, the result may be fairly called photography until a better name is forthcoming. Seeing is no longer believing, but photographing is, and upon the testimony of our plates we may call this strange radiation light until we know it isn't.

This peculiar invisible light, then, is produced by an electrical discharge *in vacuo*, but under certain conditions, for in the first place it is necessary to have an electrical stress or *potential*, as it is called of very high tension, and, secondly, the vacuum through which this electricity has to force its way, and thereby give birth to the X rays, must also be very high—that is to say, it must be a very nearly perfect vacuum. Potential is that quality of electricity which gives it the power to overcome obstacles tending to hinder its passage. Air at ordinary pressures is an obstacle which, if its potential is high enough, it overcomes by piercing its way through, disruptively as a flash of lightning does. A glass globe containing nothing but air, and having an electrode at either end in connexion with a source of high-tension electric energy, such as an induction coil, may be the scene of a miniature thunderstorm. If the air be gradually drawn out of the globe, the thin streaks of lightning will grow thicker, until, with quite a moderate degree of exhaustion, they will broaden out into a violet glow which will fill the whole globe. As the residue of air is still further drawn from the vessel, the character of the discharge will change, until, at a certain point when a very high degree of exhaustion is reached, the actual light of the discharge will disappear altogether and a peculiar invisible radiation from the cathode will take its place. What this radiation consists of, nobody knows, but it has the power of making the glass vessel fluoresce with a pale green light wherever the rays strike it. Professor Crookes was the first to study the phenomena of electric discharge in such high vacuo, and this effect of green fluorescence in the glass is called after him, and the high vacuum tubes are known as Crookes' tubes.

The cathode is the technical term for the negative electrode, that is to say, the electrode by which the electric fluid leaves the tube. In a Crookes' tube it takes the form of a plate of aluminium, and from this plate the Crookes' radiations, or cathode rays, proceed in all directions. They have the power of making several other substances besides glass brilliantly fluorescent, but these substances must be enclosed within the tube, for the cathode rays cannot pass through the glass. X rays are not the same as cathode rays, and they are not necessarily produced with them. It would seem that, in order to give rise to the X rays of Röntgen, a higher vacuum is necessary than that which is required to produce the Crookes' effect. Moreover, the Röntgen rays do not appear to proceed directly from the cathode, but to be generated at the point where the cathode rays strike the glass.

Since the publication of Professor Röntgen's great discovery there has been no such important step made as that of Mr. Herbert Jackson of King's College, who introduced what he called the "focus tube." Reasoning that cathode rays appeared to be propagated in greatest profusion at right angles to the cathode plate, and that the X rays seemed only to make their appearance where the cathode rays met with some obstruction, he designed a tube in which the aluminium cathode was concave, and at the centre of its curvature he placed a small platinum reflector at an angle of 45° to its axis. By this means the cathode rays appear to be brought to a focus on the small reflector—which often gets red-hot under their action—and from this point the X rays are propagated in the direction in which the mirror faces. With this tube photographs may be made with ease which far surpass anything which could be done with a tube of the older pattern, and this is not to be wondered at when it is considered that the rays proceed from something near a mathematical point within the tube, instead of from every portion of its surface.

The character of the electrical supply to the tube is of the greatest importance; as has already been said, it must have sufficient pressure or power to enable it to force its way across the space between the electrodes—a space which contains as nearly as possible absolutely nothing. As a matter of fact, tubes for the production of X rays are exhausted to about the one-millionth of an atmosphere; that is to say, they would, if opened to the air, contain one million times as much of that substance as they do when they leave the glass-worker's hands; in other words, a Crookes' tube—say three inches long—when ready for X ray work, only contains a mere handful of billions of air molecules instead of about a million times as many.

To sufficiently overcome the resistance of such a tube as this requires very high electro-motive force, but not much of it. Imagine a small water motor, which is very stiff in its bearings; all the water of the Thames would be unable to make that motor work; but take a gallon of the water to the top of the Monument, and lead it from there by a small tube to the motor below, and it will turn merrily for hours. It is small quantity at high pressure that it wants, and so with the Crookes' tube. If you had all the electricity of a big supply station at your disposal, you could not take a single "new photograph," but it is possible to transform a small quantity of that electricity and transform it from its low pressure to one several thousand times as high, and, although the quantity will thereby be proportionately reduced, still there will be plenty for the purpose.

The instrument by which the transformation is accomplished is called an induction coil, from the fact that the high-tension current is *induced* in a coil of wire by the passage of the low-tension current in another and quite separate coil, so the effect is really not a transformation at all. The instrument consists of a coil or helix of thick, insulated copper wire—usually in two or three layers—through which flows the primary current—in comparatively large quantity but at low pressure it will be remembered. Surrounding this as closely as possible is a second coil of very fine copper wire, also insulated, in which the secondary current is induced. The *quantity* of current induced in this secondary coil depends upon the thickness of the wire and the *quality* or pressure upon its length. As it is very high pressure, but small quantity, that is required in this case, several miles of exceedingly fine wire are used. Through the centre of the thick wire or primary coil a bundle of soft iron wires is laid, which serves two purposes; in the first place, the magnetism induced in it by the primary current is an important factor in the production of the secondary or high-tension electricity, and in the second it serves to actuate a contact-breaker; for the induction effect in the secondary wire is only produced at the moment when the current in the primary either starts or stops flowing, and therefore a vibrating contact-breaker, like that on an ordinary electric bell, is necessary to continually interrupt the passage of the current in the primary coil, that the induced current in the secondary may be more or less continuous. The more frequent these interruptions are the better, therefore, the vibrating armature of the contact-breaker should be short and of light weight.

The apparatus and materials for taking an X-ray photograph may be said to consist of four principal items: The sensitive plate; the high vacuum tube wherein are produced the X rays which effect the sensitive plate; the induction coil for producing the high-tension electric disturbance wherewith to excite that tube, and the source of low-tension electrical supply to the induction coil. It is this last—which in the natural order of things should be first—that I want to speak about more particularly.

There are three principal sources of electrical energy which are suit-

able for the purpose: A primary battery; a battery of secondary cells—storage cells or accumulators they are often called, though neither name is good; and the electric lighting supply, which is now to be had at so much a unit at a number of places. Let us take these in the order named.

There are a large number of primary batteries, but only one or two are suitable for this work. What is required is a battery giving an electromotive force of about ten volts, and having low internal resistance, so that a large current may be able to flow around the circuit. A battery of five Grove or Bunsen cells answers these requirements, but the former is very expensive on account of the platinum foil, which is an important factor in its construction, while both have the disadvantage of requiring to be charged with fuming nitric acid, which is always an unpleasant neighbour. The single fluid bichromate of potash cell is better in this respect, but it quickly becomes polarised, and cannot therefore be used for more than two or three minutes at a time. If primary batteries must be used, the choice lies practically between these two, Grove and Bunsen cells are so much alike that they may be counted as one. For ordinary laboratory work, where it is feasible to keep the battery in a well-ventilated cupboard of easy access—for the solutions must be emptied away, and the cells kept clean when not in use—a Bunsen battery will be found the best. On the other hand, where portability and freedom from smell are important considerations, the bichromate battery is the one for the purpose. Five or six cells will be sufficient—such a battery will give about ten or twelve volts—and they should be of large size, that they may not tire too quickly, and may last some time without requiring fresh solution. Remember, however, the size of the cell does not affect its strength; but a large cell has less internal resistance, so that it will allow more current to pass through, and it will, with a given current, last longer, and work for longer periods at a time without getting temporarily exhausted.

It is hardly necessary to say that the cells must be coupled up in series, the zinc terminal of one being joined to the carbon of the other, wires from the two outermost cells only being connected with the primary wire of the coil.

In the case of secondary cells or accumulators, it must be remembered that, when they have done a certain amount of work, they will require recharging with electricity from a dynamo or other source of supply. This is practically their only drawback, for, as regards ease and simplicity of working, they have no rival, for they are always ready to give off their supply of current just as it is required, at the mere turning of a switch. As far as portability is concerned, they are heavy certainly, but if a suitably light form of battery be chosen, not excessively so, and they take up very little space.

In using secondary cells great care should be exercised to prevent them becoming short-circuited even for a moment. The internal resistance of an accumulator is practically nothing, so if the wires should be allowed to come into contact with one another, there would be a great rush of current around the circuit, and the battery would be drained in a very few minutes Even if the contact were only momentary, it would probably do harm to the battery, for secondary cells should never be allowed to exceed the rate of discharge for which they are designed. In order to prevent an accidental short circuit injuring the cells, they should be provided with a "fuse," that is to say, a piece of tin or lead wire should be included in the circuit, which, though large enough to pass the required current, would immediately melt and break connexion should the amount become seriously increased. A piece of number twenty wire gauge, pure tin wire, will fuse at about eleven ampères, which is far more than would be required for a coil of ordinary size.

When ordering a secondary battery for, say, a four or six-inch coil, the specification should be somewhat in this wise: Four or five cells, of about twenty ampère hours capacity, capable of being discharged at six to eight ampères for short periods intermittently. The cells to be as small and light as possible consistent with the high rate of discharge. As regards capacity, the consumer must be guided entirely by circumstances. If he be so placed that recharging at frequent intervals can be easily accomplished, he may choose cells of small capacity and correspondingly great portability; but, if not, he must be content with a heavier outfit. He cannot do better than tell the battery-maker his requirements and be guided by his advice.

The question as to the third source of electric energy for radiography—the ordinary house-lighting supply—resolves itself into a consideration of a suitable and convenient means of connexion with the electric mains, and of the controlling of the current to render it suitable for the purpose. For the pressure of 100 volts—which is the usual potential led into private houses and public buildings—having practically no resistance behind it, would burn up the coil in no time, were it allowed to work its own sweet will unchecked. The way to check it is to place an extra resistance in circuit, for the resistance of the circuit itself, being, practically merely that of the coil, is quite insufficient. A resistance is something which the electricity experiences difficulty in passing, some of its energy being therefore converted into a different form, such as heat or light. German silver wire offers great resistance to the passage of electric currents, much of whose energy therefore becomes converted into heat. Carbon is another substance of similar property and I have found that carbon in the form of incandescent lamps makes the most convenient resistance for this work. A single twenty-five-candle-power lamp will allow about one ampère of current to pass when placed across a 100-volt circuit, but in doing so it will consume all its energy, which takes the form of light and heat; but, if the lamp be connected in series with the coil so that the current must pass first through one and then through the other, the energy will be divided between the two, and, the total resistance being nearly double that of the coil alone, only about half an ampère will pass. So, in order to get our five ampères through the coil, a bunch of ten of these lamps will be required, arranged in *parallel* with one another, but in *series* with the coil, as shown in the diagram (fig. 1). Thus the current will have ten different paths through the resistance, half an ampère going through each path, and uniting, about five ampères in all, to traverse the primary coil.

The beauty of this arrangement is that the amount of current is variable to any required extent, for any number of lamp-holders can be connected up in this way, and it suffices to merely insert or take one out to increase or decrease the current passing through the coil by about half an ampère. In practice I find it best to use four or five fifty-candle-power lamps, each being responsible for about one ampère, and one or two smaller lamps may be used to give the power of finer adjustment when necessary.

Fig. 2 shows a convenient arrangement for a lamp resistance which I have used for some time with considerable success. It consists of a mahogany board 5 × 8 inches, to which are attached eight standard lamp-holders, four on each side. Lamp-holders are made to fit ordinary gas brackets, &c, to which end they are screwed internally with either ⅜, ½, or ⅝-inch standard (gas) threads. Mine were of ½-inch gauge, and, in order to attach them to the board, I used short pieces of ½-inch brass tube, tapped to fit, and these, screwed for half their length into centre-bit holes in the wood, made good, firm connexions. Another, and perhaps better, plan is to use "bottom plate" lamp-holders, which can be screwed direct to the board by means of ordinary wood screws. Down the centre of the board, on the face, run two omnibus bars of copper or brass, and, from four different points on each, spring two wires which go to the two lamps on the right and left side respectively. The arrangement can be easily understood by reference to the sketch (fig. 2), in which the dotted lines represent the paths of the wires at the back of the board,

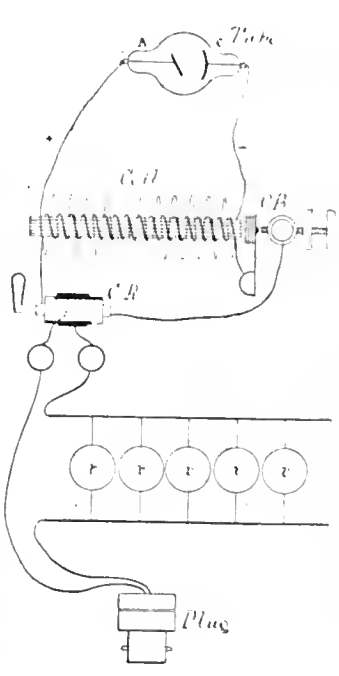


Fig. 1.

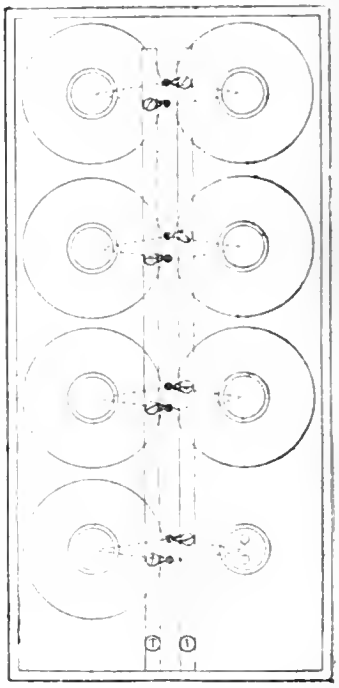

Fig. 2.

and from which it will be seen each lamp is fed independently of any other from the two omnibus bars. In other words, all lamps which are in the holders (in the sketch one is removed) are "in parallel" with one another, but the complete arrangement is connected "in series" with the coil, current reverser, &c., as shown in the connexion diagram (fig. 1).

A simple and convenient way of making electric connexion with the ordinary house mains is by means of a plug to fit the usual standard lamp-holder, when the lamp is removed. Such a plug can be procured from any large suppliers of electric-lighting accessories, and, when the wires to the coil, &c., are joined up, it is merely necessary to slip out the lamp from an adjacent bracket and insert the plug in its place. There is one point, however, which must be carefully attended to, and that is to see that the amount of current it is proposed to draw from the lamp-holder does not very seriously exceed the quantity which the fittings are required to carry. A single sixteen-candle-power lamp is only expected

to take about half an ampère, and, if from its fittings five ampères are taken, it is hardly surprising if a "fuse" gives out somewhere. As a rule, there is nothing to be feared from the wiring of such a fitting, for it is usually substantial enough to carry five ampères for the short, intermittent periods the current is required for coil work. Some fitting should be found, such as an electrolier, in which one fuse does duty for eight or nine lamps; it will then be quite safe to draw five ampères from one, provided the others are not burning at the same time.

In the connexion diagram (fig 1.) the two wires proceeding from the plug pass to c. r., the current reverser of the coil, one of them—it does not matter which—being broken, that the resistance *r r r r*, may be inserted. Thence one wire goes direct to one end of the primary coil, and the other to the screw pillar of the contact-breaker, c b, the vibrating armature of which is in connexion with the other end of the primary, or thick wire coil. Thus, the primary circuit is complete in itself, and the current is free to travel round it. The two ends of the secondary or thin wire coil are connected to the terminals of the Crookes' tube, thus making the other circuit—the secondary—also complete in itself.

There merely remains one word to say, and that is as regards the direction in which the secondary current flows through the tube, for the cathode must be connected with the negative terminal of the coil. If the current is flowing in the wrong direction, the glass of the tube appears to be covered with a kind of fern like pattern in green, fluorescent light, while the metal work inside will probably rattle ominously. When rightly connected up, the glass should glow equally with a steady green light, all over, except where the anode—the inclined mirror—casts a distinct "shadow" upon it. A very little experience will enable one to tell at a glance whether the current-reverser requires reversing or not.

CECIL M. HEPWORTH.

ON THE REDUCTION AND INTENSIFICATION OF LANTERN SLIDES.

I.

IT is generally admitted that an operator has much greater latitude in working and control over the production of lantern slides, by means of wet collodion or one or other of the dry-collodion methods, than by means of a gelatine lantern plate. No doubt, the reason for this generally accepted opinion lies in the fact that with wet collodion any one who possesses a thorough knowledge of this old but invaluable process can reduce and intensify, and so ring the changes on a collodion picture as to turn out almost any class of image from any kind of negative, and, once possessed of experience in collodion-working, an operator looks down upon a gelatine lantern slide with more or less scorn as an inferior production in every respect. I am far from saying that I hold such a poor opinion of gelatine slides so universally produced by means of a lantern dry plate. Nevertheless, once an operator becomes possessed of the numerous "Kens" attending the production of lantern slides by means of collodion, it is just about ten to one he will be animated more or less with the feeling of preference for the latter, for, no matter how beautiful a gelatine slide may appear in the hand, and very often such have a charming appearance by daylight, it cannot compare on the screen with a carefully executed sample of collodion work. This has been argued over and over again, there is a cut or crispness about a wet or dry-collodion slide that does not exist, nor, in fact is, capable of being produced by means of a gelatine emulsion, and which must ever yield the palm to collodion productions.

On the other hand, there is no doubt that very beautiful results are obtained by means of the modern lantern dry plate, and not the least inducement towards the employment of such for this work lies in the perfection to which dry-plate makers have brought this kind of plate, as well as the low price they are sold at to the public. "It's only a penny, so let us try and get a better result by another one," is a remark not only universally made day after day, but such is carried into execution, to the benefit of the dry-plate maker, and there are thousands of workers who never grudge exposing dozens of lantern plates in the hope of being able to get "one" good slide only from a negative. The preparation of a dozen wet-collodion plates would be a different matter; but, on the other hand, there is no doubt a much greater delight is experienced in the preparation of such plates than can ever be derived from opening a box of dry plates. It is in this preparation that the charm of working collodion lies, and which an enthusiastic worker looks upon with so much pride once he has become proficient in collodion work.

I have sometimes been shown results obtained on gelatine plates, and asked if better results could have been obtained by means of my pet process, so pleased have been the parties with the excellence of their productions. "Yes, if you try both on the screen," is invariably my reply. Then the one that looks the best in the hand will have the worst appearance on the screen.

That lantern dry plates have, however, taken a strong root among advanced amateur workers no one can deny, and, although there does not exist the same latitude when working with such on inferior negatives as lies with collodion, still there *is* more or less latitude that can be utilised in reduction and intensification when an improvement is desired upon a result got by development alone.

The best gelatine slide I ever witnessed was produced by means of reduction and after intensification, and there is no doubt that a great power lies here when an operator knows how to set about improving a flat, over-exposed plate—an operation which in many respects is similar to reducing or clearing away the deposits on a collodion plate by means of iodine, and then finally strengthening the purified image by means of intensification.

Many workers stand aghast at the mere mention of intensifying a lantern slide. Yet such means improve wonderfully the appearance of the slide on the screen, and, when the operation is skilfully performed, there will not be the slightest discolouration or degradation of the high lights. There is always a right and wrong way of doing everything, and, if intensification of lantern slides be conducted properly, great improvements follow such treatment. It is not that intensification is a wrong treatment to submit such delicate work to, as many imagine. The error lies in applying intensification *to all and sundry* productions, without the exercise of discretion whether such should be applied or not. Any slide that is judged too weak or thin by reason of lack of vigour only, but which has all the elements of a good slide otherwise, viz., some portions absolutely free from any deposits, *i.e.*, the highest lights, good middle tints and shadows, will take no harm from intensification if properly conducted.

On the other hand, poor, flat productions which have not a single high light or bit of clear glass in them, and whose half-tones are as sickly as shadows, will certainly suffer if such treatment be applied.

Intensification and reduction of lantern slides is an operation that should always go hand in hand, and the one follow the other as a natural consequence; and, once a worker grasps the advantages such treatment affords in the production of lantern slides, he will have mastered the entire operation, and spoil fewer plates when conducting this work.

Every worker in lantern slides knows quite well that the best negatives will always yield the best slides, but it does not follow that good results cannot be obtained by ringing the changes on indifferent negatives, by such means as partially screening or shielding those portions during exposure, and then, by having recourse to reduction of density, either locally or as a whole after development, high lights of great purity are obtained, that otherwise would be quite muddy or veiled over.

These bright high lights are beauty spots in a slide, and, when they exist, they lend a charm upon the screen that is so delightful to see.

How are these beauty spots to be acquired, however, from negatives where the necessary high-light deposits do not exist to yield such? The answer is very easily given, viz., by strengthening the points of the negative, and a clever worker will do so in an incredibly short space of time, and in a manner surprisingly easy. Let any of my readers who wish to temporarily increase the high lights of a negative just try the effect of applying by means of the tip of a finger a very small modicum of crimson lake *oil* paint to the glass side of a negative at the parts that it is desired to yield greater opacity, and, then by gently dabbing or rubbing the oil paint, it will or can be made of any consistency, and lie perfectly flat and smooth. With such an addition print your lantern slide, and, when all is right, rub it off again, and a stranger's negative never shows the dodge that has been applied. And no judge at a show or any one else that called for the production of the negative could say any retouching or doctoring had been resorted to.

I often think that such strictures, as no retouching or doctoring allowed, so frequently found in some of the conditions attached to societies' Exhibitions, about the silliest of all rules to apply, and such only shows how ignorant the parties are who frame such strictures. Any experienced operator can doctor a negative to any extent, pull prints from same, and remove any of the working up, making it impossible for any one to say that the negative has been doctored. But why should such doctoring not be encouraged rather than prohibited? Any means that will tend to the improvement of results ought surely to be commended rather than condemned, and, were prizes offered for the cleverest system of doctoring negatives, such would tend to teach a lot to those who have but little practical experience in photography. I wonder if an absolutely perfect negative was really ever produced, or one that did not permit of some improvement being effected after the development stage. I have never met such a *beau idéal* in photography.

T. N. ARMSTRONG.

COLOURING LANTERN SLIDES.

WE have always maintained that a photographic lantern slide coloured was a lantern slide spoiled, but an exhibition given in the Auditorium by Major W. H. Coughlin, the well-known Brooklyn artist, of British and American scenery, the slides having been photographed and coloured by himself, changed our opinion. Some of them, says the *American Amateur Photographer*, were so beautiful and so different from anything that we had hitherto seen, that, although aware that the man, in such work, is more than the method, we asked him, for the benefit of our readers, to tell us all about it, and what he said was practically as follows:—

Lantern slides should be tinted rather than coloured, and preferably with certain liquid aniline colours because of their beautiful transparency. Suitable kinds are kept by dealers in artists' materials, and known as

"Egyptian colours," or "Acme colours," and sometimes by dealers in photographic materials under other names. The following list includes all that are necessary for first-class work :—

Sky blue,	Lemon yellow,
Dark blue,	Orange,
Light green,	Brown,
Dark green,	Lilac,
Light red,	Scarlet,

and the general method of employing them, including colour values, contrasts and colour study, is exactly the same as in ordinary water-colour painting.

The colours, excepting sky blue, faint green, brown and light red, are dyes rather than colours in the ordinary acceptation of the term, and, while the slides should be tinted darker than they are wanted to appear on the screen, they cannot, without streaking, be laid on deep enough by one operation, but by several successive applications of the brush, each being allowed to become *nearly* dry before the application of the other. But, although the tints must be darker than they should appear on the screen, they should only be deep enough to be effective, or give due effect to the natural colour of the subject.

The sky of the slide should be perfectly transparent before colouring, coloured a suitable blue, and clouds picked out in white, and cloud shadows made by the application of a grey tint of sky-blue, red and faint yellow. The colours of distant hills are given by an intenser shade of the same mixture.

In colouring trees the whole object should be tinted green, which as purchased will be found too intense, and must be reduced with lemon yellow, and while moist the shadows touched in with a reddish purple.

Before beginning to apply colour the slide should be moistened with a wet brush and allowed to become *nearly* dry, as this makes the application easier and prevents streaking.

As most of the colours are readily decomposed by ammonia, clouds may be put in and errors corrected by its application. In one of the slides shown an effective moon in a deep bluish-grey sky was produced by touching the spot with a wire dipped into the ammonia bottle.

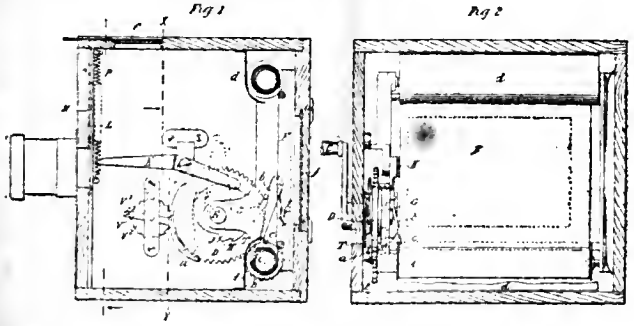
A favourite method of the Major's is to colour the cover instead of the slide itself. The slide is supported on a suitable easel, film side off, and a gelatine-coated cover laid on it, gelatine side out. A few drops of water may be placed between to produce optical contact. The cover is then treated just as if it were the slide, and when turned face to face the register is, of course, perfect.

Major Coughlin gets his gelatine-coated covers by soaking ordinary slide plates in a solution of hypo, but, of course, the economical amateur will make them much cheaper and equally good by coating ordinary thin glass with a filtered solution of gelatine.

FRIESE GREENE'S IMPROVEMENTS IN CAMERAS AND LANTERNS FOR ANIMATED PHOTOGRAPHS.

Mr. Friese Greene's invention relates to photographic cameras of the kind in which a series or number of photographs or pictures are produced successively upon a continuous film or strip made to travel intermittently in the camera. The invention is also applicable to magic lanterns of the kind in which a continuous slide, in the form of a strip or band of photographic or other transparencies, is employed for the purpose of producing panoramic, dissolving, or changing views, or for throwing a number of views in succession upon a screen.

The object of the invention is to simplify the means by which the film or strip is intermittently moved, and, in the case of cameras, to effect, as required, either a continuous or an instantaneous exposure whilst the film



is stationary. Means are also provided for indicating the number of films or sections of films used, and for finding or selecting the view.

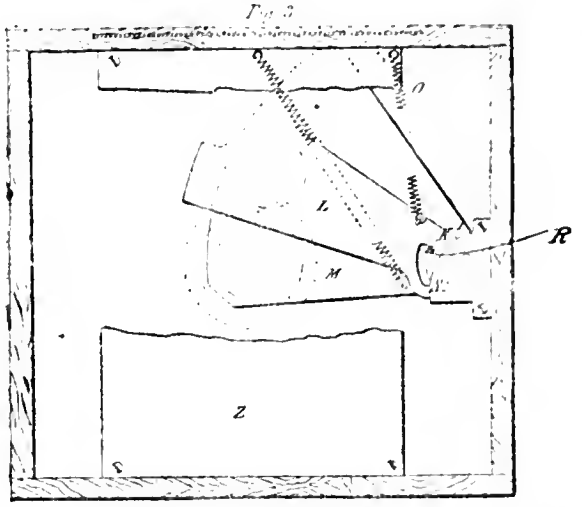
The patentee says: "I will describe my invention as applied to a camera :—

"Fig. 1 is a side elevation of the camera with the box or case in section.

"Fig. 2 is a section on the line, x—y, of fig. 1.

"Fig. 3 is a view of the shutter device, looking towards the lens with the plate, z, partially broken away.

"The camera may be fitted in the ordinary way with two rollers



carrying the film; its application to magic lanterns of the kind referred to will be understood without further explanation. The wind up roller, A, is fitted as usual with a toothed wheel, B, which is rotated by a handle, C, through the intermediation of another toothed wheel, D, mounted on the spindle, E. This last-mentioned toothed wheel, D, has the teeth for a certain portion of its periphery cut away, so that, during a certain part of the revolution of the handle, C, the film, F, is not moved. During this stationary period of the film, the exposure is effected by means of a cam or other arrangement, worked preferably off the handle spindle. This may be effected as follows :—

"On the handle spindle, E, I arrange a cam, G, having two steps, H J, which by a suitable lever or levers operate the shutter. I so arrange the cam which is to operate the shutter, that, by stopping the handle at a certain point, the shutter can be used as a time shutter; whereas, if the handle is continuously rotated, the shutter acts instantaneously.

"I prefer to use a double-shutter arrangement to give the necessary exposure. When one cam and one lever are used, I arrange them as follows:—The lever, K, is operated by the cam, O, and moves the two shutters, L M, which are so arranged that the inner shutter, L, covers the aperture, N, in the outer shutter, M. The two shutters travel together, and there is no exposure as they thus travel. Springs, O P, are attached to the shutters, L M, respectively, so that, when the lever, K, is released by the cam, O, the shutters are drawn quickly across the lens. A pin, K^1, on the end of the lever, K, is released from a notch, R, in the inner shutter, L, at a certain point by means of the projection, S, fixed to the side of the camera, and this shutter then flies back by forces of the spring, O, to its normal position. On the cam, G, being further rotated the lever, K, is released from the cam step, H, and comes upon the cam step, J, which is so adjusted that the aperture of the outer shutter, M, is brought exactly opposite the lens, and will remain in this position until the cam be further rotated. When the cam is further rotated, the lever is released from the cam step, J, and the spring acts on the shutter, M, and the exposure ceases.

"In lieu of the springs, the shutters can be worked by gravity.

"In order to indicate the number of films used, I place another cam, T, on the spindle, E, of the handle, C; this cam works a small dial by means of a suitable lever, V, pawl, V^1, and ratchet, V^2.

"In order to indicate the sections of films used so as to tell where to cut the film, I place a projection, *a*, on the toothed wheel, D. At a certain point of its revolution the projection, *a*, comes into contact with a lever, *b*, which, by means of the pin, C, makes a notch or prick on the film, F, thus indicating exactly which part of the film has been exposed. It is desirable that the film on the wind-up and wind-off rollers be protected by shields, *d d*.

"To adjust the focus or to select the view, I insert preferably in the top of the camera, in an aperture made for the purpose, a piece of ruby glass, *e*, so that it is possible to see the image on the film itself. This glass can be suitably protected by a metal or other cover to prevent its being damaged. I also provide at the back another piece of ruby glass, *f*, so as to facilitate the inspection of the image. In using this part of my invention, a piece of red glass or non-actinic film must be inserted in the front or back of the lens. By these means I am enabled to see the photograph on the film itself, thereby ensuring great accuracy.

"In order to use the camera above described as a magic lantern, the glass, *f*, should be removed, and a suitable light applied to the aperture."

The claims are :—

1. In photographic cameras and magic lanterns a toothed wheel in

combination with a wind-off roller, such toothed wheel having the teeth for a certain portion of the periphery cut away, whereby intermittent feed motion is imparted to the film by the continuous motion of a rotary spindle.

2. In photographic cameras the combination of a double stepped cam and a lever for operating the shutter, so that the shutter may act either as a time shutter or an instantaneous shutter at the will of the operator.

3. In photographic cameras the combination and arrangement on the same spindle of means for imparting an intermittent motion to the film of means for indicating the number of the film and means for indicating the parts of the film which have been exposed.

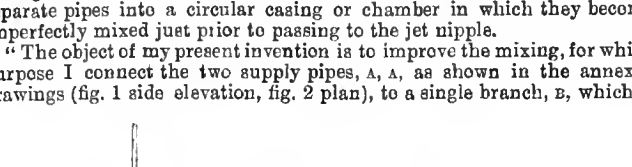
4. In photographic cameras, means substantially as described whereby the image can be focussed on the film itself.

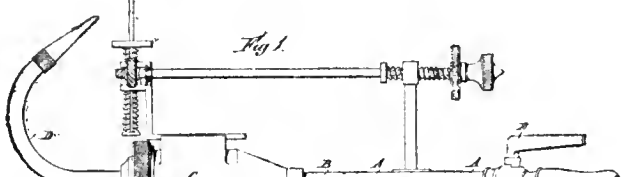
5. The combination and arrangement of parts whereby the same rotating spindle imparts an intermittent motion to the film, operates the shutter either as a time shutter or an instaneous shutter, and operates devices for indicating the number of the film.

GWYER'S IMPROVED MEANS FOR THOROUGHLY MIXING GASES FOR LIME LIGHT.

Mr. George Wright Gwyer says: "According to the usual method of producing a mixture of oxygen and oxy-ether gas, the gases are forced through separate pipes into a circular casing or chamber in which they become imperfectly mixed just prior to passing to the jet nipple.

"The object of my present invention is to improve the mixing, for which purpose I connect the two supply pipes, A, A, as shown in the annexed drawings (fig. 1 side elevation, fig. 2 plan), to a single branch, B, which is





attached to a mixing chamber or vessel, C, of long rectangular, circular, or equivalent shape, and preferably coned at the juncture, from the opposite end of which vessel, C, a curved pipe, D, projects, with a nipple end in line with the lens.

"By this invention the gases from the two pipes, A, A, strike each other at the junction of the branch, and flow along the branch in a partially mixed condition, and then become thoroughly and completely mixed in the chamber or vessel, C, before passing through the curved pipe, D.

"The introduction of ether saturators has rendered necessary an improvement in the mixing of the ether gas with the oxygen. The specific gravity of the gas being more than the hydrogen formerly used, more thorough mixing is required to get good results. This is usually accomplished by increasing the size of the existing circular-shaped mixing chamber. There is, however, a limit to the size of the mixing chamber, because the nipple must not be above the middle of the lenses of the condenser.

"By placing the jet horizontally, it enables a great length of mixing chamber to be obtained.

"Instead of carrying oxygen and oxy-ether gas in separate pipes to the mixing chamber as formerly, the gases commingle as soon as they enter the branch before they come to the mixing chamber, and a cock, E, can be placed that both the oxygen and the oxy-ether gas, or either of them, can be cut off at once, or regulated, an important feature to a lanternist when he sees that the ether in his saturator is getting exhausted."

The claim is for connecting two supply pipes, A A, of a saturator of the kind described and shown to a single pipe, B, in which a partial mixing of the gases can take place prior to passing into the mixing chamber, C, for the more complete saturation, admixture, commingling in proportional quantities, for improving the action on the lime at the point of combustion.

THE AMERICAN LANTERN-SLIDE EXCHANGE.

The following notes on the operations of the American Lantern-Slide Exchange, for which we are indebted to a Transatlantic contemporary, form an interesting record of work done. It may be pointed out that such a scheme is one well within the capacity for British Photographic societies to undertake:—

"During the month of September the interchange of lantern slides among the several clubs and societies was resumed, and the season of 1896–97 begun.

"The season of 1895–96 may be said to have produced a very fair average of work, and to have been rich in collections of foreign slides, there being no less than five sets of these in circulation, giving amateurs and slide-makers a very good opportunity to observe how far ahead or behind the work of Americans is as compared with that of our foreign friends. The stimulating and elevating effect of examples of fine work, thus brought to the attention of American slide-makers, has been the means of raising their standard, both as regards the artistic and technical qualities. In the present season it is doubtful whether the foreign sets will be as numerous as heretofore. Of those on hand the slides of the Photographic Society of the North of France, at Douai, exhibit to the poorest advantage, the subjects being of ordinary interest, and the technical work not up to the average American quality. Of the clubs in the Interchange doing any special work, we are informed that the Buffalo Camera Club is engaged in preparing a new series of views, illustrating modern Niagara, to be accompanied by a consecutive brief description of the pictures, which promises to be interesting. The best slide-makers of the Club are at work in getting up the slides, and the members are enthusiastic over the idea. The Camera Club, of this city, we are advised, contemplates getting together a unique set of slides, which are to be arranged with suitable descriptive notes with reference to consecutive exhibition.

"Two sets of American slides are now in Japan, one of which illustrates the 1893 Chicago World's Fair, and it is expected the Photographic Society of Japan will forward for exhibition in the United States another set of their beautifully coloured work as a return compliment. The sets of English slides, now in circulation among the clubs of the Interchange, are of excellent quality. A new set from the London Lantern Society is promised for the coming season. There is also a prospect of additional new clubs entering the Interchange, especially from Canada, and some domestic clubs who have ceased for a time to contribute slides will begin anew. During the past year the St. Louis Camera Club gave up its membership, but was succeeded by the St. Louis Photographic Society, all of its best slide-workers joining that organization. Among the new clubs admitted was the New Britain Camera Club, of New Britain, Conn. The following are the active clubs at present in the Interchange: The Camera Club, New York, Photographic Society of Philadelphia, Newark Camera Club, Orange Camera Club, Frankford Camera Club, Bethlehem Photographic Society, Schuylkill Camera Club, Photographic Club of Baltimore City, St. Louis Photographic Society, Omaha Camera Club, California Camera Club, Oregon Camera Club, Portland, Oregon, Minneapolis Camera Club, Rockford (Ill.) Camera Club, Chicago Society of Amateur Photographers, Buffalo Camera Club, Toronto Camera Club, Syracuse Camera Club, Albany Camera Club, Portland (Me.) Camera Club, New Britain Camera Club.

"There are nine sets of domestic slides in circulation, from which, in October, 1896, a selection of 100 of the choicest slides will be made, to form a special set for circulation among the societies and clubs in England. In addition to the foregoing is the *American Amateur Photographer* revised prize set of slides, and five sets of foreign slides. During the month of September each club should elect a lantern-slide director, to represent it in the Interchange for the year beginning on November 15 next. In October the newly elected directors elect, by mail vote, a board of five managers, who meet November 15 to select from the numerous sets of slides only those of meritorious quality. The general plan of the working of the Interchange is for each club to set dates for exhibitions, and for the general manager to arrange for the shipment of sets of slides to them a week or ten days before wanted. Then, after exhibition, the slides are shipped to the next club on the list, until every set (about one or two per month) has been the rounds of the route. New clubs wishing to participate in the Interchange should address the General Manager, F. C. Beach, 361, Broadway, New York, for rules and particulars."

ANIMATED PHOTOGRAPHS: A NOTABLE EXHIBITION.

Thanks to the enterprise of the Council of the Liverpool Amateur Photographic Association, the members and their friends had an opportunity, on October 29, of hearing Mr. Birt Acres, of London, one of the leading pioneers of the latest departure in instantaneous photography, and of seeing some of his latest achievements. So great was the demand for tickets, although issued only to members of the Association, that it was necessary to engage the smaller St. George's Hall, and even this was barely large enough.

The chair was occupied by the President, (Mr. J. Sirrett Brown),

and he was supported by the Secretary and most of the other officers of the Association.

Mr. Acres, in the course of his introductory remarks, paid a handsome tribute to other workers who had contributed to the gradual development of the moving photographic picture from the root idea furnished by the zoetrope of a generation ago. The first of these, Mr. Friese Greene, never quite surmounted the initial difficulties, but Mr. Muybridge did, with the excellent results which are so well known. It was not, however, until the plan of a range of cameras, each taking one picture, was abandoned in favour of one camera with a succession of exposures, that further progress was made. The pictures shown on the sheet were each the result of from 800 to 2000 distinct pictures taken on rolls of sensitised film at the rate of fifty or sixty per second. Among these were some admirable examples of well-selected subjects, including scenes at the marriage of the Princess Maud, the visit of the Prince of Wales to Cardiff, the Prince's Derby, Henley Regatta, railway trains in motion, fishing boats leaving the harbour, human boxers, the boxing kangaroo, Lancers exercising on horseback, children playing, merry-go-rounds at a fair, the German Emperor at a review, and waves breaking on the shore at Dover. The exhibition of these fascinating selections from real life was received with continual applause, and at the close of the proceedings a vote of thanks, felicitously proposed by the President, seconded by Mr. E. Rimbault Dibdin, was carried by acclamation in the heartiest manner.

Speaking after a dinner at which he was entertained earlier in the evening by the Council of the Photographic Association, Mr. Birt Acres made the interesting announcement that he has now practically brought to completion improved mechanism by which perfect steadiness is secured in the exhibition of his series of pictures, a result hitherto found unattainable, and the conquest of which will be of the greatest value.

LEEDS PHOTOGRAPHIC SOCIETY.

At the bi-monthly meeting of the Leeds Photographic Society, held in the Society's rooms, Mechanics' Institute, Mr. S. A. Warburton gave a demonstration in lantern manipulation. In his opening remarks, he stated that, at the request of the Hon. Secretary, he intended preparing a short paper for the benefit of "beginners" in the art of lantern projection, but had been carried by his subject further than originally suggested. Producing three lanterns and two screens, he commenced with an Exhibition (by means of diagrams) of the construction and use of the lenses in the modern optical lantern. He then proceeded to show the various effects produced by the following illuminants, viz., paraffin oil, oxyhydrogen light, using various forms of burners, and finally applied the new gas, acetylene, as an experiment. In the latter he was very ably assisted by Mr. G. H. Rodwell, an ardent co-worker in this direction. During the course of the evening ninety-nine slides, kindly forwarded by Mr. J. T. Sandell, of South Norwood, were exhibited and tested by means of the various illuminants. Many of the transparencies were of especial interest, both as regards subject, and as specimens of photographic production, the most noticeable being *Interior of Milan Cathedral; The Choir, St. George's Chapel, Windsor; North Transept, Westminster Abbey; Sacrarium, Westminster; Still Room, Apothecaries' Hall; Entrance Hall, Ironmongers' Company;* also the Hall Marking-room, Drawing-room, and Staircase of the Goldsmiths' Company. Two specimens of memorial windows (the Caxton and Cranmer) in the Stationers' Hall were remarkable for their perfect freedom from halation. It need scarcely be added that the paper was an interesting one; in fact, Mr. Warburton so thoroughly engaged the attention of his audience that "closing" time came as a surprise, and the meeting dissolved with a brief but very hearty vote of thanks. Messrs Walter Beilby and Joseph Horner were elected members of the Society.

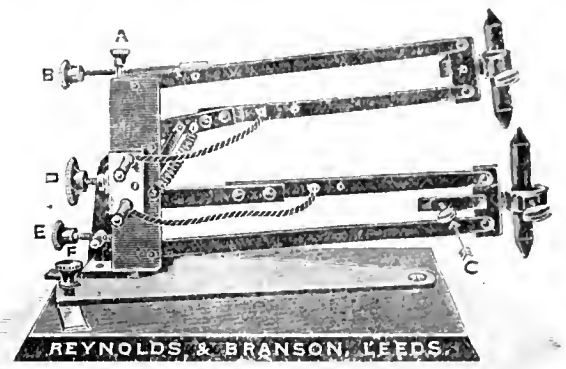
MANCHESTER PHOTOGRAPHIC SOCIETY.

The first Lantern Meeting of the season was held on October 28, at the new rooms of the Society, 44, Mosley-street. The evening was devoted to an exhibition of slides by the members, sent in for selection, to be shown at the Royal Photographic Society on November 7. Close upon 300 slides, made by the principal lantern-slide making members, were shown upon the screen, and the standard of excellence was very high. Mr. T. M. Brook showed his charming series of figure studies, also several landscapes; Mr. F. W. Burton, architecture and hand-camera shots; Mr. A. E. Casson's toned-cloud effects were very effective; Mr. W. G. Coote, bits of Cheshire scenery and rocks and breaking waves at Donglas; Mr. S. L. Coulthurst kept up to his usual standard with landscapes; Mr. Abel Heywood, scenes in Norway; Mr. Harry Wade, views from the Lake District, Shakespeare's country, Cheshire by-ways, and *genre* studies; Mr. W. B. Wood showed the possibilities of pictorial photography round about Urmston; and Mr. J. Whittaker had a series of flower studies. The descriptions were read by Mr. Harry Wade, and Mr. J. Whittaker manipulated the lantern.

REYNOLDS & BRANSON'S ARC LAMP FOR THE OPTICAL LANTERN.

Reynolds & Branson, Leeds.

This Arc Lamp, which we hope to have an early opportunity of trying, has all the usual movements, but differs from others of its kind in that it possesses a parallel feed, the carbons thus travelling in a straight line. In use, one carbon is set slightly in advance, so that the arc is thus arranged to give a maximum illumination in the direction of the condenser. We are informed that with a continuance current of fifty volts



very satisfactory results are obtained. Expert tests have also been applied to the lamp with satisfactory results. Messrs. Ross have the London agency of the lamp.

The Reynolds & Branson Arc Lamp is extremely well made and compact. The adjustments, lateral and vertical, work very smoothly, and have evidently been arrived at from great practical knowledge of what is required in a lamp of this description.

BEST'S IMPROVEMENTS RELATING TO GAS LAMPS FOR PHOTOGRAPHIC AND OTHER PURPOSES.

Mr. R. H. Best's invention consists of improvements relating to gas lamps for photographic and other purposes, his object being to arrange a cluster or combination of lamps within a reflector in such a manner that an intense light can be readily directed upon the required object.

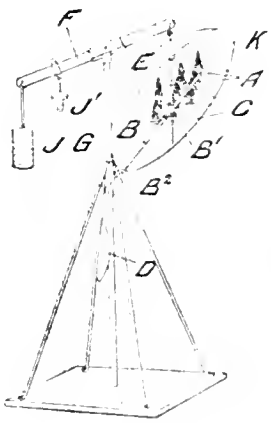


FIG. 1

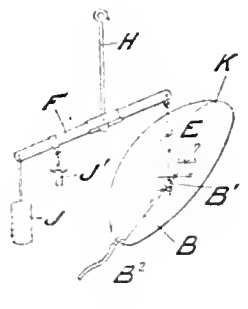

FIG. 2

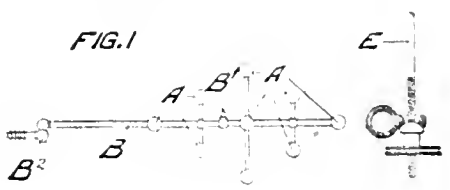

FIG. 3

FIG. 4

"Fig. 1 is a general view of my improved illuminating apparatus mounted upon a stand, and fig. 2 a similar view of the apparatus as arranged for suspension from a ceiling or other over-head support.

"Fig. 3 is a plan to a larger scale, showing the disposition of the burners, and fig. 4 a sectional view of the central joint of the tubular frame.

"The same reference letters in the different views indicate the same parts.

"In carrying my invention into effect, I attach a number of incandescent or other suitable gas lamps or burners such as A to a tubular framing consisting of one common base or delivery pipe, B, having connecting branches, C. To the end of the base or delivery pipe, B, is attached a flexible supply pipe, D, conveying the coal, acetylene, or other gas, to the burners.

"The base or delivery pipe, B, has a joint, B^1, at or about its centre, and a joint, B^2, at the supply-pipe end, the joint, B^1, permitting of movement in a horizontal plane and the joint, B^2, of movement in a vertical direction. The complete tubular framing is suspended by means of a rod, E, from a balanced crank arm or lever, F, such as described in my Specification No. 6907 of 1893, on which letters patent have been granted to me, which is mounted upon a stand such as, G, fig. 1, or is itself suspended by a rod, H, from the ceiling or other over-head support. The burner framing can be readily moved up or down the rod, E, and secured at an any desired position by a screw, nut, or other suitable means.

"The weight of the burners and frame suspended by the rod, E, is balanced by the fixed weight, J, and the smaller and moveable weight, J^1, which is so set that the lever will be in exact balance in any position to which it may be adjusted by raising or lowering the complete framing together with the enclosed reflector, K.

"The reflector, K, is attached to one end of the base or delivery pipe, B, as illustrated, and is held in position on the rod, E, by an adjustable collar or bearing permitting of its being turned in a horizontal plane. The reflector is of such dimensions, and is so arranged, as to cover the cluster of burners as illustrated. I preferably construct the reflector from a thin metallic plate or plates pressed or formed to a semispherical shape, and upon the inner surface I rivet or otherwise attach asbestos or other suitable sheeting painted white.

"The cluster or combination of burners, A, are so disposed in rows or files upon the base or delivery pipe, B, that the row or file of the greatest number of burners coincides approximately with the centre of the reflector when placed in position. The rows or files on each side of the central file contain a gradually diminishing number of burners to coincide with the diminishing space between the opposite sides of the reflector. I place one or any required number of burners in the reflector according to the intensity of light that is necessary.

"By thus arranging the lamps within a reflecting shade I am enabled to readily direct a powerful light on to the required object without loss from diffusion of the rays or other like causes."

The claims are for:—

1. The improved illuminating apparatus for photographical and other purposes consisting in the arrangement of gas burners such as A within an enclosing reflector such as K.

2. In illuminating apparatus the combination of a cluster of gas burners such as A, mounted upon the branches, C, of the base or delivery pipe, B, having the enclosing reflector, K, attached thereto, with a suspension rod, E, and balanced lever, F, mounted upon a stand, G, or suspended from the ceiling or other support by the rod, H.

3. The improved general construction and arrangement of an illuminating apparatus for photographical and other purposes.

LANTERN SLIDES MADE TO ORDER.

This article proposes to treat of lantern slides made from designs, engravings, prints, photographs &c. We will suppose, says the *Philadelphia Exhibitor*, that an engraving is received with order to make one lantern slide, no more definite directions; the engraving is six inches long by three inches wide; it is placed in front of the camera and a negative made by the usual process, from this negative, placed in like manner, a positive is made, now the lantern slide will be three inches long by one and a half inches high; it is made according to order and is sent to the customer. It is returned with the complaint that it is not of the standard size or shape; you answer that it cannot be made so unless both or one end of the engraving is cut off so as to make it as long as it is wide; the answer is, that the slide must contain the entire picture, you have done the best possible, the lantern slide will always be of the same shape and in the same proportion as the original.

If the design permits of a sky effect, then the picture can be dropped to the bottom and the sky carried up until the slide is of the standard shape. When there is both sky and water, and the slide is to be coloured, it may happen that the water line can be carried downward as well as the sky line upward, thus to balance the picture, and obtain the full-size opening; but, if it is to be a plain slide, this cannot be done, as the lower line will show across the slide; by colouring, this line may be hidden.

When the slide is to be coloured, directions should be given in regard to the grade of slide wanted.

Of course, there are all qualities of paintings; these depend on the ability of the artists, irrespective of the method by which the slides are made. There are two grades of coloured slides. The best grade is made by the sealed process; this process increases the transparency, adds to the durability, and tends to improve the sharpness of detail. This sealed slide is a water colour-slide over which Canada balsam is flowed, it must be made on plate glass so that the surface of the picture glass and covering glass will press closely together and not permit any air bubbles to work their way into the film of balsam. The other grade of coloured slide is not sealed, the colours are varnish colours; the glass need not be plate.

It is obvious that the sealed slide, by reason of the balsam, cannot have any mat, and that the slide glass and its covering should be held together until the balsam hardens; this, requiring an indefinitely long time, caused the makers of these slides to place them in wooden frames, that and the wire rings secured the glasses, the openings in these frames are round or square; tin frames round or square, as may be desired, are also furnished. The object sought by the tin frame is to furnish slides as near the size of plain slides as possible; this is attained except in thickness. Coloured slides vary in price according to their shape; if the picture is three inches in diameter, it costs less than one that is three inches square, because, being hand-painted there is less surface to paint, and this takes less time.

A square slide is more difficult to seal and also more difficult to mount in the wooden frames; for these reasons an extra twenty-five cents is charged for stock slides. Parties ordering from designs, &c., should state whether the slide is to be round or square.

In many cases a circle will include all of the subject that may be necessary; this can be determined by holding a ring over the design, then look through the ring and see that it includes what is needed; a convenient ring can be made by the thumb and fore finger, the hand is moved towards and from the design until the top and bottom lines of the design coincide with the thumb and finger, and then the portion of the picture circumscribed will be shown.

WARM TONED LANTERN SLIDES.—For bromide plates for a peculiar warm purple colour there is nothing to beat the plain washing-soda developer, composed of washing soda, 2 ounces; ammonium bromide, 20 grains; and water, 16 ounces, to every ounce of which just before use add 1 grain of dry pyro. For those who, objecting to pyro and its stain, prefer hydroquinone and yet want warm tones, we can advise the use of hydroquinone, 2 grains; ammonium carbonate, 24 grains; ammonium bromide, ½ grain; and distilled water, 1 ounce.—*Photographic Record.*

MR. HALL-EDWARDS's fresh achievements with the Röntgen rays continue to surpass their predecessors. His most recent triumph has been the discovery by their means the location of a sovereign which was swallowed some two months ago by a boy living in the neighbourhood of Villa Cross. When the lad first swallowed the coin, it did not appear to incommode him much; but, later on, the foreign body caused inflammation and swelling, rendering breathing difficult. The efforts of Dr. Shillito to give relief by medical means proving unavailing, it was deemed advisable to resort to an operation. Before, however, an operation could be undertaken with a reasonable prospect of success, it was necessary to locate the swallowed sovereign, and for this purpose recourse was had to the skill of Mr. Hall-Edwards with the X rays. The impossibility of keeping the boy still preventing a photograph being taken of his gullet, Mr. Hall-Edwards brought into application a new fluorescent screen he had obtained, and an exceptionally fine Crookes' tube by Casson, of London, and on this screen the position of the coin was defined. We understand, however, that, in order to assist the operation, a Röntgen-ray photograph will be taken, so that the surgeon may have the object before him at his work. These fluorescent screens are most interesting. An *Argus* man called on Mr. Hall-Edwards yesterday, and was shown, clearly displayed on the fluorescent screen, the skeleton of his own hand and fore arm, those of Mr. Hall-Edwards, also the skeleton of his foot through the boot, with all the rivets in the sole sharply displayed, the shin bone and knee joint, and the operator's watch and metal buttons through his body. In about six months this amazing discovery has given us almost a surfeit of wonders.—*Birmingham Argus.* Since the above was written, a most successful radiograph has been taken, the child being placed under chloroform. The gullet was then opened, and the coin removed. The photograph shows quite plainly the position of the coin.

MR. T. T. WING, of Chatteris, Cambs, send us his catalogue of chromolitho slides, lanterns, &c., also his lists of new sets, some of which are of recent and very great interest.

FROM Mr. W. Hume, Lothian-street, Edinburgh, we have received his interim list of his well-known cantilever enlarging apparatus. This excellent lantern is made in many patterns, and, being a practical instrument, its popularity need not be wondered at.

MONTHLY SUPPLEMENT

To the "British Journal of Photography."] [*December* 4, 1896.

THE LANTERN RECORD.

CONTENTS

LANTERN MEMS.

The electric supply companies are seriously considering increasing the voltage of their currents where the "direct" currents are supplied, from 100 volts or thereabouts to 220 volts; in fact, some of the provincial corporations, and at least one London company, have already adopted this higher standard. The reason is that, as far as they are concerned, it is more economical, for with about the same amount of electricity double the number of incandescent electric lamps can be supplied. In order that the new voltage may be acceptable, the provincial supply offer, so I have heard, to replace any lamps now in use for others suitable for the higher voltage free of charge.

* * * * *

This is all very well for the incandescent form of lamp, but the arc-lamp users are handicapped somewhat, for there is a waste of power and the cost of the higher resistance which has to be employed. As regards the former, it need not be considered by those who use the arc lamp for optical projection, as the cost of the current for the few hours it is required is fractional; in respect to the resistance it is another matter, and means a much larger resistance or two of the size necessary for a 100-volt current for each arc light. All who have any interest in large halls should endeavour to get the proprietors to fit up a proper main wire and suitable resistance for their particular supply of electricity, so that the expense does not fall on the lanterniet using the current at the hall. If this were done, the electric light would become more and more popular for projection purposes, as it has become in theatres and places of entertainment.

* * * * *

As it is now, every month sees additions to the ranks of those who use electricity in their lanterns, for not only is the light so convenient, brilliant, and clear, but it gives such splendid definition, even with objectives or front lenses of average quality. There are still a few things to be done by apparatus-makers or lanternists to get the very best results for dissolving-view apparatus; but, in the pros and cons, the preponderance of benefit is on the side of the arc light, as it confers on the user very great advantages, while the difficulties (they can hardly be called serious drawbacks) will sooner or later be surmounted.

* * * * *

One of these difficulties is dissolving, as we understand it, with limelight work, using gas dissolving taps, that is, the gradual dying away of the picture equally all over the disc, the switching on and off of the current not being quite all that can be desired for this purpose. The dying away of one picture can be well managed by gradually lengthening the arc of light until it ceases to illuminate; but the bringing on of the light has to be sudden, as the "striking" of the arc, as it is called, is a necessity, and therefore mechanical obscuration of the light has to be resorted to. The sharp definition of the arc light produces a curious effect on the screen if fans, iris diaphragms, or graduated shutters, are used in front of the objective.

* * * * *

Rolling curtain shutters between the condenser and the slide can be effectively used, or two Davenport carriers will give a pleasing effect, while solid flap shutters, worked together in a suitable manner, as nearly as possible approach the ideal dissolving of the lime light. A mechanical arrangement has to be attached to the front to save the operator the trouble of moving two shutters at once, and so engaging both his hands, and also to ensure the proper rate of travelling, to gradually expose one slide and shut out the other.

* * * * *

Since writing last month about cinematograph films, I have had submitted to me some excellent samples of large-size films having an area nearly double that of the regular size, which is the same as the visual kinetoscope. However, the apparatus to show these is naturally more expensive than the smaller size, and as I have, from personal knowledge and reports from those using the portable cinematograph sold at 36*l.*, every reason to say a good word for them. This being so private or professional lanternists who wish to add a novelty to their entertainments need not hesitate to invest at once, for by its means funds can be raised for charitable purposes, or to expend the amount necessary to purchase a machine for taking one's own animated photographs when the fine weather comes again in the spring.

* * * * *

What lovely transparencies some of the French lantern slides are, a new series of Pompeii being real gems in their way, while, for sunlight and shadow effect, a set of thirty-six views of Venice would be difficult to beat. These photographs, produced by the albumen process, give transparency in the darkest shadows, and for a certain class of work such as these subjects embrace, and for scenery with mountains and water, it is, in my opinion, the best method of production, also for copying prints, &c. For amateurs it may be too troublesome, and I understand, from the large producers of slides commercially, it would be difficult, with all their arrangements made as they are, to substitute this method for collodion; but I should certainly like, in the interest of the "home-grown industry," so to speak, to see it more used in England for slides to be sold by the trade. One house, I think, uses it for their special copyright slides, and are reaping the reward of their discernment in this matter.

* * * * *

There are several really clever mechanical slides for single lanterns introduced this season, which, by levers and springs, make excellent effects on the screen, and yet are simple to operate

Among them may be mentioned *Blondin Crossing Niagara;* the feet of the tight-rope walker moving, and the wheel of wheelbarrow revolving. Another is *Past and Present*, with cyclists and the inevitable Motor carriage passing along the road; also a good one of the Tower Bridge by day with mechanical movements to open basculea, the view to change to night, with cabs, omnibuses, &c., to cross the bridge.

* * * * *

I AM glad to learn that Professor Lewis is to give, as one of the series of the Cantor lectures, one on the acetylene gas light, when, no doubt, he will touch on the best methods of using the light with the minimum of risk. I trust also he will show how this light can be used to most advantage for projection purposes. At present it is about the same as a good oil lamp, in its practical results, although I was recently told it was capable of projecting a twelve-foot picture. When this size picture can be obtained commercially, without danger and without anything in the way of a disagreeable smell, the apparatus should have a good demand, especially in country places or those far removed from rail, and where compressed gas (oxygen and hydrogen) cannot be obtained. G. R. BAKER.

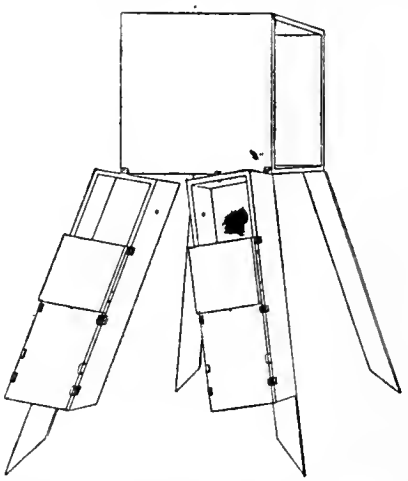
A CONVENIENT LANTERN STAND.

IT has often been said, and wisely, that cylinders containing compressed gases should always be worked in an upright position, so that, if there should be any fluid deposit in the nature of condensation from the gas, there should be no risk of it getting into the passages of the valve or regulator, and interfering with the even flow of the gas to the jet. There is no doubt that under certain conditions there is a deposit on the sides of the cylinder—in the case of the coal gas at all events; for, unlike wine, coal gas does not improve by being kept long in bottles; it deposits one or more of its constituents in a liquid form upon the sides of the containing cylinder, and, if this cylinder is being used in a recumbent attitude, so to speak, the sticky, dirty mess is pretty sure to find its way into the valves and inward parts of the regulator, with the unpleasant and disconcerting effect of untimely "dousing the glim." However, this is not likely to happen if the bottle be kept in an upright position while being used, and if, before commencing a lantern show, the operator turn the cylinder upon its nozzle end, and, having left it to drain for a few minutes, he suddenly opens the valve to blow off the collected liquid, he need have little fear of trouble from this cause.

Here is an idea for a kind of combination lantern stand in which the two heavy cylinders are supported in an upright position and their weight is made use of to give rigidity to the lantern. The advantages of such an arrangement as that shown in the sketch are that the complete apparatus for a limelight lantern show takes up but very little room in the hall, while everything is compact and ready to the lanternist's hand, and great rigidity is secured to the whole structure, at the same time that it is quickly and easily set up or taken to pieces. It packs up into very little space and there are not many separate pieces, which is a great advantage when there is much travelling to be done.

It consists of a strong box in which the lantern ordinarily travels, two light wooden legs to be affixed to the front of the box in any suitable manner, and two long wooden boxes in which the cylinders are placed, and which serve the purpose of the back legs. The question, whether the cylinder boxes will of themselves be sufficiently long to serve this purpose without any extension pieces, will depend entirely upon the size of the cylinders. Forty-foot bottles (long pattern) will be plenty long enough, for the regulators add a certain amount to the length; but, where bottles of less capacity are used, short extension pieces like those shown in the diagram will be necessary, and these may well take the form of sliding legs permanently attached to the back of the cylinder boxes in such a manner that they can be quickly drawn out to the required length, and clamped in that position by means of a screw and wing nut in the manner familiar to users of camera stands.

The method of fastening these hind legs, as it were, to the box whose function it is to support the lantern for the time being, may vary with the different tastes of the divers individuals who may construct the apparatus, and the one which I have adopted is, I think, open to improvement. To the bottom of each cylinder box, at the regulator end, and at that corner which will be outermost when the apparatus is set up for a lantern show, is screwed a hinge, one of whose flaps is drilled and countersunk in the usual way, while the other is provided with a slot, so that it may be quickly slipped behind a set screw and clamped in place without involving the removal of the screw. At the two extreme bottom corners of the back of the lantern box are two bolts fitted with wing nuts for the reception of these hinged flaps, and a similar arrangement at the front of the box provides for the attachment of the front legs. In those cases where the cylinder boxes are too long to be used in this



way, and make a stand of convenient height, boxes, say, for bottles holding fifty or sixty cubic feet of gas, the difficulty may be overcome by putting the bolts for holding the hinged flaps not at the bottom of the lantern box, but somewhere nearer the top, according to the length of the bottles.

The four legs should be prevented from spreading out to more than the required distance by bits of cord stretched between them, after the manner of the household pair of steps. But these cords ought not to be permanently attached, because that would necessitate that all four legs be packed up in one parcel for travelling, which is not desirable, for each of the bottles is quite heavy enough to travel by itself, and should do so without any additional *impedimenta.*

The method which I have adopted for attaching the lids to the boxes containing the bottles may be of interest. As will be seen from the sketch, each lid is fitted with a hinged flap, which folds back to a sufficient extent to allow of the valve of the cylinder being comfortably operated without removing the main portion of the lid. Three iron angle pieces on each side of either box hold the lid in such a manner that it is free to slide back to a certain extent until the cut-away gaps are reached, when the lid may be lifted off altogether. Just on the edge of each flap, where it is hinged to the main portion of the lid, is a screw projecting a little way from the surface of the wood in such a manner as to prevent the lid sliding at all, except when the flap is open, so that the box is closed beyond all chance of becoming accidentally opened, when this flap is shut down and held by the hook with which it is provided. A hole is drilled in the inner side of each box near the top, so that the tubes from the regulators may be passed through, and the boxes closed up if thought desirable. It is desirable occasionally; when the lantern is being operated at a boys' school, for example. CECIL M. HEPWORTH.

ON THE REDUCTION AND INTENSIFICATION OF LANTERN SLIDES.

II.

As an example of the advantages to be derived by having recourse, first to the reduction, and afterwards the strengthening, of the image on a lantern slide, mention may be made of such subjects as are included under the category of black and white.

This may mean intricate and delicate plans, where lines of varying breadths in the original have to be faithfully represented on the screen by means of clean slides, or even such every-day common examples as hymns and printed matter, &c.

In making the negatives from such originals, an experienced worker in collodion will know well the value of iodine as a reducing agent for the removal of any surface deposits that may have been thrown down by development on those parts that it is absolutely necessary should be represented by clear glass. I often think that in the use of iodine lies the great power and value of the collodion process, for an experienced worker can, with its aid, produce such beautifully clean results upon a wet-plate negative or positive with the greatest of ease; and, once having

removed all surface deposits from those parts of the plate that must be clean glass, the building up of the remaining image, or the intensification of the same, as some choose to term the operation, is easily performed by any of the well-known methods.

Many writers, no doubt, when referring to the utility of a gelatine plate for the production of black-and-white results, speak of the same as quite unsuitable for this kind of work, and hence the strong recommendations so often seen to use a collodion process in such cases.

In this respect I often think the value of gelatine is not sufficiently appreciated by those who have mastered the working of collodion.

I know the value of my wet bath as well as any one, and I have derived as much pleasure and benefit from the use of the same as any worker in the kingdom; but, at the same time, I don't deride gelatine in black-and-white working, for I know quite well that, once a worker conscientiously gives his attention to the use of gelatine on such subjects, although it takes a lot to remove the prejudice, he will alter his opinion, and find that equally good results can be obtained with gelatine in many instances as with collodion.

To obtain absolutely opaque blacks and clear glass (by which I mean the film, whether it be that of collodion or gelatine, must be free from any deposit or reduction of silver in such parts) requires the strict observance of certain well-recognised rules of working, no matter whether it be conducted by mean of collodion or gelatine.

With the former of these processes iodine is the sheet anchor, as I have already stated; with gelatine the operations are entirely different, but, when properly understood and executed, quite as clean and brilliant results are obtained as with collodion.

The first necessity is a suitable plate, and I have no hesitation in saying that such as Mawson's lantern or England's photo-mechanical, or any other good slow lantern plate, if used with suitable apparatus, will, at any time, turn out first-rate results.

Every different subject, as lighted, will require its own correct exposure, and if this be carefully attended to, and the plate developed by means of a well-restrained but strong hydroquinone developer, any amount of density in the opacities, without any deterioration of the clear glass portions, can be obtained by means of development alone, for an observant operator, who uses plenty of light—and with these very slow plates the most comfortable light is permissible in a dark room—will know the exact moment that the development should be arrested, so as to preserve the clear glass portions from being veiled over; but even, through failure in this respect, should it be found, on closely examining the plate after being fixed, that some reduction has taken place, it is very easy to remove the same—in fact, quite as easy as would be the case when treating a collodion plate by the application of iodine; and, even should there be no veiling over apparent, almost every production in black-and-white working is improved by the slight application of a suitable clearing or reducing bath.

With many workers, poor, thin images are obtained when they first try gelatine for this kind of work, and hence the opinion so freely expressed that gelatine is not suitable. I firmly believe these thin results are obtained by the use of a developer that is not suitable. Any ordinary formulæ, such as are frequently given out for the development of lantern slides, are far too weak for the production of a bold, vigorous black-and-white subject, no matter whether it be a positive or a negative. Plenty of hydroquinone and bromide should be used in conjunction with a saturated solution of carbonate of soda, by which means a surprisingly strong image is easily developed out, *when the exposure has been carefully timed to dovetail with the developer employed.* By using the carbonate of soda in a saturated condition, the hydroquinone solution is not weakened down to the same extent as when a slush of soda solution is employed, and if the saturated solution of carbonate of soda be added very cautiously in small quantities, and plenty of time given between each addition, the first appearance of the image is easily noticed, and, when seen, it will come along and build itself up in a beautifully vigorous manner, without acting upon those parts where no reduction is required. By this means results are obtained that very probably will require no after-intensification.

As an example of this kind of work, let it be supposed that it is desired to print by reduction through the camera a black-and-white negative, such as would represent some hymn or other black-and-white printed matter.

A good lantern plate is provided and used in conjunction with suitable apparatus, for let it be borne in mind that, when making reductions through the camera, faulty apparatus often yields curious results.

I well remember once having a clever young foreign gentleman as a pupil, who could make excellent slides with the apparatus he possessed from ordinary negatives, but could not get along without producing ghosts, as he termed it, when reducing black-and-white negatives.

I pointed out to him that what he termed ghosts were nothing more nor less than images produced by irregularities in his front diffusing screen. I found out he had been using a sheet of tissue paper, placed about three inches in front of the negative. The clear glass portions of the negatives permitted these spots in the tissue paper being represented in the slide. On adopting a different diffusing screen these ghosts disappeared entirely. Failures of this description are very liable to arise where negatives are used that have absolutely clear glass in some portions, and the greatest care is necessary to use clean screens, as well as placing them in a sufficiently distant position to be out of the focus of the lens, for it must be borne in mind that these clear glass portions yield the opacities in the slide, and, if they are irregular or spotty, the slide is sure to be faulty in such places.

Sometimes, when the sky is evenly overcast, such can be used with advantage, and often make an excellent source to direct the negative to in this kind of work.

Opal glass is to be preferred, where good illumination exists, to coarse examples of ground glass, if these irregularities put in an appearance in lantern-slide making when reducing by means of the camera and copying box. Such are often traceable to faulty screens in advance of the negative.

The plate being exposed and developed fully out by means of such a developer as I have indicated, it is quite possible a slight veiling over of the clear glass portions may be observable when such is fixed and examined with the aid of strong daylight. Should, however, such be present, it is easily got rid of by preparing a weak solution of ferricyanide of potassium, and, after the slide has been slightly washed, immersing the same in it for a few seconds, then taking it out and washing it well in clean cold water. This first application, provided any hypo be left in the film, will certainly have acted upon the veil apparent on the clear glass portions of the slide, and, if it is desired to continue the action further, a few more rapid immersions, all of which should be followed by copious washing, will soon remove the last trace of veiling or degradation of a high light. The use of ferricyanide of potassium with a gelatine plate at this stage almost exactly coincides with the application of iodine to a collodion film previous to intensification; and, in the case of gelatine, if the exposure has dovetailed with the developer, it will be found that plenty of density has been obtained without the necessity of having recourse to intensification. Should such, however, be deemed necessary, a gelatine image is easily strengthened by any of the well-known methods.

To a beginner the application of a solution of mercury to a film reduced or cleared in the manner I have stated must prove a good object lesson. If, on the application of the mercury, the slightest whitening be apparent on the clear glass portions, it is a certain sign that the reduction has not been carried sufficiently far, and errors made in this direction are easily avoided in future. If the plate has been properly cleaned for intensification, there will be no deposit of mercury on parts other than the blacks, and intensification in such cases does no injury.

In the above we have what may be termed an example of plain black-and-white working, which requires nothing in the way of expert or difficult manipulations. Although many look upon the production of an almost absolutely clear glass black-and-white slide as one of the most difficult feats in lantern-slide making, the production of such by the means I have described is simplicity itself, and should afford no trouble if conducted in the manner indicated.

It is not, however, in black-and-white examples only that reduction and intensification plays such an important part; there are other equally great advantages to be derived by such means when it is employed in the case of ordinary subjects.

T. N. Armstrong.

WARM TONES ON LANTERN SLIDES AND TRANSPARENCIES.

[St. Louis and Canadian Photographer.]

The following two methods of changing the tone of lantern slides and transparencies I have never seen published, and, as they are simple and in season, I hope they will prove acceptable. In my experiments I used Seed's lantern-slide plates, developed with their metol-hydroquinone developer, and fixed in a chrome alum hypo bath. After fixing, plates were washed and *dried*.

DARK PURPLE TO BROWN.

Hypo	4 ounce.
Water	32 ounces.

Heat nearly to boiling, and add powdered common alum, one ounce. Should be used cold. If used hot, it will deposit sulphur in the film. Bath works better if it is heated moderately hot several times, and allowed to cool. It should not be filtered, and improves with age. Place the dried slide in the bath until it is toned, which may take a number of hours. The longer it is in the bath, the browner it becomes. The tone is also dependent on the strength of the image. After toning, wash well and dry. The colour seems to be permanent; at least it has withstood the action of the sun for several days.

DARK BROWN TO BRICK RED.

Potassium bichromate	10 grains.
Common alum	150 ,,
Table salt	20 ,,
Water	4 ounces.
Nitric acid, c.p.	10 minims.
Sulphuric acid, c.p.	20 ,,

Bleach the image thoroughly in the above solution. This will take but a few minutes. Rinse well and tone in a strong solution of hydrogen sulphide. For the benefit of the uninitiated I will state that hydrogen sulphide is the compound that gives the eau-de-Cologne odour to aged eggs

and some mineral waters. It is used in all chemical laboratories, and can be very cheaply and easily made. The tone of the slide depends upon the original density of the image. The darker the slide the browner the image. After toning wash and dry. Slides lacking in density can be treated advantageously by this method, as it intensifies them. The conversion of the chloride into the sulphide appears to be complete, for no perceptible change could be noticed when tested by placing them in fixing bath.

MILTON B PUNNETT.

LUCIUM.

THE following is the draft complete specification of Prosper Barrière, of Paris, in the Republic of France, for improvements in the preparation and production of bodies for use in what is known as incandescent gas lighting.

Incandescent gas lighting, which consists in suspending fireproof luminous substances within the flame of a Bunsen burner, has been carried out hitherto in several different ways.

The illuminating properties possessed by various metallic oxides, such as those of the zirconium, lanthanum, yttrium, thorium, and magnesium, have suggested the idea of making these oxides serviceable as luminous odies.

The distinctive features of the various metallic oxides hitherto employed have been precisely determined from the points of view of both physical science and chemistry.

These oxides are derived from corresponding ores, such as thorite, erite, gadolinite, zircons, and the like.

The treatment of these ores is a question which has not as yet been fully cleared up and I shall not attempt to deal with it, inasmuch as my own efforts have been directed to the study of other minerals.

But the numerous experiments which I have made have enabled me to discover and to satisfy myself of the presence of a novel illuminating body (I will refer to it under the letter A) in a special ore of a sandy nature, obtainable at different places, and known as monazited sand.

This body has properties different from those possessed by the substances used hitherto.

The ore, which possesses a sandy appearance, is really rich river loam, found in small ruby-like pebbles.

The following is an example of an analysis made on a sample of this substance :—

($Si O_2$) Silica	69·7	per cent.
(P_2O_5) Phosphoric acid	6	,,
Fe_2O_3) Iron	1·92	,,
(Al_2O_3) Alumina	15	,,
Cerium, lanthanum, didymium ..... about	2·13	,,
Moisture	2·05	,,
Lime, magnesia, and other miscellaneous matter ..... about	2	,,
A body	1 80	,,

This new body, A, enters into the composition of the ores named in the proportion of from 1·5 to 6 per cent., according to the sample dealt with.

Treatment.

The composition indicated above necessitates special methods of treatment, having for their object to eliminate any harmful substances which the body treated may contain.

The purity of this body is the main condition upon which a satisfactory yield depends.

The ore, on having been porphyrised, is slowly melted in suitable furnaces, with an addition of carbonate of sodium in the proportion of one part of ore for every two parts of carbonate. This operation, which takes about three hours to complete, is intended to convert the oxides into insoluble carbonates.

After cooling, the powdered mass is lixiviated; thus, by means of decantation, the elimination of the silicates and phosphates of sodium is proceeded with

When the carbonates are exhausted by the water, they are subjected to the action of the sulphuric acid, the surplus of which is eliminated by slow calcination; the sulphates are dissolved in cold water and precipitated by means of ammonia. The precipitate, on being washed, is dissolved in hydrochloric acid, care being taken to properly neutralise it.

The greater part of the iron and alumina is then removed by precipitating it by means of oxalic acid.

The insoluble oxalates are converted into sulphates, when partial calcination in a muffle furnace is proceeded with.

The calcination is interrupted at a certain period of the operation, which, however, can only be determined by taking into account the appearance of the material under treatment, the proper time for this being when the greater part of the acid has been eliminated. The sulphates obtained are then pulverised and put in cold water in small quantities, so that the saturation stage is, as nearly as possible, reached.

The solution obtained is then precipitated by means of ammonia, whereby magnesia and the salts of lime are eliminated. Then, by filtering, a gelatinous precipitate of oxides is obtained, which is dissolved in sulphuric acid.

The sulphuric solution obtained, having had sulphate of sodium in solution, saturated while cold, added to it, is used as a precipitating medium, there being crystals in suspension in the mass, and the saturated solutions being allowed to digest for from five to six hours, thus the group, cerium, lanthanum, didymium, is precipitated.

The double sulphates thus obtained are filtered and then thoroughly washed.

In order to remove thorium, the solution is made in sulphuric acid, and the precipitate obtained by means of sulphate of potassium.

Thus all the bodies mentioned above as being present with the A body may be eliminated.

Now the principal operation of the process has to be commenced. It consists in precipitating the solution by means of hyposulphite of sodium in the condition of a concentrated solution. This operation is started with a slight action of heat. When the boiling point is reached, the A body is precipitated first. The body obtained contains as impurities small quantities of ytterite earths, principally ytterbia.

It only remains after this to effect a most thorough washing of the hyposulphite thus obtained, using cold water for the purpose. After the washing, a solution is made in hydrochloric acid.

A reaction with sulphocyanide of ammonium will at that moment show whether there are any traces of iron left, and these, if present, may then be eliminated by the ordinary methods.

In the same way, traces of other metallic substances may be eliminated by means of a current of sulphuretted hydrogen sent into the solution of hydrochloric acid.

After precipitation by means of ammonia, the body is energetically washed with distilled cold water.

By such means a body is obtained which in itself is luminous, and which is made use of in the manner which I will now describe.

Generally speaking, the oxides employed for illuminating purposes, as well as the body to which I have referred just now, produce light which is illuminating and radiating only to a certain degree.

Radiation, which constitutes the illuminating power proper, and more particularly the brilliancy desirable in a luminous body, is obtained owing to the molecular conditions which I have found to be realisable with exceptional ease in a body which, after many trials, I have discovered to be oxide of zinc. Any other body fulfilling the same conditions may, however, be employed without departing from the principle of the inventions.

Oxide of zinc, which, upon being heated at an ordinary temperature, assumes a greenish-yellow hue, when subjected to the heat of a Bunsen burner, becomes phosphorescent as it were. It is sufficient to add a small percentage of it to the illuminating solution.

I employ a nitric solution of the oxide in question.

After a fabric, which should be as fibrous as possible, has been impregnated with the said solution, when the wick thus formed has been incinerated, the decomposition of the nitrates will take place under the most favourable conditions conceivable.

Part of the oxide of zinc, the surplus thereof, is volatilised, while the remainder will be in that molecular condition referred to just now.

It is not impossible to use other oxides, which, if employed under certain conditions, and mixed or combined in a certain definite manner, and either combined or not with the body A, may form novel bodies.

The fabric which I employ is made of special thread or filament, such as the fibres of flax, china grass, or the like, and it should have about ninety meshes per square centimetre. It is washed in a one-tenth solution of hydrochloric acid, and then with water having a slight amount of ammonia incorporated in it.

The fabric, after drying, is cut into strips of, say, twenty centimetres, and strengthened at their upper part with a strip of muslin or tulle.

Impregnation may be advantageously substituted by aspersion, by means of a special injector, which process offers the advantage of not necessitating protracted handling of the fabric, whereby certain impurities might find their way into it.

The bath employed is a nitric aqueous solution, containing as much as ten per cent. of the luminous body. Each wick should absorb at least six cubic centimetres.

After the wick has been placed on a special form of mould, it is secured to a hanger of nickel by means of an asbestos thread.

A Bunsen flame is rapidly and circularly passed round the upper portion of the said wick, while another burner is worked from below. Incineration will then take place, and the earths will form gradually. By such means a skeleton is obtained, which is placed over a burner for about half an hour in order to secure complete calcination; the wick is then in readiness for being supplied in a marketable form, and may be fitted to any burner.

The novel illuminating body which I have referred to as A I have named "Lucium."

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare what I claim is :—

1. For incandescent gas lighting, a new body derived from monazite sands.

2. For incandescent gas lighting, the body A referred to in the preceding claim, in combination with a small percentage of oxide of zinc, or

other body capable of imparting the necessary intensity and power of radiation.

3. The purification of the A body referred to in the first claim by treating monazite sands by oxalic acid, sulphate of sodium, sulphate of potassium, and hyposulphite of sodium.

4. For incandescent gas lighting, the combination of the aforesaid body A (either alone or in combination with other bodies, as indicated in the second claim) with fibres or filaments.

THE LIVING PICTURES—THE SKELETON.

[Written for the ALMANAC, but received too late.]

SUCH a bustle and a hurry
O'er the "living picture" craze,
Rivals rushing, full of worry
In these advertising days.

Each the first, and each the only
Each the others wildly chaff
All of them proclaiming boldly
There's the first A-kind-o-graph,

But it is a wonder really
How the constant flood of life
O'er the screen keeps moving freely,
Full of action—stir and strife.

There the waves are wildly breaking
There the swimmer stems the tide.
The cyclist his record making,
With countless varied scenes beside.

'Tis far from perfect in its movements,
'Tis very hard upon the eyes;
The jolty wobble no improvements,
Smooth running films a surprise.

Still successful beyond reason,
Spite of all its erring ways,
Holding first place in the season
Is the "Living picture craze."

We pass the out-door show and come
To the "Interior Views" we'd say—
X-ray exposures—held by some
The greatest wonder of the day.

In this the Crookes' tube plays its part,
Producing pictures—gruesome things—
Skeleton hand and beating heart
Bony fingers adorned with rings.

The products are not pleasant; still
They've proved the means of great advance
New powers, before unknown, that will
The scientist's results enhance

The "Cinemato" runs along,
Giving pleasure by its pace,
The X rays' function being strong
To benefit the human race.

Each plays its part in the season,
Each fills a niche of its own.
To place them together's no treason,
For side by side have they grown. MARK OUTE.

PORTRAITURE BY THE ELECTRIC LIGHT.

AT a recent meeting of the New York Camera Club, Mr. G. G. Rockwood gave a lecture on this subject. The lecturer, whose prompt adoption of new ideas and appliances has been a characteristic of his long photographic career, was peculiarly qualified to speak on the subject of artificial light in the studio, both from his experience with the arc light and his present labours to introduce an incandescent form of gas light for the same purpose. This latter novelty he promised to demonstrate before the Club when perfected. In his introduction he drew attention to the fact that artificial light, though possessing many advantages in convenience, was necessarily inferior to diffused daylight for the purpose of portraiture, Sunlight, consisting of rays virtually parallel, is transmitted in a homogeneous medium, as the atmosphere, through long distances without sensible diminution in intensity; but artificial light, on the contrary, advancing from its source in divergent rays, diminishes according to the square of the distance. It is very essential, therefore, in employing an artificial light in portraiture, even one as powerful and rich in actinic quality as the arc light, to have the object very near the source of light. This is especially the case with the Club's studio, where the electric light is first thrown on a white screen so as to use the softer light diffused by the reflector. Now, this nearness, while it sufficiently illuminates the side toward the light, introduces a new trouble, hardness of shadows, from the great intensity of the light near its source. To remedy this evil, Mr. Rockwood recommends the use of a head screen, generally made in the form of a hoop covered with thin tissue paper or cheese cloth, and mounted on the usual adjustable stand. The greater part of Mr. Rockwood's lecture was a practical exposition of the proper way to utilise the arc light, using the Club's duplex lamp and Secretary Canfield's head and shoulders as a model. He explained what is called a normal lighting, or where the light comes at an angle of forty-five degrees from the front and side of the subject. It was at once evident that the screen, as rearranged in the present disposition of the Club rooms, was too low to give the best modelling; also, in changing the studio from the east to the west side of the hall so as to leave the windows unobstructed, they had made another error, for the wrong side of the face is thereby presented to the light Mr. Rockwood contended that in nearly all instances the left side of the human face presents the greatest number of characteristic features, and hence should be generally presented to the light in making a portrait. He proved this by various presentations of his own features and those of Mr. Canfield, and also cited cases of well-known public characters who had been his sitters. It was noticed that Mr. Rockwood obtained the desired lighting, and composed his picture by giving his entire attention to the arrangement of the light and the model, and did not once resort to the camera or study the ground glass. One cause of the failure of tyros in picture-making is their anxiety to keep their heads continually under the focussing cloth. This is a poor way to take a portrait, and the sitter is nearly always tired out before a single exposure is made. With these photographers the lens and the wonderful electric light are expected to do the work and supply all the deficiencies in the operator. Mr. Rockwood extemporised a head screen with a sheet of tracing paper, and showed how the shadows were softened and yet lightened by its use. He said that, while the high lights were reduced in intensity, the exposure did not have to be prolonged, the increased illumination of the shadows more than compensating for the loss. It was recommended to so arrange the head screen that, while the shadows on the face are mellowed, a stronger light may be thrown on the draperies around the shoulders and bust. This produces a remarkably brilliant effect. What is termed a slant light, which is now frequently used as a substitute for the old combination of side and top lights, was shown by Mr. Rockwood to be actually an easy and more economical way of obtaining the same results; for, in effect, most photographers, by screening the side light from the bottom and the over-head light from the top, have all along been producing this same slant light, which is now hailed as a novelty in studio construction. Mr. Rockwood kindly answered the numerous questions put to him by the members of the club, and invited all to visit his son's establishment on the Boulevard, which has been fitted out with all the latest studio requirements.

FLASHLIGHT PHOTOGRAPHY.*

[From the Australian Photographic Journal.]

A PHOTOGRAPH illustrating a scene in *The Sleeping Beauty* extravaganza was taken in the largest building in Hobart—the Theatre Royal. So me brief account of the *modus operandi* may not be out of place. The camera was placed and carefully levelled on a strong kitchen table in the centre of the stalls, which, in the above building, occupy the sloping floor from the orchestra back to the level of the dress circle. The lamps (pipes) were erected as far to the left as possible without throwing a shadow from the wings across the stage. As the floor is so much below the level of the latter, a third length of rod was inserted between uprights one and two to raise the lamps above the camera, and to prevent the shadows of the front ranks of performers from falling upon those in the rear. To throw the light forward, my lantern sheet was suspended from the front of the dress circle to act as a reflector. It is well to have an assistant to light and extinguish the lamps, while you occupy the table and blow off the flash, &c.

There is no special difficulty in taking photographs of theatrical scenes, although I believe several attempts had been previously made without success. All preparations may be made, and the camera focussed, without interfering with a "full-dress" rehearsal, any special scene being rearranged at the close of an act. By this means very little delay indeed is occasioned. On one occasion I took four flashlight pictures of scenes in the *Bohemian Girl* without delaying the rehearsal more than ten or twelve minutes altogether. The scenes from the *Sleeping Beauty* were taken at the close of a performance as soon as the audience had left; but this is not advisable if it can be prevented, as the performers are tired and may wish to get home, and it necessitates the extra trouble and delay of rearranging both scenery and the scenes. When the scene to be photographed includes a few characters only, it is better to have both camera and lamps quite close to, or even on, the stage, or to use a lens having a much longer focus.

And now as to the development of the negative. I have read a good deal about "special" developers for flashlight photographs, but there is no need to trouble about any of these. The Ilford pyro-soda developer will bring out all the detail and density one can desire, if used with

* Concluded from page 77.

intelligence and care. Should the subject photographed contain great contrasts, such as white dresses and dark surroundings, use less pyro and dilute with water according to requirements. Develop for detail rather than density, but continue development until the negative looks somewhat dense by transmitted light, or on fixing it will be too thin. There should be no need to force development by using more than a normal quantity of the soda. "Let patience have her perfect work," and you will not be disappointed.

A word of warning with regard to the light used. As the plates are very sensitive, work some distance from the lamp, or keep the flame low until development is nearly completed, and cover the dish, which is all the better if it has a glass bottom and well for the developer to run into when tilted up for examination. Do not be tempted to use an extra ruby glass before the lamp when developing instantaneous plates, as you will be deceived as to the density of the negative, and find it miserably thin after fixing. Use the light you have been accustomed to, but, if possible, turn it up and down as required.

I have also read a great deal about "doctoring" flashlight negatives, such as reducing density locally or entirely; "bringing a great amount of skill upon the back of the negative" in the form of "raw sienna moistened and rubbed into matt varnish with the finger over the thin portions," to bring out "the detail" in printing; scraping off the varnish over the too dense portions, &c.—in short, "using all the dodges known to retouchers to complete a successful negative for printing." Those, and suchlike, "little details" are far more apt to *discourage* than *encourage* one about to take up flashlight work, as one is apt to imagine that every negative requires an awful amount of such messing to make it at all serviceable. Personally, I can assure my readers that only one of my negatives has really required any "doctoring" whatever; and all that was needed was the scraping away of a portion of the fan and pink vase which ran into the features of the lady at the piano, and which gave no indication to the eye of blending with the face in any way. The intensity of the light did the mischief.

It is, of course, open to any one to expend any amount of skill upon doctoring his negatives if he so desire; but it is not always, nor often, necessary to the production of good pictures. CHARLES GRUNCELL.

STRAY THOUGHTS ON LANTERN-SLIDE MAKING.

IN the course of his remarks upon the above subject, before the Edinburgh Photographic Society recently, Mr. Patrick said that no branch of photographic art was more full of promise of practical utility and pleasure than the making and exhibition of lantern slides. It is the one method above all others which affords the greatest pleasure to the greatest number.

The excellence of the slide will depend, of course, upon the quality, pictorially and technically, of the negative from which it is made, the negative being (so to speak) the backbone of the transparency. A good plucky negative, with a full range of gradation, will be found to give the best results.

Mr. Patrick then pointed out that at the present time there seems to be a tendency to produce thin weak negatives, brought about, no doubt, by the extensive use of gelatino-chloride papers. Such a character of negative was not well adapted for the best transparency work, although a great deal could be done in the way of obtaining passable results from such negatives by skilful manipulation. From a fully exposed negative, for instance, a crisp result can be obtained by under-exposing the transparency slightly; or, from an under-exposed negative, the harsh feeling caused by too strong contrasts can be rectified by fully exposing the transparency, but by doing so you lower the keynote, as it were, of the whole picture.

In order to produce good results in negative-making, the exposure and developer must go hand in hand, and both must be suited to the subject. There is no such thing as one correct developer, or that the constituents of the developer must be mixed in certain fixed proportions for all negatives.

We will sometimes find aid to picture-making in under and over-exposure, and even fog sometimes, in careful hands, will help to create pictures.

By over-exposure and a well-restrained developer, or by the reverse, delicate atmospheric effects or strong contrasts may result at the will of the photographer. He can so render his interpretation of the scene either as a hard, matter-of-fact picture, or suggest in the finished transparency the impression nature conveyed to him; he can, in fact, cause his mind to pass into the finished picture.

One of the essential qualities of a good lantern picture is, undoubtedly, artistic composition. What I mean by artistic composition is the arranging of the subject in such a manner that, as the eye wanders over the picture, it is focussed (so to speak) on the principal object. The object of composition is really to secure unity, to concentrate the eye on a point, and keep all accessories subordinate to that object.

Speaking of the wet and dry-plate processes, Mr. Patrick said: "After all, it is not so much the process as the worker that has a great deal to do with the question. More depends on the man and his method of working than upon the process employed."

The gelatine dry plate as manufactured at the present time is an article of great perfection and capable of yielding the very best results. Of the various brands in the market there is not very much to choose among them, each brand has some special feature which requires a little practice to understand. Take up a certain brand, work at it, get into its little ways, stick to it, and you will be rewarded.

Much has been said and written on the colouring of lantern slides. The daubing of more or less transparent colour on a lantern slide was in Mr. Patrick's opinion an insult to nature. A monochrome slide, if otherwise good, is without doubt the most attractive, and the range of tone at our disposal is quite sufficient (without overstretching one's imagination) to suggest colour values. Another important matter in lantern-slide making is the shape and opening the picture is permitted to have. The shape of the mask of a lantern picture will either make or mar it. The great thing is to suit the mask to the subject, and not the subject to the mask.

OPTICAL ILLUSIONS.

BEFORE the Midland Institute Scientific Society, Newcastle-on-Tyne, Mr. P. L. Gray recently lectured on *Optical Illusions as distinct from Delusions*. They had, he said, some sort of real, outside basis, from which a non-existent appearance was deduced by the observer, either from physiological causes in the eye itself or from errors of judgment due to a variety of causes in translating the actual impression on the retina into a mental impression. Delusions, on the other hand, required no real object to excite them, or, in other words, were entirely subjective. On the whole, he thought that of all senses that of sight was the most, and that of smell the least, easily deceived. This was due to the enormous extent to which the interpretation of the phenomena presented to the eye was dependent upon experience. One did not in ordinary cases actually see what would be seen by a blind man suddenly restored to sight. In the latter case persons had described their impressions as that of all surrounding objects suddenly crowding upon them. If a fly came suddenly between the eye and the page of a book, the first impression was that of a large eagle flying across. Atmospheric absorption also played an important part in one's visual impressions. The fact that the figure of an ordinary man suddenly looming upon one out of a fog appeared like that of a giant was due to one's experience of perspective; the man, being dimly seen, appeared to be at a distance, but without any diminution of his height. Some of the commonest illusions depended on contrasts of geometrical forms. For instance, as the lecturer demonstrated, straight lines in association with curves appeared to be curved, and straight lines might be so associated that those which were parallel appeared to be not parallel, and *vice versâ*. A space broken up by cross lines appeared wider than it actually was. This had an important bearing on such matters as dress. A short person wearing a dress with horizontal stripes would appear stouter; vertical stripes would increase one's apparent height. Other illusions depended upon pseudo-perspective effects. An arrangement of straight lines might be looked at as representing a solid—a truncated pyramid, for instance, with the small end towards one, or a cooking tin with the open side nearest. These two impressions could be alternated by a conscious mental effort. Another linear drawing would become at will a picture of a flight of steps, or of a cornice in which the steps were inverted. A considerable number of illusions owed their origin to irradiation, a luminous body appearing larger than a dark body of the same area. The most familiar example was that of "the old moon in the new moon's arms." A row of spaces illuminated in graduated degrees of brightness, but each in itself of uniform intensity of illumination, appeared to represent a fluted surface, the edge nearest the darker shade appearing lighter than it really was, and the edge of the lighter space correspondingly darker. The voluntary choice of interpretation in the case of a drawing which might represent either a relief or an intaglio gave many curious results. Another class of illusion depended upon the retention of an impression by the retina for a short time after the stimulus had ceased. A stick held between the lantern and a patch of red light appeared to give a green shadow; with green light the shadow was red; with yellow light it was blue or violet; with blue it was orange. Even if perfect colour photography became an actual fact, the untouched photograph would not reproduce the actual visual impression of a scene. In a golden sunset the photograph would show the distant mountains not purple, but probably an inky black, because the photographic plate would not give the same contrast of colours which the eye saw. The work of the artist was to make the best artistic effect out of illusions, whether in form or in colour. The born artist in colours was the man who saw distinctly all colours, such as had been seen in the experiments. The ordinary observer did not see them, because the brain unconsciously corrected the visual impression; the artist saw the colour shadows clearly, and by slightly exaggerating them in his picture recalled the actual contrasts of colour as seen to the eye. Ordinarily one knew that grass was green, and, in spite of the impression on the retina, one declined to admit, what the artist clearly saw, that the shadows had a distinctly reddish tinge. An artist had described how he alone of a party saw the sails of a boat look a vivid green against a red sky. One theory of colour vision was that we were capable of three double sensations of colour—the white-black, the red-green, and the blue-yellow sensations; so that, while one part of the retina was affected by light of a certain colour, the other parts experienced a reaction, resulting in a

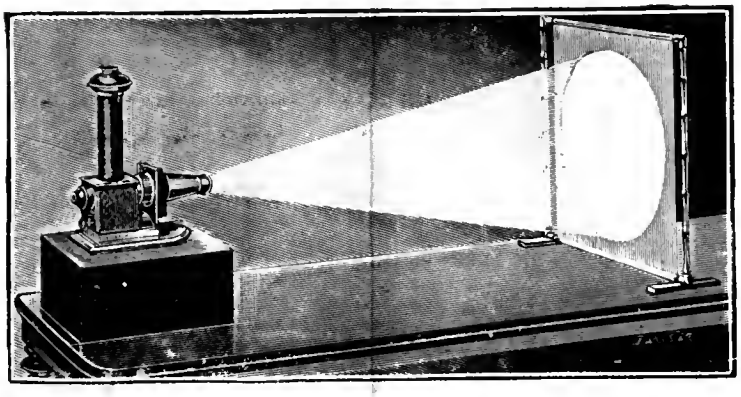
sensation made up of complementary colours. The other theory postulated only three simple colour sensations, but the lecturer preferred the former, as accounting better for the colour shadows or "after-images." The "optical top," which on rotation made black lines on white appear to be of colours, varying as they approached the centre and changing their order on the rotation being reversed, was shown with excellent effect. The explanation suggested was that the colour sensations varied in quickness, the red being the nimblest both in beginning and in ceasing. The lecturer, however, as on all other points, cautioned his hearers against accepting any theory as a complete explanation. For the most part, the theory was to be taken either as little better than a restatement of the facts or as a provisional hypothesis.

"PRIMUS" DRAWING-ROOM LANTERN AND SCREEN.

Butcher & Son, Blackheath.

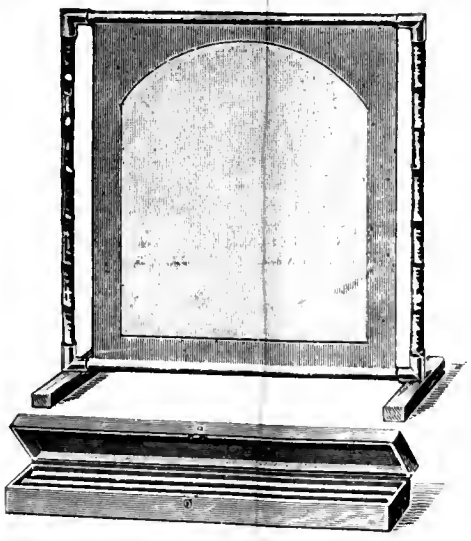
Messrs. W. Butcher & Son, of Blackheath, send us an excellent little catalogue of lanterns, accessories, and slides, which includes references to all their well-known specialities, of which we select two for illustration:—

The "Primus" P-K Lantern is specially constructed for the exhibition



of lantern slides made from negatives taken with the Pocket Kodak Camera and is designed for use, on the table, in the drawing or dining-room.

The second illustration depicts the "Primus" P-K or Drawing-room Table Lantern Screen. It gives a picture three feet square, and stands



on the ordinary dining-room table. The screen is hung on a portable bamboo frame, which takes to pieces in a minute or two, and packs up into a neat box. It is very compact, and the total weight is only 3 lbs.

WRIGHT AND ANDERTON'S IMPROVED SCREEN FOR OPTICAL PROJECTION PURPOSES.

Messrs. Lewis Wright and John Anderton say:—

"Hitherto, metallic-faced screens for optical projection purposes have been made with a plain surface, and, as a result, the superior brightness possessed by them over screens of other kinds has been apparent only within a somewhat limited angle of view; also portable screens used for optical projection that are faced with paper, metallic foil or other material, are liable to buckle and curl at the edges, and by so doing destroy the evenness of the surface.

"By our present invention we overcome these defects in the screens for use with magic or optical lanterns, lantern microscopes, and all other optical projection and reflecting apparatus, and our improved method of arrangement consists, firstly, in applying to calico, linen, canvas, or other suitable material or substance forming the screens, or covering of the same, or to wall surfaces or other situations as required, a facing or surface composed of silver or other metal or metallic sheets, films, or leaves, or powdered bronze, or any other metallic surface, which surface is covered all over with indentations, corrugations, or irregularities of any suitable form or kind, or with fine grooves or striations, arranged perpendicularly or otherwise if desired upon the said surface, for the purpose when in use of causing the rays of light to be scattered laterally, and thus increasing the lateral reflection of the light, and thereby causing the projected image or images to be seen with equal brightness from any point of view within reasonable limits. To remedy the defect of buckling when the screens are faced with paper, metallic foil, or other substance, before referred to, we paste, or otherwise apply, a coating or lining of paper or other suitable material to the back of the screen of sufficient strength or substance to counteract the strain of the front surface, and thus obtain a flat and even hang of the screen.

"By these means much better results are obtained in all cases than by the present arrangements.

"We do not necessarily limit ourselves to the more precise details herein set forth, as we may sometimes deem it expedient to vary the same, without departing from the essential features comprising the principle of our improvements; but the claims are, firstly, an improved screen for optical projection purposes; secondly, in screens composed of any suitable material or substance for use with magic lanterns, lantern microscopes, and all other optical projection and reflecting apparatus we claim the combination with the calico, linen, or canvas covering of said screen, or, upon walls or other situations, of a surface composed of silver or other metal or metallic sheets, of films, leaves, or powdered bronze, or any other suitable surface of metal, and the formation and arrangement in or upon the said metallic surface of a series of fine grooves or striations, arranged perpendicularly or otherwise, or indentations, corrugations, or other irregularities of any kind upon said metallic surface; thirdly, in screens the means for remedying the defects caused by possible liability of the surfaces buckling when faced with paper, metallic foil, or other substance likely to buckle when strained."

PROJECTING APPARATUS FOR SHOWING MOTION ON THE SCREEN.

[Anthony's International Annual.]

It is now about twelve years since Anschütz announced his first Schnellseher, with which he succeeded in a very complete way in uniting a series of views so that the object—for instance, a running horse—could be seen in its natural motions. For the production of his views Anschütz uses as many cameras standing close together as he intends to make views, generally twenty-four. The instantaneous shutters of these cameras are released by electricity within one to two seconds. This arrangement gives, therefore, but a limited time for all the motions to be taken. For motions occupying a minute or so at least one thousand cameras would be required.

The Schnellseher, as known, is so arranged that for the observation of the picture you have to look through a small opening in the body of the apparatus. At first Anschütz did not attempt to project the moving pictures enlarged upon a white screen, as considerable difficulties were connected herewith.

The American, Muybridge, occupied himself likewise with the production of such views, and constructed an apparatus for their projection. He exhibited it at the Urania Club in Berlin, but many defects were apparent.

In 1894, Anschütz took up the idea again, to introduce his pictures by way of projection, and it was reported in 1895 that he had mastered all technical difficulties. The chief drawback was that, on account of the limited number of cameras, the series of pictures was too short. To make a change in this direction was Edison's effort. The introduction of films, which could be had in almost any length, facilitated his endeavours considerably. He constructed an apparatus which, provided with only one objective, has as picture-carrier a roll of film. That sounds very simple, but in reality the difficulties are great. During exposure the film is not permitted to move, because no sharp pictures, even at shortest time of exposure, could thus be obtained. But, as in order to have in the picture uniform motions, uninterrupted by stoppage, *at least* fifteen views per second have to be taken, it can be imagined that the solution is not an easy one. Fifteen times in a second the film has to pass forward and stop again. Edison solved this problem in a magnificent manner. With his apparatus he was enabled to take a long series of pictures. To unite these pictures in the Schnellseher, he printed the negative film upon a second one, which shows as a positive. The latter he fastened in an apparatus (kinetoscope).

Edison's pictures are about 2 cm. wide and 1¼ cm. high; each strip of film carries from 600 to 700 views. These series of pictures represent the motions made within twenty-five to thirty seconds. The pictures are looked at through a lens which enlarges them a little. Edison did not attempt to project his pictures, as an enlargement by projection would show the pictures without sharpness upon the white screen, and only with great difficulty could the succeeding picture be put in the exact position of the preceding one. Anschütz, in 1895, called attention to these difficulties. The very small pictures, as contained in the kinetoscope, hardly show this trembling motion to the eye of the observer, owing to their size.

To offer something new upon this field, efforts had to be made to introduce series of views with a considerable number of pictures in good projection. More than one scientist has worked in this direction during the last years. Lately the efforts of some have indeed not been without partial success, and progress can be seen. At present two instruments have been introduced to the public in Europe. One is the Kinematograph of Lumière, in Lyons, the other the Kinematograph after the French Irola patent. The inner arrangements, I have to remark, are not shown to visitors, but the arrangement of the Lumière apparatus is described in Eder's *Year-Book*, 1896, pp. 391–400. Both apparatuses have an electric incandescent lamp as light source for the projection. In both the pictures are on film rolls. The size of the pictures is about the same as Edison's (1½ to 2 cm.). The size of the projected picture is about 1½ to 2 metres. Regarding the arrangement of Lumière's apparatus, the German patent gives the following description:—

"The film strip is pushed forward by uniform turning of the roll, so that a fork with its prongs catches the holes at the edge of the strip, carrying the latter periodically along, but by a motion in opposite directions liberating the same again. Between objective and film is a window upon a rotating disc, which admits the taking of the picture or the projection of the same."

We would mention here that in December, 1893, a patent was granted on an arrangement corresponding to that of Lumière.

Lumière Bros. say that they make fifteen views in a second, and project the same. That is almost too little to obtain a smooth, not trembling, motion in the projected picture; but, as the motions are smooth, certain authorities are of the opinion that Lumière prints the pictures perhaps twice upon the positive film, so that in the projection apparatus thirty pictures pass the objective in every second. That by such a process the trembling of the pictures can be essentially relieved is demonstrated by practical experience.

Lumière speaks of nine hundred pictures upon one strip in his circulars. A personal test with the second clock has proven that the time for running off a series of pictures deviates between thirty and forty-five seconds. Therefore on one roll would be only from $15 \times 30 = 450$ to $15 \times 45 = 675$ pictures.

Complaint has repeatedly been made that at the exhibitions the handle which sets the roller in motion was turned too quickly, and that the motions appeared too hasty. At all the exhibitions seen by the writer the apparatus worked with normal rapidity, and the motion left a natural impression.

How is it, now, with the solution of the most difficult problem—the exact fitting of the several pictures? We have pointed already to the fact that, if a picture does not fill *exactly* the place of its predecessor, the total picture will move in all directions.

The Lumière Bros. solved this problem in a satisfactory manner. Still even Lumière's apparatus is open yet to improvement. Regarding total effect and rigidity of the pictures, they surpass the Edison kinetoscope that I have seen. To produce his series of pictures, Edison constructed a stage-like place, on which the brilliantly illuminated figures set off from the dark background. This arrangement is wrong. If we have light pictures upon a dark ground in projection, the eye will catch much quicker the interrupted passages from one picture to the other than if the picture was light upon a light ground. Edison's arrangement was therefore discarded, and in preference sunny street scenes, with application of a shady background, were selected.

The trembling of the picture is also observable in the Lumière apparatus, particularly where houses and other immovable objects form the background. We see a fine picture, a fisherman in his boat upon the high seas, the boat passing proudly through the rolling waves, everything faithful to nature; but the house that can be seen at the side moves to and fro as if shaken by an earthquake. Still more painful to look at is the wall of the Exchange at Marseilles, looking as if it was to tumble down every minute.

These defects can never be removed entirely. The producers of series views should therefore be careful in the selection of their objects.

Some of Lumière's pictures are extremely beautiful, for instance, their Aquarium, playing children, &c. The Irola apparatus has no such meritorious properties. The trembling of the pictures is much stronger, and the motions are not so rounded and smooth.

The opinion that the kinematograph will soon take the place of the ordinary projection apparatus we cannot agree with. The above-mentioned very considerable defects, which are tiresome to the eye of the observer, can hardly be removed, but we should not forget that only under great difficulties can such pictures be taken. DR. R. NEUHAUSS.

MR. ALFRED UNDERHILL, of 32, Clarendon-road, West Croydon, Surrey, sends us his supplementary and clearance sale list of optical lanterns, slides, and photographic apparatus, which includes many bargains.

FROM Mr. E. G. Wood, of 74, Cheapside, we have received the fifty-third issue of his catalogue. About 150 pages are devoted to classified lists of slides, and the remainder of the book to lantern apparatus.

NEWTON'S CATALOGUE.—We have received the catalogue of Messrs. Newton & Co., of 3, Fleet-street, E.C., which is devoted to particulars of the firm's many varieties of optical-lantern apparatus, slides, &c. With it is a supplementary list of lantern slides for the season 1896-97, from which we gather that among the new sets are series dealing with *Queen Victoria's Reign; Life of the Duke of Wellington; Egypt and the Nile; Italy; Turkey and Ephesus; Astronomy; Poultry-rearing; Wood-carving.* Most of the sets are made from photographs taken during the present year.

"I WAS THERE!"—A few weeks ago, when Mr. Mathieson, of Invercargill, N.Z., was giving his limelight entertainment, a youth attempted to show his wit and disturb the proceedings by remarking every now and again, as scenes from Ireland were being put through the slide, "I was there." Without showing the least symptom of annoyance, Mr. Mathieson threw an imposing-looking building upon the screen, and paused for his tormentor's remark. It came right enough. "I was there," said the now familiar voice. "Ladies and gentlemen," said Mr. M., "this picture represents Kilmainham Gaol, Dublin." The funny man dropped out of sight like a shot, while the audience fairly screamed with laughter. That young man will be more cautious in future before making audible remarks on similar occasions.

A MINISTER IMPROVING THE OCCASION.—There is a church in London whose rector brightens his Sunday evening services with magic-lantern slides, and who himself plays a silver trombone in the pulpit. This is the church of St. Mary-on-the-Hill, and the rector is the Rev. Wilson Carlisle. Last Sunday evening the "sheet" turned to account the inauguration of the new carriage, and entertained a vast congregation with scenes from the motor-car procession on the road to Brighton. It is a topical service, and the magic lantern utilises every passing fancy of the day before. The rector turned the point thus: "We are all oil motors. The Holy Spirit is the oil, religious enthusiasm the electric spark." Obvious comparisons were also drawn by the reverend gentleman between the faint-hearted ones, who, through mud, the gibes of the multitude, or the quality of their oil, abandoned their motors and travelled to Brighton by train, and those who are moved to abandon their spiritual path at an early stage by the sarcasm of former boon companions.

"I LIKE Alfred Maskell as I like the 'Merry Andrews' of my younger days. Not that he means to be funny, but he is so, all the same. In an article in THE BRITISH JOURNAL OF PHOTOGRAPHY, in which," says "Watchman," in the *American Amateur Photographer*, "he advances some curious reasons why painters should not be Judges at photographic exhibitions, he almost outdoes himself. Speaking of lantern slides, he says: 'It is difficult to be serious in applying the term art to those very mechanical and easily made transparencies.' It is easy—to those who know how—to make a bust in marble from the clay model furnished by the sculptor, or to print from an engraved plate of, say, the Sistine Madonna, but the results are generally regarded as works of art, for all that. Equally ludicrous, and, of course, equally amusing, are his notions of marine work. One of his proofs of the unfitness of the painters to be judges is the fact that they, or at least he thinks it must have been them, awarded prizes at a certain exhibition to 'snap-shots of smoking steamers which the rawest practitioner with a Kodak could accomplish.' What will the Wests or Adamsons say to this? It is very evident that Alfred Maskell has yet much to learn of art, slides, and snap-shotting."

MAGIC pictures, which only become visible by gradual development on the lantern screen, are made as follows: Upon a glass of the desired size, perfectly clean, we pour a solution of indiarubber in benzine, working as we should do with collodion, of a strength analogous to that of collodion. This must be allowed to dry, after which it is placed upon the design that we desire to reproduce. (There is nothing to prevent this from being a photograph.) Then, with a very fine brush, dipped in a solution of bromide of copper, we trace the design. If the lines made are very heavy, the image will be visible, and the effect will be wanting; it must therefore be done very delicately. After having outlined the image, we carefully paint the trees, foliage, grass, in a word, all the verdure, with bromide of cobalt; the sky and water must be done with a solution of acetate of cobalt, with the aid of a very soft and fine brush. We mount this as we should do an ordinary lantern slide. If the work is well done, the image ought to be entirely invisible, but, when placed in the lantern, it will gradually appear to perfection under the influence of heat. By these means may be depicted winter scenes, which under the action of the heat of the fire are transformed into scenes of summer; these return to their primitive appearance on cooling. With a little care and ordinary skill it is possible to obtain this pleasing and novel transformation with photographs.—*Post Express, Rochester, N.Y.*
